THE
REVIEW OF SCIENTIFIC
INSTRUMENTS

EDITOR
Gaylord P. Harnwell

ASSOCIATE EDITORS
D. W. Bronk
F. K. Harris
P. H. Miller, Jr.
W. A. Wildhack

EDITORIAL BOARD

Term ending December 31, 1950
W. Fowler
S. A. Korff
F. N. D. Kurie
C. D. Montgomery
L. S. Taylor
R. E. Zirkle

Term ending December 31, 1951
W. Bleakney
J. B. H. Kuper
T. Lauritsen
J. R. Pappenheimer
L. B. Snoddy
C. H. Townes

Term ending December 31, 1952
Kenneth S. Cole
Bernard T. Feld
W. K. H. Panofsky
R. S. Shankland
C. F. Squire
J. H. Williams

VOLUME 21, NEW SERIES
JANUARY-DECEMBER, 1950

A publication of the
AMERICAN INSTITUTE OF PHYSICS
57 East 55 Street, New York 22, New York

SUGGESTIONS FOR CONTRIBUTORS

Send **manuscripts** to Gaylord P. Harnwell, Randal Morgan Laboratory of Physics, University of Pennsylvania, Philadelphia, Pennsylvania. Textual material (abstract, body of the paper, tabular material, references, and figure captions) must be in English, typewritten (except mathematical expressions) double spaced with wide margins on a durable, white paper, preferably letter size. The original copy, not the carbon, should be submitted. For general style, spellings, abbreviations, and form, consult recent issues of this journal.

An **abstract** must accompany each article. It should be adequate as an index and as a summary.

All but the simplest **mathematical expressions** should be carefully printed in by hand. Be sure to distinguish between capital and small letters. Indicate clearly superscripts and subscripts by inverted carets and carets, respectively. Avoid complicated superscripts and subscripts. Avoid repetition of a complicated expression by representing it by a symbol. Identify in the margin Greek letters and unusual symbols. Use fractional exponents instead of root signs. Use the solidus (/) for fractions wherever its use will save vertical space.

References should appear as footnotes, numbered consecutively, and arranged thus:

[1] A. B. Smith, Phy. Rev. 41, 852 (1932).

[2] H. Lamb, *Hydrodynamics* (Cambridge University Press, Teddington, England), sixth edition, pp. 573, 645.

Tables may be typewritten on sheets separate from the running text. Each table must have a caption which will make the data in the table intelligible without reference to the text. Avoid complicated column headings.

Wherever possible **figures** should be planned for the width of a column (3 in.). A convenient reduction ratio is about 2:1 or 3:1. Lettering should be large enough on the original that when reduced it shall not be less than about $\frac{1}{16}$ in. (~1.5 mm.). Line drawings must be in *India ink* on white paper or tracing cloth. Coordinate paper is not desirable but if used must be blue lined and the coordinate lines which are to show must be inked over. Photographs should have maximum black and white contrast. Identify each original drawing or photograph on the back with the author's name and the figure number. Figures should be numbered consecutively. Captions should be typed on a separate sheet of paper.

A limited number of **alterations** in proof are unavoidable, but the cost of making extensive alterations after the article has been set in type will be charged to the author.

Proof and all correspondence concerning papers in the process of publication should be addressed to the Publication Manager, American Institute of Physics, 57 East 55 Street, New York 22, New York.

INFORMATION FOR SUBSCRIBERS

THE REVIEW OF SCIENTIFIC INSTRUMENTS is a monthly journal published by the American Institute of Physics and devoted to scientific instruments, apparatus, and techniques. Its contents include original and review articles on instruments in physics and allied sciences and sections on laboratory practices, book reviews, new instruments, new materials, news, and current literature of physics. One volume is published annually.

Subscriptions and orders for back numbers should be addressed to the American Institute of Physics, 57 East 55 Street, New York 22, New York.

Subscription Price

	U. S. and Canada	Elsewhe
To members and associate members of the American Institute of Physics	$5.00	$6.00
To all others	7.00	8.00

Back Number Prices

Yearly rate when complete year is available	$10.00
Single copies	$ 1.00

Advertising rates will be supplied on request.

American Institute of Physics

CONTENTS

JANUARY, 1950

New Method for Surface-Temperature Measurement . . . Nobuji Sasaki 1
Improved Schlieren Apparatus Employing Multiple Slit-Gratings . . . Tage A. Mortensen 3
Design Study for a Three-Bev Proton Accelerator . . . M. S. Livingston, J. P. Blewett, G. K. Green, and L. J. Haworth 7
Simple Pressure Balance . . . C. A. Swenson 22
Versatile Pneumatic Instrument Based on Critical Flow . . . W. A. Wildhack 25
Design and Use of Piezoelectric Gauges for Measurement of Large Transient Pressures . . . A. B. Arons and R. H. Cole 31
Background Eradication in Thick-Layered Nuclear Emulsions . . . Martin Wiener and Herman Yagoda 39
Choice of Suitable Gap Forms for the Study of Corona Breakdown and the Field Along the Axis of a Hemispherically Capped Cylindrical Point-to-Plane Gap . . . Leonard B. Loeb, James H. Parker, E. E. Dodd, and William N. English 42
Coincidence Experiments for Noise Reduction in Scintillation Counting . . . Hartmut Kallmann and Carl A. Accardo 48
Note on the Detection of Coincidences and Short Time Intervals . . . Robert Hofstadter and John A. McIntyre 52
Large Dempster-Type Double-Focusing Mass Spectrograph . . . Henry E. Duckworth 54
Diaphragm Cell for Thermal Diffusion Measurements . . . E. S. Huse, D. J. Trevoy, and H. G. Drickamer 60
Investigation of the Possible Use of the Glow Discharge as a Means for Measuring Air Flow Characteristics . . . F. D. Werner 61
Small Milligaussmeter . . . G. D. Adams, R. W. Dressel, and F. E. Towsley 69
High Speed Synchroscope . . . C. G. Kelley 71
Design and Construction of Universal Function Generating Potentiometers . . . Granino A. Korn 77

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

Small Probing Geiger-Müller Counters . . . C. V. Robinson 82
Book Reviews . . . 85
  Author Index to Books Reviewed . . . 93
  Other Books Received . . . 93

Laboratory and Shop Notes:

  Units of Radioactivity . L. F. Curtiss, R. D. Evans, Warren Johnson, and Glenn T. Seaborg 94
  Temperature-Controlled Resistance Furnace for High Temperature Measurements . . . W. G. Schneider and N. R. S. Hollies 94
  Behavior of Rectangular and Square Section Transparent Beta-Counters . . . L. M. Silver and J. B. Warren 95
  New Type Mass Spectrometer . . . Larkin Kerwin 96
  Improved Method of Directing Liquid Flow in a Closed System . L. G. Stang, Jr., and G. J. Selvin 97
  Measurement and Amplification of Minute Displacements by Frequency Modulation . . . P. A. Bricout and M. Boisvert 98
  Scintillation-Type Ion Detector . . . Paul I. Richards and E. E. Hays 99
  Method of Supplying Low Pressure Gases on a Vacuum System . . . Raymond H. McFee 100
  Convenient Gas Sample Tube Holder and Break-off Applicable to Mass Spectrometers . . . Frederick Highhouse and Julius White 101
  Simple Contamination-Free Electron Gun . . . H. E. Farnsworth 102
  Bent Crystal X-Ray Monochromators . . . B. E. Warren 102
  Motor for Use in Vacuum Systems . . . C. P. Butler and F. E. Carpenter 103
New Instruments . . . 103
New Materials . . . 107
Index to Advertisers . . . xxxiv

FEBRUARY, 1950

Precision Faraday Effect Apparatus . . . Samuel Steingiser, George J. Rosenblit, Robert Custer, and Chas. E. Waring 109
Velocity-Acceleration Response from a Seismic Pick-Up via Controlled Damping . . . Robert J. Jeffries 115
Variation of Grain Density with Temperature of Exposure in Nuclear Emulsions . . . Elsie M. Dollmann 118
Design and Construction of a Stark-Modulation Microwave Spectrograph . . . A. Harry Sharbaugh 120
Vortex Thermometer for Measuring True Air Temperatures and True Air Speeds in Flight . . . Bernard Vonnegut 136
Wire Recorded Magnetic Pulse Timing Circuit . . . C. R. Emigh 142
Wide-Band Audio Phasemeter . . . John R. Ragazzini and Lotfi A. Zadeh 145

CONTENTS

Positive Displacement Pump for Corrosive Fluids . . . E. E. GLENN, JR., AND NORMAN HACKERMAN 148
Frequency Modulation Pressure Recording System . . . J. H. HETT AND R. W. KING, JR. 150
Analog Computers for Servo Problems . . . DONALD MCDONALD 154
Gas Phase Counting of Low Energy Beta-Emitters . . . W. BERNSTEIN AND R. BALLENTINE 158
Measurement of Fast Neutron Energies by Observation of Li$^6(n, \alpha)$H^3 in Photographic Emulsions . . . GEORGE R. KEEPIN, JR., AND JAMES H. ROBERTS 163
Automatically Synchronized Electronic Switch . . . W. A. BUDLONG AND BRUCE C. LUTZ 167
Recording Microwave Refractometer . . . GEORGE BIRNBAUM 169
Integrator for Small Beam Currents . . . T. A. HALL, S. D. WARSHAW, AND J. DORSEY 177
Electronic Circuit Which Extracts Antilogarithms Directly . . . F. CURTIS SNOWDEN AND HAROLD T. PAGE 179
Magnetic Suspension for Small Rotors . . . J. W. BEAMS 182

PHYSICAL INSTRUMENTS FOR THE BIOLOGIST

On Adapting a Powder X-Ray Diffraction Camera for Reflection Patterns . JONATHAN PARSONS 185

Laboratory and Shop Notes:

- **Experimental KVAH-Meter** . . . G. M. PETROPOULOS 187
- **Simple Low Power Electronic Relay** . . . WILLIAM P. RATCHFORD AND M. L. FEIN 188
- **Point-Focus X-Ray Monochromators for Low Angle Diffraction** . . . JESSE W. M. DUMOND 188
- **Ultrasonic Tissue Disintegrator** . . . F. F. BIRD AND K. S. LION 189
- **Reprojection Method for Studying Cloud-Chamber Photographs** . . . D. A. BROMLEY AND R. D. BRADFIELD 190
- **Nomogram for G-M Counter Resolving-Time Corrections** . . . HOWARD L. ANDREWS 191

New Instruments . . . 192
New Materials . . . 198
Index to Advertisers . . . xxxviii

MARCH, 1950

High Resolution Recording with Soot . . . K. R. ELDREDGE 199
Ratio-Recording Double Beam Infra-Red Spectrophotometer Using Phase Discrimination and a Single Detector . . . ABRAHAM SAVITZKY AND RALPH S. HALFORD 203
Focusing Properties of a Generalized Magnetic Spectrometer . . . DAVID L. JUDD 213
Scintillation Counter as a Low Resolution Gamma-Ray Spectrometer . . . ROBERT W. PRINGLE, KENNETH I. ROULSTON, AND HARRY W. TAYLOR 216
Radiofrequency Spectrograph and Simple Magnetic-Field Meter . . . R. V. POUND AND W. D. KNIGHT 219
On the Use of Photographic Plate Detectors in Neutron Experiments . . . J. C. ALLRED, A. N. PHILLIPS, L. ROSEN, AND F. K. TALLMADGE 225
Analog Computer . . . J. G. BAYLY 228
Photographic Methods of Measuring Slow Neutron Intensities . . . M. BLAU, I. W. RUDERMAN, AND J. CZECHOWSKI 232
Microcalorimeter Suitable for Study of Easily Absorbed Nuclear Radiations . . . C. V. CANNON AND G. H. JENKS 236
Study of Plateau Slopes in Self-Quenching Geiger-Müller Counters . . . SANBORN C. BROWN AND CLAUDINE MARONI 241
Time Lags in Geiger Counters . . . ARTHUR R. LAUFER 244
Electric Field in a Geiger Counter . . . ARTHUR R. LAUFER 252
Laboratory Modifications in the RCA Model EMC Electron Microscope . . . S. G. ELLIS 255

Laboratory and Shop Notes:

- **Degassing Extended Glass Systems** . . . ALBERT B. STEWART 258
- **Liquid Air Level Control** . . . MARK S. FRED AND EVERETT G. RAUH 258
- **Series Parallel Linear Thermopile with Interchangeable Receiving Units** . . . ROBERT A. CRANE AND FRANCIS E. BLACET 259
- **Low Temperature Gasket** . . . A. WEXLER, W. S. CORAK, AND G. T. CUNNINGHAM 259
- **Simple Method to Seal Liquids of High Vapor Pressure into Glass or Quartz Capillaries** . . . Z. V. HARVALIK 260
- **Simple Recording Manometer** . . . FRASER P. PRICE AND PAUL D. ZEMANY 261
- **High Pressure Fitting for Scintillation Counting** . . . K. D. TIMMERHAUS, E. B. GILLER, L. H. TUNG, R. B. DUFFIELD, AND H. G. DRICKAMER 261
- **Automatic Equipment for Electrolyzing Heavy Water** . . . RALPH W. WANIEK 262
- **Optical Centering System for X-Ray Diffraction Samples** . . . EUGENE L. PERRINE 262
- **Electronic Water-Level Control** . . . R. D. MILLER AND J. S. HOPKINS 263
- **Manometer Leveling Procedure** . . . JOHN E. WERTZ 263

Errata:

- **A High Speed Synchroscope** . . . G. G. KELLEY 264
- **Note on Sealing Nylon Films to Geiger Counters** . . . ROBERT A. BECKER 270
- **Formation of Insulating Layers by the Thermal Decomposition of Ethyl Silicate** . HAROLD B. LAW 270

VOLUME 21, NUMBER 1 *JANUARY, 1950*

A New Method for Surface-Temperature Measurement

Nobuji Sasaki
Chemistry Institute, Department of Science, Kyoto University, Japan
(Received April 29, 1948)

The surface temperature of a body is equal to the temperature of the measuring junction of a thermocouple, if this temperature has been, by heating or by cooling, so adjusted that the meter in the couple circuit does not deflect when the measuring junction makes a brief contact with the surface being measured. The validity of this principle was confirmed experimentally by measuring a surface whose *true* surface temperature was known independently. The new method does not sensibly affect the surface conditions as long as the junction is very small in comparison with the object being measured and the contact is short and light. It was shown that the temperature rise due to the proximity of the measuring junction was negligible in the case of a 0.4-mm thick glass sheet or the human skin. The new method can give the correct surface temperature even when radiation comes from above or from below. Consequently the opacity of the surface layer does not matter as in the case of the radiation pyrometry.

THE knowledge of surface temperature of living and inanimate objects has become increasingly important in science and industry. But the method of measurement seems not to have been well standardized.[1]

The method presented here makes use of a thermocouple[2] whose measuring junction can be adjusted to any temperature. The temperature of the junction indicated by a millivoltmeter in the couple circuit is also the temperature of the surface, if the junction temperature has been so adjusted that the needle of the meter shows no deflection, when the junction makes a light brief contact with the surface.[3]

The temperature of the measuring junction may be adjusted by means of a fine heating coil put round the thermocouple wire near the junction. To measure the temperature lower than the room temperature the junction must be overcooled by contact with a suitable constant cold source and adjusted by heating.

The temperature jump the junction undergoes during its short contact with the surface can be made large with a suitable design of the thermojunction. The meter in the thermocouple circuit may be a millivoltmeter (less exact), a potentiometer (more exact but awkward), or both a millivoltmeter in the full e.m.f. circuit and a zero instrument such as a sensitive, short-period galvanometer in an extra circuit in which the e.m.f. has been either partly compensated by keeping the reference junction near the temperature of the measuring junction or almost completely compensated by a symmetrically-connected secondary thermocouple.

To be precise, the temperature of the measuring junction which has been adjusted to T at some distance from the surface, will change to $T+\Delta T$ just before the contact is made.[4] Obviously $T+\Delta T$ is then equal to the surface temperature if no deflection occurs. To minimize this inconvenient ΔT, the adjustment of the thermocouple should be made just in front of the surface, if this does not sensibly affect the surface temperature (see below).

The validity of the new method can be tested by comparing the *true* temperature of the surface being measured with the surface temperature as measured by the new method. What is important is to get a surface whose *true* surface temperature is exactly known. As such a surface we may use a metallic surface at the junction of a thermocouple of rather large diameter,

---

C. Houghten and H. T. Olson, p. 855. (2) "Temperature of Incandescent Lamps," W. E. Forsythe and E. M. Watson, p. 1188.

[2] In principle a resistance thermometer or even a liquid-in-glass thermometer can be used as well.

[3] For a wet or liquid surface a non-wetting junction should be used.

[4] This is caused by the temperature gradient in the ambient air and to the radiation from the surface, apart from the irregular air draughts. ΔT depends on the speed of approach and apparently also on the quickness of response on the part of the meter.

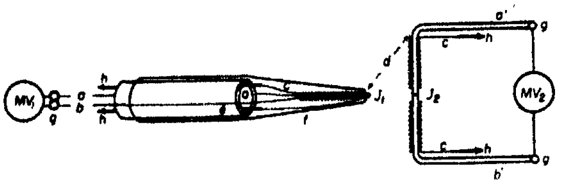

FIG. 1. *a*: Iron wire, diam. = 0.19 mm; *a'*, diam. = 1.17 mm; *b*: constantan wire, diam. = 0.15 mm; *b'*, diam. = 1.00 mm; *c*: heating nickel wire, diam. = 0.08 mm; *d*: thin glass tubings; *e*: ebonite tube; *f*: glass cap; *g*: cold junctions, in a water-ice Dewar vessel; *h*: to a constant a.c. source through a regulator; *J*: hot junctions; and *MV*: millivoltmeters.

which can be electrically heated with two coils on both sides of the junction (J_2 in Fig. 1). Let us suppose that the junction is heated in air and shows a certain e.m.f. Then the *true* surface temperature at the junction may be put equal to the easily measurable temperature of the oil of a bath, in which J_2, with the coil currents off, shows the same e.m.f. In the oil bath the temperature throughout the cross section of the wire at J_2 is uniform, but when the wire is heated in air, there will arise a small temperature drop from the center to the surface of the wire at J_2. It should, however, be negligible, because only a narrow surface is left bare between the heating coils.

The thermocouple J_2 was made by soldering end to end the squared ends of a larger iron wire (a') and a constantan wire (b'), with a heating coil round the glass-covered wire extending 12 mm long on either side of the junction where a narrow collar of surface is left free for measurements.

Thus far the description has concerned the standard surface whose *true* temperature is exactly ascertainable. The following description deals with the measuring junction proper. This junction J_1 (Fig. 1) for the measurement of the surface temperature is made by soldering end to end the flattened and widened (by hammering) ends of an iron wire (a) and a constantan wire (b), each in a fine glass tubing. Both wires are then so bent to the form of a hair pin that both glass tubings now in parallel position touch each other. A coil of fine nickel wire is then formed round these tubings. By finely adjusting the heating current through the coil J_1 can be given any desired temperature without much delay. The thermal capacity of the assembly as described is about 0.0017 cal./deg. The coil is protected against air draughts by a conical glass cap f. The shape of the wire at J_1 as mentioned just before favors the quick establishment of the thermal equilibrium, when J_1 is touched by or removed from the surface being measured.

Now the couple wires of J_1 and those of J_2 are all held in a horizontal plane, the former being perpendicular to the latter (Fig. 2), the junction point J_1 being about 0.5 mm apart from J_2. In *this* configuration the surface temperature of J_2 is measured by means of J_1 by adjusting the heating current of J_1 and noting the e.m.f. on the millivoltmeter MV₁ when the needle ceases to deflect as J_1 touches J_2, while the *true* surface temperature of J_2 is given by the millivoltmeter MV₂.

The surface temperature thus obtained shows deviations from the *true* surface temperature, which are as likely positive as negative, so that the algebraic mean of these deviations, 0.08°C for 12 measurements,* is relatively very small as compared with the individual deviations. This satisfying result is, however, only valid as far as we are concerned with the surface temperature at J_2 *in the presence of* J_1 just in front of it, because on removing J_1 the *true* surface temperature of J_2 drops by about 0.2°C. Theoretically we must always expect a systematic error of this sort, for it is due to the heating effect of the measuring junction brought in proximity to the surface to minimize ΔT mentioned earlier. But the error should be small if the accumulating heat at the point on the surface being measured be rapidly conducted away therefrom. Any significant error will arise, if the specific thermal conductivity of the surface material is very low, or if the object being measured is a free thin film without a massive support, a fine wire, or a small particle.

The heating effect on the surface being measured can roughly be estimated in the following way. About 5 mm apart two points A and B at nearly the same temperature are chosen on the surface. The thermocouple is always held perpendicular to the surface, J_1 being kept about 0.5 mm from it. The temperature of point A is measured as usual and then, without changing the heating current, the junction is shifted to the position just in front of point B and kept there for some minutes until the possible heating effect at A would disappear. Now the junction is rapidly shifted back and made to touch A. If the needle does not move at this moment the suspected heating effect at A did not exist. If it moves to the lower temperature it did exist. This time the glass cap f (Fig. 1) has been replaced by a brass one to prevent

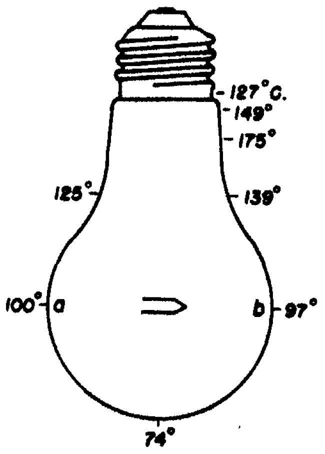

FIG. 2.

---

* These measurements were carried out at several temperatures between 33–65°C in a room at 32°C. Since the magnitude of the deviation is roughly constant throughout this temperature range, the probable error for a single observation was calculated from these 12 deviations, giving ±0.2°C.

the radiation from the hot heating coil from falling directly on the surface. This experiment was made with a burning 20-watt lamp bulb. The surface temperature of the bulb glass about 0.4 mm thick was 92°C. Though the dissipation of heat along the glass sheet and to the air was bad, no heating effect was observed within 0.05°C.† The same was also found true with the human skin.

Some earlier results of surface temperature measurement with a Mazda gas-filled 40-watt electric lamp bulb in a porcelain socket burning at 400 ma are shown in Fig. 2, the room temperature being 30°C.[6] The figures are exact within ±1.5°C. That the point *a* is hotter than *b* indicates a complicated gas current inside the bulb.

It is to be emphasized that, unlike ordinary methods, the measurement should in no way be affected by the intense radiation from the hot filament, because the way of heating the measuring junction to the surface temperature, whether by radiation, by electric current, or by both, is immaterial. To prove this the surface temperature of J_2 is measured with J_1 just above a burning 40-watt electric lamp. To keep the air current steady these are placed inside a vertical cylinder loosely fitting the lamp bulb. When the lamp is lighted, the temperature of J_1 rises from 35 to 63°C or the heating current 120 ma with the lamp off, must be reduced to 45 ma to keep J_1 at 63°C. The algebraic mean of the errors of 6 measurements carried out in the range 54–75°C is +0.07°C and the probable error of a single observation ±0.4°C. So also the measurement may be performed in a high frequency electric field. The surface temperature of a finger nail was found about 0.5°C higher than that of the neighboring skin. The validity of this result is not affected by the degree of opacity of the nail to any heat radiation from the underlying tissue.

In order to see how the accuracy depends upon the nature of the surface being measured, special measurements were made at the point *a* and on the brass skirt of a 40-watt electric lamp burning with the base down. The mean temperature from 8 measurements and the probable error of a single observation are respectively 109.6°C and ±0.3°C at *a* and 50.0°C and ±0.1°C on the base skirt. The measurement can be performed more easily and rapidly with the metallic surface than with the glass surface. The accuracy seems to depend, among others, on the thermal conductivity, the thermal capacity per unit volume, and the deformability, the smoothness, and the size of the surface. The replacement of the inconvenient trial and error method by an automatic one is planned.

---

† 20 scale divisions of the 0.2-sec. period galvanometer now in use correspond to 1°C.

[6] Forsythe and Watson obtained for the base temperature 105°C and for the maximum bare bulb temperature 127°C. With an iron-constantan couple of 0.05-mm wire diameter we found after the method suggested by the authors the temperature always somewhat 10°C lower than that obtained by the new method.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

An Improved Schlieren Apparatus Employing Multiple Slit-Gratings

TAGE A. MORTENSEN
Midwest Research Institute, Kansas City, Missouri

(Received May 30, 1949)

In the schlieren apparatus described in the following, the conventional knife-edge elements are replaced by multiple slit-gratings. The main advantage gained by this design is the fact that larger-sized working fields can be achieved with an objective lens of given aperture. Also, in some cases, greater intensity of image illumination is obtained, and usually the over-all length of the system is reduced.

1. OPERATING PRINCIPLE OF SCHLIEREN APPARATUS

FIGURE 1 shows a widely used knife-edge arrangement employing a lens as the image forming element. It consists of a light source *C*, a set of condenser lenses *D*, a screen *S* with a narrow slit *Q*, an objective lens *L*, a screen *K* with a straight horizontal boundary, the so-called knife-edge and, finally, an observing screen (or a photographic plate) *B*. The working field is located in the plane *A*, and the system will record the density variations in the points of the working field as changes in light intensity at the corresponding points of *B*.

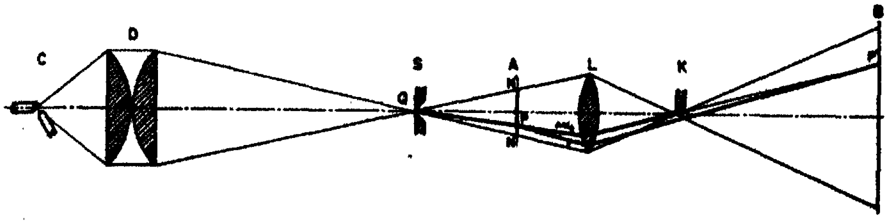

FIG. 1. Schlieren apparatus employing knife edges.

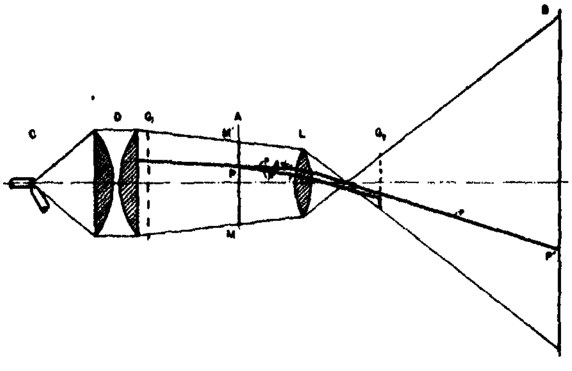

FIG. 2. Schlieren apparatus employing gratings.

The new type of schlieren apparatus is shown on Fig. 2. It employs, as before, a light source C, a condenser D, an objective lens L, and an observing screen B. But the slit Q and the knife-edge K (Fig. 1) are now replaced by two gratings G_1 and G_2. The first grating G_1 is located immediately after the condenser in the direction of the light rays. It is a ladder-like device with rungs or bars and clear spaces in between. The width of the clear spaces is of the same order of magnitude as that of the bars. The second grating G_2 is in the plane where the image of G_1 is formed and is, in fact, a photographic negative of G_1. Therefore, with a certain vertical position, G_2 will completely cover the image of G_1 and no light will pass through G_2. The "slices" of light formed by the first grating all will be intercepted by the opaque bars of G_2 (except stray light caused by diffraction). The ratio of the sizes of G_1 and G_2 will depend on their location relative to L. Normally, the grating G_1 will be larger than G_2, as shown on the figure. The working plane is located between G_1 and L and its image is formed in the plane B.

The operating principle of the set-up is, of course, the same as that of a knife-edge arrangement. In Fig. 2, a heavy line indicates a pencil of light rays p. It is passing through one of the clear spaces of G_1 and a point P of the working field. We assume that the second grating is in such a position vertically that p is allowed to pass through and arrive at the screen B at the point P' which is the image point of P. If now the local index of refraction at P is different than along the rest of the path of p, then the pencil will be deflected an angle $\Delta\alpha$ and will assume the path indicated by p'. In this position, part of p' or all of it (as in the figure) may be stopped by one of the opaque bars in G_2, and the illumination of P' will be correspondingly smaller. Through P will pass rays from other parts of G_1 but, in all cases, the effect of the deflections will be as described for p. There is a possibility that some of the rays will be refracted so much that, instead of being stopped at one of the opaque bars of G_2, they will pass through the next clear space between two bars. With a proper selection of the dimensions and location of G_2, this possibility is only remote. With a different deflection $\Delta\alpha$ at P, rays that would ordinarily have been intercepted by G_2 might now pass through a clear part of G_2, thus resulting in a greater illumination of P'.

All points of the working field will have their image points in B. For all of them, the situation will be as described above. A change in the index of refraction at any point will be transformed into a change of light intensity at the corresponding point in B.

The sensitivity of a schlieren apparatus may be defined as the relative change in light intensity produced by a given angular deflection of the rays at the point P. It will be proportional to the focal length of the objective lens L and inversely proportional to the width of the bars of the grating G_2. These values must therefore be selected according to the desired sensitivity. But the sensitivity will depend also to some extent on the vertical position of G_2 relative to G_1 (for the knife-edge setup, on the vertical position of K relative to Q). Therefore, the grating G_2 (respectively, the knife edge K) shall be adjustable in a vertical direction. This also will provide a regulation of the over-all illumination of the screen B. Since both the illumination of B and the sensitivity vary with the position of G_2 (but not in the same manner), there are certain positions where there is maximum contrast in the schlieren picture.

Both the schlieren systems described are sensitive only to changes in the index of refraction which deflect the rays in a vertical direction or, more correctly, in a plane perpendicular to the knife-edge (respectively, the direction of the bars in the gratings).

2. COMPARISON OF THE KNIFE-EDGE SYSTEM AND THE GRATING SYSTEM

The two schlieren systems described above are alike in operating principles, but they differ in several respects.

In the knife-edge system, the cone of light formed by the condenser lenses is focused on the screen S before it arrives at the objective lens. At the other side of the

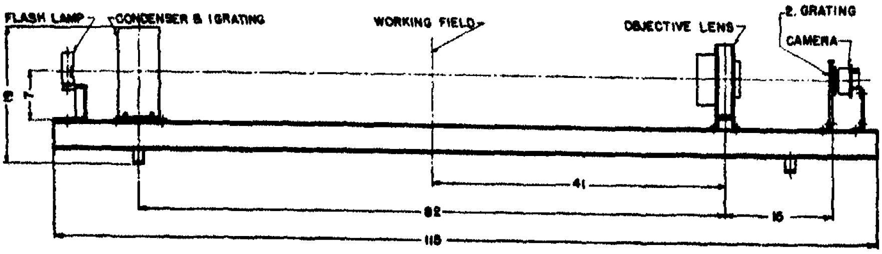

FIG. 3. Side view of schlieren apparatus built at Midwest Research Institute.

FIG. 4. The second grating.

lens, the light cone is again intercepted at its focus by the knife edge *K*. In the grating system, the light cone is focused at a point between the objective lens and the second grating. Instead of being intercepted at its foci, as in the knife-edge system, the light cone encounters the gratings at two planes conjugate to each other with respect to the lens *L*. Also, where the knife-edge system employs one slit *Q* and one knife edge *K*, the grating system uses a number of slits in G_1 and a corresponding number of knife edges in the form of the edges of the rungs in G_2.

By this arrangement a notable advantage has been attained: The size of the working field in comparison to the size of the objective lens has been increased. In Fig. 1, the area in which density changes will be recorded by the apparatus is represented by its diameter *NN'*, which must always be smaller than the diameter of the objective lens. For the grating apparatus this is no longer the case. Here, with the convergent light rays, the diameter *MM'* is greater than that of the lens *L*. With the schlieren apparatus described in the beginning of Section 3 a working field of 17.5 sq. in. has been obtained. This is almost 2½ times as large in area as what could have been effected with a knife-edge setup. The objective lens for any type of schlieren apparatus must be of high quality in all respects. Such a lens is difficult to obtain with a large diameter, and is always very expensive. The fact that a given objective lens permits a larger working field when used in a grating apparatus constitutes, therefore, a considerable advantage. Excepted from this are the cases where parallel light through the working field is required. For many applications, however, slightly convergent light will suffice.

The need for a schlieren apparatus that would effect a greater intensity of illumination of the screen *B* was one of the factors that originally led to the design of the grating apparatus. This requirement was met very satisfactorily. The apparatus built proved to be superior to a comparative knife-edge setup, and in particular to be excellently suited for projection of schlieren pictures for an audience.

From Fig. 2, it will be seen that the grating setup is somewhat shorter in over-all length than the knife-edge system shown. This may not always be the case. It is possible to move the light source itself to *Q* (Fig. 1), provided it has sufficiently small dimensions and well defined boundaries.

FIG. 5. General view of schlieren apparatus built at the Technical University of Denmark, Copenhagen.

3. DESCRIPTION OF A SCHLIEREN APPARATUS EMPLOYING GRATINGS

A schlieren apparatus operating according to the principles described in Section 1 has been built at the Midwest Research Institute. The instrument is for photographic use, recording a working field of 3½"×5" on 35 mm film. Figure 3 is a side view of the apparatus giving its main dimensions. By comparison of Fig. 2 and Fig. 3, it will be seen that they correspond element for element, except for the camera which is not shown on the schematic Fig. 2.

To the left in Fig. 3 is the light source, in this case a flash lamp of 100 microseconds duration. Next follows the condenser unit, consisting of two 12-in. diameter condensing lenses and the first grating, mounted together in a cylinder. The objective lens shown to the right in the figure is an f:3.5, $f=13\frac{1}{2}''$ Eastman Kodak anastigmat lens. The second grating which is seen at the right end of the apparatus is also shown on the photograph Fig. 4. It has been mentioned previously that this type of schlieren apparatus is sensitive to pressure gradients in one direction only. Therefore, to be able to employ the sensitivity of the apparatus in all directions, provisions are made for rotating both gratings about the optical axis of the apparatus. Figure 4 shows a screw adjustment for moving the second grating in a direction perpendicular to the bars in the grating.

Immediately behind the second grating follows the camera with the secondary objective lens. The use of such a lens has not previously been explained. It was assumed that the schlieren image would be recorded by replacing the screen *B* with a photographic plate or film. Some advantage is gained, however, by introducing another objective lens behind the second grating. Normally the schlieren image formed by an arrangement as shown on Fig. 2 would be considerably larger than the working field itself. This would require a large size of film, and—because of the large area to be exposed—a high intensity of the light source. Furthermore, it would leave only a small depth of field. The working field will always in practice have some depth in the direction of the optical axis, and all points in this three-dimensional field must be reproduced with sufficiently good definition in the plane of the film. A secondary objective lens can eliminate the disadvantages mentioned above. It will give a suitable size of the schlieren image, reduce the amount of light required for exposure, and increase the depth of working field.

The diameter of the secondary objective lens must be nearly equal to the diagonal of the second grating. Because the lens works under favorable conditions, it need not be of high quality. An achromatic lens is to be preferred; it is not necessary, however, especially if monochromatic light is supplied.

The body of the camera is that of a standard 35-mm camera. A Packard shutter is mounted between the lens and the camera. The shutter is operated by hand. It is synchronized with the flash lamp so that the flash occurs when the shutter is fully open. Instead of this arrangement, it is possible for photographing transients to get a signal from the transient itself which can trigger the flash.

The critical part of the apparatus is the relative position of the first grating, the main objective lens, and the second grating. Therefore, these elements are supplied with sturdy supports. The base for the optical elements is an I-beam. Once the apparatus has been assembled and adjusted, there are only a few adjustments to be made during the operation. These are the direction of the bars in the gratings which changes the direction of the sensitivity, and the crosswise position of the second grating which changes the size of the sensitivity and the background illumination. The base and the supports for the optical parts are made in an ordinary machine shop since no extremely accurate parts are required.

Figure 5 shows another schlieren apparatus of the grating type. The apparatus was built at the Laboratory for Technical Physics at the Technical University of Denmark in Copenhagen. It is used mainly for projection, demonstrating the operating principle of an acoustic air jet generator which is seen as the second element from the left on the photograph. Since it is designed with a view to easy transportation to other laboratories the light source is not included in the apparatus. A standard carbon arc lamp or a projection lamp is normally used in connection with the apparatus. On Fig. 5 the two gratings and the objective lens, an $f{:}4.5$, $f = 15$ cm Zeiss Tessar anastigmat, will be easily recognized. The figure shows the apparatus as used for projection, and therefore, of course, no secondary objective lens or camera appear in the picture. The apparatus also differs from that shown on Fig. 3 in the fact that the gratings cannot be rotated about the optical axis of the system. Instead of this the air jet generator can be rotated if various directions of the pressure gradient are to be accentuated. This feature eliminates the necessity of adjusting the bars in the two gratings so that they are parallel each time the direction of the sensitivity (relative to the object investigated) has been changed. The total length of the apparatus is about 30 inches.[1]

4. ACKNOWLEDGMENTS

The schlieren apparatus employing gratings instead of knife edges was invented by Mr. F. Larris of the Laboratory of Technical Physics at the Technical University of Denmark in Copenhagen. The apparatus described above was developed at the suggestion of Dr. Jul. Hartmann, the head of the laboratory, who has made extensive use of the schlieren method during his experimental work on acoustics. The writer wishes to express his sincere thanks for the fine cooperation with Dr. Hartmann and Mr. Larris which made this paper possible.

Design Study for a Three-Bev Proton Accelerator*

M. S. Livingston,† J. P. Blewett, G. K. Green, and L. J. Haworth
Brookhaven National Laboratory, Upton, New York

(Received March 22, 1949‡)

A design study is presented for a proton synchrotron (to be called a "Cosmotron") to accelerate protons to energies of the order of three billion volts. Protons are injected from a four-million volt Van de Graaff machine. They are deflected electrostatically into a racetrack orbit including four quadrants of thirty-foot radius of curvature, and four straight sections ten feet long. The energy gain per revolution supplied by the radiofrequency system will be about 1000 ev. Acceleration will continue to 1.0 seconds to a final energy of about three Bev. Construction of this machine is now in progress.

1. INTRODUCTION

THE synchrotron principle of phase-stable acceleration in a magnetic field can be used to accelerate protons to energies well in excess of one billion volts (Bev). Energies of this magnitude are needed in order to study the processes of formation of mesons. From such studies it is anticipated that much can be learned regarding the role of mesons in nuclear forces. The simplest nuclear process—the bombardment of single protons by other, highly energetic protons—will be the most informative; in this process less than half of the kinetic energy is available for meson formation. The threshold for production of π-mesons (about 300 times electron mass) by this process would be about 300 Mev, and for adequate intensities an energy of 600 Mev is desirable. Production of multiple meson showers or of possible heavier mesons (such as the 700 mass mesons reported in some cosmic-ray observations) would require even higher energies. Furthermore, an energy greater than the 2-Bev theoretical threshold for heavy particle creation is certain to yield interesting and significant results. Accordingly, the design energy for the first Brookhaven proton accelerator (to be called a Cosmotron) has been set at 3.0 Bev. The AEC has approved the program, construction is now proceeding and the accelerator is scheduled for completion in late 1950. This paper is a report of the present design status, and a discussion of the factors leading to the design.

Magnetic accelerators for electrons, such as the betatron or the synchrotron, have a practical energy limit of the order of 1 Bev due to the rapid onset of radiation losses. Linear accelerators are in too early a stage of development to permit prediction of their possibilities in the Bev range. The synchro-cyclotron requires a solid core magnet which, at these energies, becomes exorbitant in weight and cost. A ring magnet is indicated to reduce cost, and protons can be used to avoid the radiation loss limitation. Under these conditions, the synchrotron principle provides a practical method of acceleration of particles to energies of several Bev.

The first proposal of a proton accelerator using a ring magnet, in which both magnetic field and frequency of the accelerating electric field are varied, was made by Professor M. L. Oliphant of the University of Birmingham, England, to the Directorate of Atomic Energy in 1943. This is reported in a detailed design study published in 1947,[1] accompanied by a theoretical analysis of orbit stability.[2] Construction of this accelerator, which will produce protons of 1.3 Bev, is in progress and it should be completed in 1950. Meanwhile the principle of phase stability in synchronous accelerators was announced independently by McMillan[3] at the University of California and Veksler[4] in the U.S.S.R. in 1945; both papers describe the possibility of acceleration of protons in a synchrotron by means of a variable frequency accelerating field.

Designs for super-energy accelerators have been in progress concurrently during the past two years at Brookhaven National Laboratory[5] and at the University of California.[6] These design studies show that energies of 10 Bev are attainable although the cost and time required for development are formidable. The simpler design problems, lower cost, and earlier completion date influenced our decision to start at 2 to 3 Bev. At some later time, when results on the first proton synchrotron justify it, the 10-Bev design may be reactivated.

2. THE PROTON SYNCHROTRON

The proton synchrotron uses a ring magnet to produce a magnetic field over an annular region, in which a doughnut-shaped vacuum chamber is located. Protons produced at low energy in an external source can be focused and deflected into the vacuum chamber. The magnetic field guides the particles in a circular orbit of constant radius, and is modulated from low to high intensity as the protons gain energy. An electric field to accelerate the protons is provided at one point in the circular path, so that the particles acquire an increment of energy on each revolution; this accelerating field must be oscillatory in nature and synchronized with the motions of the ions. Since proton velocity increases with energy, the frequency of the applied electric field must be varied during the acceleration to match the increasing angular velocity of the particles. This frequency must be precisely controlled to provide the correct phase of the accelerating field, so as to maintain constant orbit radius and prevent loss of particles by striking the walls.

The protons being accelerated in the vacuum chamber are bunched by the phase focusing inherent in the synchrotron. Across a gap at one point in the orbit, is applied a sinusoidal accelerating electric field with a peak voltage about double the value required per revolution to maintain constant radius. The radius, R, which at any moment satisfies the relation $v/2\pi R=$ frequency of accelerating signal, for the protons of velocity v, is known as the "equilibrium radius." If protons traveling on the orbit which has this radius arrive at the correct or "equilibrium" phase they will continue to circulate in the same orbit and to arrive at the correct phase. Protons arriving at other phases will oscillate in phase about the equilibrium phase provided their initial phase and radius do not differ too much from the equilibrium phase and radius; otherwise they will enter unstable orbits and be lost. Associated with the oscillations in phase are radial oscillations. The theory of these oscillations has been developed elsewhere.[2-4,7] The limitations on initial phase and radius are discussed further in Section 7 below. The frequency of the oscillation in the present case varies between about 2600 cycles per second at injection, and 1300 cycles per second at the end of the accelerating cycle. Initially, if the field is rising linearly with time, the amplitude of the radial oscillations will be inversely proportional to the magnetic field. In the extreme relativistic range, the amplitude will decrease as the inverse three-quarters power of the field.

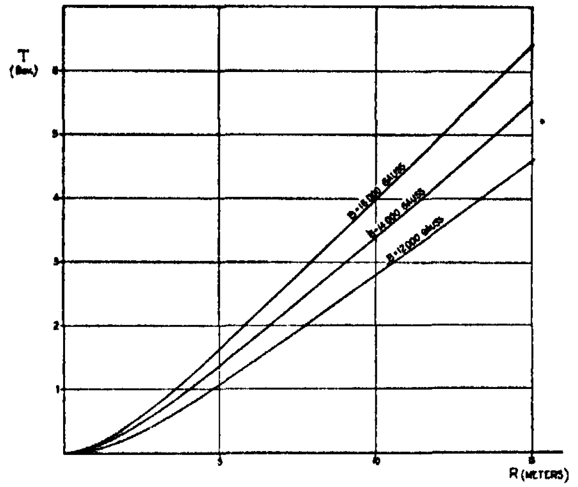

FIG. 1. Proton kinetic energy T *vs.* orbit radius R for several values of magnetic field B.

The magnetic field is not strictly uniform, but must decrease with increasing radius to provide restoring forces for particles which deviate from the equilibrium orbit or the median plane. These forces set up vertical and radial oscillations about the true orbit, known as "betatron" or "free" oscillations, with a frequency of 0.1–1.0 of the ion revolution frequency. These high frequency vertical and radial oscillations are superimposed on the lower frequency synchrotron oscillations to produce a flattened sausage-shaped envelope enclosing the rotating ions. At the start of the cycle when ion energy and magnetic field are low this envelope may extend halfway around the vacuum chamber and be limited in transverse dimensions by the internal size of the chamber. As energy increases, the oscillation amplitudes are rapidly damped to smaller dimensions centered on the equilibrium orbit.

Under ideal conditions the equilibrium orbit would remain fixed at the center of the vacuum chamber. However, the applied frequency may deviate from the value required to maintain a constant radius, and so cause radial displacements of the equilibrium orbit. One of the chief design problems of the proton synchrotron is to provide a control system to limit the frequency deviations and keep the resulting radial displacements within the useful aperture of the chamber.

3. TIME CYCLE

The time of acceleration, during which the magnetic field increases from about 300 to 14,000 gauss, is influenced and limited by several factors:

(a) peak kva required to excite the magnet,
(b) average power consumption—primarily heat developed in the magnet windings,
(c) volts-per-turn requirement for the accelerating electric field,
(d) loss of intensity by gas scattering.

A long acceleration time reduces the peak kva and the volts-per-turn; a short time decreases average power and loss of ions by gas scattering. The design value chosen to balance these several factors is 1.0 second, although the allowable range extends from 0.5 to 2 seconds. The reasons for this choice will be more evident in the discussion to follow.

After the protons have reached top energy and have been ejected, the current in the windings must be reduced to zero, and then the cycle is repeated. The high energy protons will be emitted in bursts over a period of a few microseconds at the end of each 1-second acceleration interval. The repetition rate is limited by the average power rating of the power supply, with a maximum of 12 per minute. The power supply and the techniques to be used for re-cycling the energy stored in the magnet are discussed in a later section.

4. ORBIT RADIUS

The product of magnetic field and orbit radius (BR) is a measure of proton energy. A practical limit on the field in iron magnets is set by saturation of the iron, at roughly 18 kilogauss. Depending on the quality of the iron and the design of the magnet, this will establish an allowable maximum field in the gap between poles. Our design of a simple "*C*" magnet structure with wedge-shaped spaces between iron plates results in average fields in the gap between poles of about 14 kilogauss for fields in the iron of 17 to 19 kilogauss. Alternate magnet designs with closer packing of iron would result in higher fields in the air gap, but would involve a more complex structure and greater expense. The design choice is essentially one of minimizing cost for a desired BR value. Our choice has been a relatively large radius and a low field.

The dimensional relation between maximum kinetic energy T_m, magnetic field B_m, and radius R is given (in m.k.s. units) by:

$$T_m(T_m+2E_0)=c^2e^2B_m{}^2R^2. \quad (1)$$

Here T_m is the kinetic energy and E_0 the rest energy of the particle being accelerated and e is the charge of the particle. This expression has been evaluated for protons and is plotted in Fig. 1, with proton kinetic energy (in Bev units) a function of radius for several values of magnetic field. The orbit radius of 30 ft. chosen for the Brookhaven accelerator, at 14 kilogauss, would allow acceleration of protons to 3.1 Bev, deuterons to 2.5 Bev, or He^{++} ions to 5.0 Bev.

5. MAGNET DESIGN

The magnet design chosen after a careful study of alternate structures involves several unusual features. It is basically a "*C*" section with minimum size "window" for the windings. Choice of the *C* shape was influenced by the desire to provide ready access on one side of the magnet gap along the entire periphery. Pump leads can be located as frequently as desired along the length of the vacuum chamber, a valuable feature when vacuum requirements are severe and chamber cross section is small. Access to the chamber for inspection and maintenance is also simplified. When the slot opening of the *C* is on the outer face of the ring, high energy ions or neutrons will emerge tangentially from the accelerator around the entire circumference. To be sure, every effort will be made to eject a concentrated beam in a narrow angle; however, this deflected beam may be limited to a small fraction of the total circulating current. The external slot is thus good insurance that the high energy ions can be utilized to the maximum for experiments. This "poleless" *C*-shaped magnetic circuit has minimum dimensions and weight and requires only two accurately machined surfaces (the pole faces), effecting a significant saving in cost of construction. The octagonal shape is a compromise between a square and the ideal circular shape, and is achieved by cutting off the corners of square plates in manufacture. The magnet cross section is shown in Fig. 2.

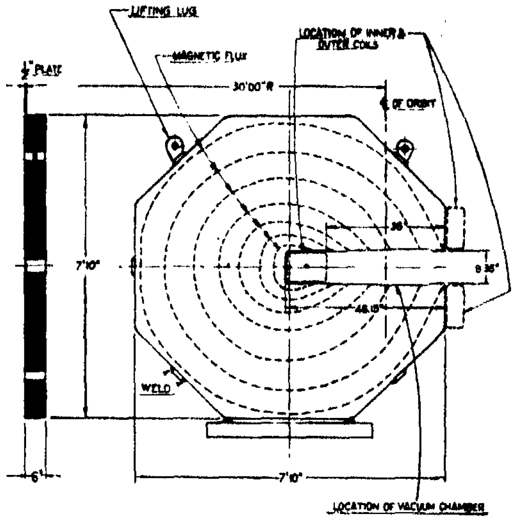

FIG. 2. Cross section of "*C*" magnet and assembly of blocks of ½-inch plates.

Since magnetic field will increase at an average rate of 14 kilogauss/sec. during the acceleration interval, lamination of the iron is essential. Detailed analysis of the eddy currents (see Section 13) has justified a choice of ½-inch plate, which has the advantage of being readily available in large dimensions and at a low base price. The material chosen is equivalent to SAE 1010 mild steel and has magnetic properties closely approaching those for soft iron.

In order to simplify the problems of machining and handling the thousands of half-inch steel plates, a procedure has been devised in which the plates will be pre-formed into bundles for handling and machining. Plates will be rough cut to the octagonal shape, fish paper insulation will be inserted, and then the plates will be stacked into bundles of 12 and welded together by tie-bars at the outer edges. These tie-bars do not link appreciable magnetic flux and so do not introduce an eddy current problem.

Since the plates are welded together, it is no longer possible to test for interlamination short circuits which might be serious if they occurred near the magnet gap. To make a short circuit test possible the insulation between laminations consists of a sandwich of two layers of 7-mil fish paper separated by a 1-mil sheet of aluminum foil. It is expected that any metallic connection which appears between blocks such as, for example, a metal chip, will puncture the aluminum foil and can be detected by a resistance measurement between aluminum foil and steel plate.

Each bundle of laminations will weigh about 5.7 tons, and will be machined as a unit to the precise dimensions and pole shape determined from model tests. There will be 288 such bundles, each about 6 inches thick,

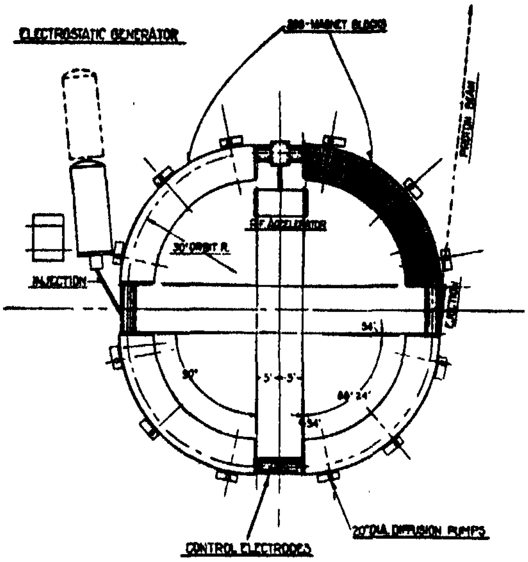

FIG. 3. Plan view of Cosmotron magnet and assembly.

assembled and joined together to form the ring structure and mounted on an accurately aligned base. The base plates will be adjustable in elevation to allow for possible settling of the foundation, and accurate instruments will be used to observe and correct for such settling.

As the design studies at Brookhaven have developed, it has become evident that there are several reasons for desiring sectors of the ion orbit which are free from magnetic field. Such a field free region is essential to accommodate the induction accelerator to be described later; it also simplifies the problem of ion injection and ejection. These considerations have led to a "racetrack" structure for the ring magnet, in which four quadrants are separated by straight runs across which the vacuum chamber extends. These straight sections will be 10 feet in length. The racetrack design was first proposed by Crane[8] and has been investigated theoretically by Dennison and Berlin[9] for the Michigan synchrotron. In this study the authors showed that four or more symmetrically placed short gaps in the magnetic field will not cause defocusing or set up excessive ion oscillations. Higher frequency angular perturbations in the field such as those caused by the magnet laminations or bundles of plates are insignificant in their effect on ion oscillations. Figure 3 is a plan view of the racetrack magnet. As indicated in Fig. 3 the quadrants will each subtend an angle slightly less than 90° at their centers of curvature. This is because the stray fields at the quadrant ends will be appreciable. Model measurements indicate that the ion beam will undergo a 90° deflection for a "quadrant" of 88.4°.

In principle a winding located in a slot of the *C* magnet can provide the necessary excitation. However, this coil of large diameter would produce magnetic fields in the air both inside and outside the circular magnet. External fields (well beyond the iron) would be of the order of hundreds of gauss when the field in the gap is 14 kilogauss. Such external magnetic fields are objectionable from the point of view of operation of instruments nearby and also represent a large stored energy in the air external to the iron of the magnet. In our first model studies the external stored energy with such a slot winding was observed to be approximately 40 percent of the stored energy in the magnet gap itself. The obvious way to reduce this stored energy and eliminate the external fields is to have return windings around the outer periphery of the magnet. Further model tests with such a return winding split symmetrically above and below the slot showed a reduction of the external stored energy to 13 percent of that in the gap. The final choice of exciting coils is indicated in the perspective drawing of the end of a quadrant shown in Fig. 4. In order to minimize the fringing magnetic field in the straight sections, the exciting coils are to be wound around each quadrant separately, but powered in series to obtain identical currents in the four quadrants.

The shape of the winding in the gap can be made to provide a uniform magnetic field in the neighborhood of the winding. Computations of the appropriate winding shape lead to a crescent-shaped cross section. Adjustment of an arbitrary parameter in the cross section leads to a special case in which the winding has a simple rectangular cross section. These theoretical predictions have been supported by model measurements.

The slot windings are made as small as practical in order to minimize the size of the "window" and thereby to reduce magnet weight, stored energy and power requirements. Water cooling will be used rather than forced air or oil immersion cooling. The conductors will be fabricated from rectangular copper tubing of $\frac{3}{4}$ inch by $1\frac{7}{8}$-inch cross section having a $\frac{3}{8}$-inch diameter hole for water cooling. There will be 48 conductors in the slot, arranged in four layers.

The return windings, located above and below the gap on the outside of the magnet, do not have as severe a space limitation, and so have been designed with a 50 percent larger cross section than the slot windings. They will consist of two bundles of 24 turns each, in which each turn will be $\frac{3}{4}$ inch by $2\frac{13}{16}$ inch in cross section and will have a $\frac{3}{8}$-inch water-cooling channel. Connectors joining the inner and outer windings at the quadrant ends will have the same cross section as the outer windings and will also be water cooled.

Water cooling leads for the conductor bars will be brought out in parallel to water manifolds located at the ends of the quadrants, as shown in Fig. 4. Insulation of the $\frac{3}{8}$-inch cooling water pipes will be provided by

---

[8] H. R. Crane, Phys. Rev. 69, 542 (1946).

[9] D. M. Dennison and T. H. Berlin, Phys. Rev. 70, 58 (1946).

5-foot lengths of rubber or plastic hose located between the manifolds and the conductors. The temperature rise in the conductors will be limited to 10°F to minimize thermal expansion and reduce the resulting abrasion of insulation. This requires a total water flow of 500 gal./min. through the 384 parallel cooling tubes, and will be supplied by a pressure head of about 20 lb./in.^{2}. The water will be recirculated through a heat exchanger and a purifier system to maintain an adequately low electrical conductivity.

6. MAGNET POWER

The power supply for the magnet must provide a pulsed current rising approximately linearly with time to a maximum in 1 second, then the current must be reduced to zero as rapidly as possible. This cycle will be repeated at 5-second intervals. The most critical design decision is on the method of energy storage and cycling. At 14,000-gauss field in the magnet gap the total energy stored in the magnet is 1.2×10^7 joules. An electrical capacitance large enough to store so much energy would be prohibitively expensive. The use of batteries would introduce insoluble switching and maintenance problems. On the other hand it is relatively easy to store large quantities of energy in a flywheel. The decision has been in favor of a motor-flywheel-a.c. generator-rectifier unit which will transfer energy to the magnet during one second and then return the magnetic stored energy to the flywheel.

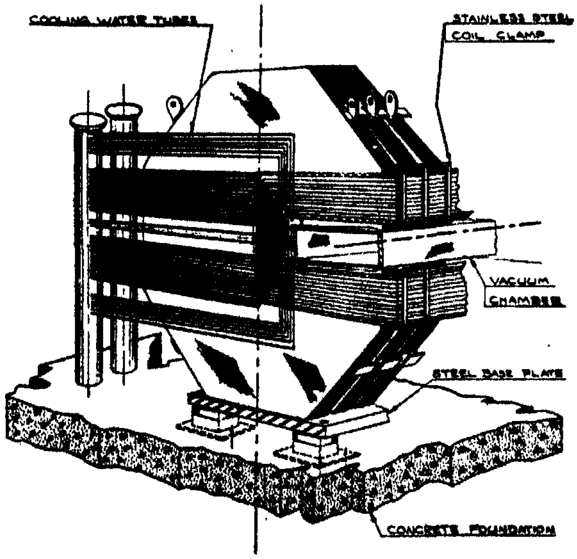

FIG. 4. End view of magnet quadrant with exciting coils and water cooling.

Advice from manufacturers indicates that a reasonable voltage rating for such a power supply would be of the order of 5000 to 6000 volts, dropping by 30 percent or so under full load. The choice of voltage fixes the number of turns in the magnet winding. The pertinent parameters have been computed and checked by measurements on scaled models. At 14,000 gauss, for example, we require a current I in an N turn coil where

$$NI=3.36\times10^5 \text{ ampere turns.} \tag{2}$$

At 14,000 gauss field the total flux in the gap, in the winding, and in the stray field is

$$\phi=88 \text{ webers,} \tag{3}$$

and its rate of change

$$\partial\phi/\partial t=58 \text{ webers per second.} \tag{4}$$

From coil dimensions the resistance of the coil is

$$R=4.95\times10^{-5}N^2 \text{ ohm.} \tag{5}$$

We can now derive the number of turns in the winding from the relation

$$V=N(\partial\phi/\partial t)+RI \tag{6}$$

$$=75N \text{ from (2), (4) and (5).} \tag{7}$$

If we assume that, at 14,000 gauss the supply voltage V has dropped to about 3600 volts, we obtain

$$N=48 \text{ turns.} \tag{8}$$

At 14,000 gauss the peak current in a 48-turn coil will be

$$I_{\max}=7000 \text{ amperes.} \tag{9}$$

The resistance of the magnet winding will be 0.14 ohm. Model measurements show that its inductance will vary from an initial value of 0.47 henry to a maximum of 0.80 henry at about 1000 gauss; as the iron saturates the magnet inductance drops to a final value of about 0.25 henry.

The power supply, which is on order, consists of a wound-rotor induction motor rated at 1750 hp direct connected to a large flywheel and a twelve-phase alternator feeding a bank of ignitron rectifier-inverters. The alternator has a nominal rating of 20,000 kva, specially designed to withstand rectifier service; it will deliver 6000 volts at no load and a peak of 7000 amp. at 4200 volts under full load. The rectifier inverter bank has 24 ignitrons in a 12-phase circuit, with grids and igniters controlled to rectify the alternator output during the 1-second acceleration interval, and then to switch to inverter action to return the stored energy in the magnet (less heat losses) to the alternator-flywheel. The flywheel will be reduced in speed by about 6 percent at the peak of the cycle, representing a 12 percent decrease in the energy stored in the rotating flywheel. The motor will bring the speed back to the original value in the interval between power cycles. This operating cycle can be repeated at a maximum rate of 12 times a minute. The average power demand by the motor at 12 cycles per minute is estimated at 1000 kw; a control system for the motor will limit line surges to 2000-kva peak. Protection against faults is obtained by removing ignitron excitation and closing a fast acting shorting switch across magnet terminals. Under these

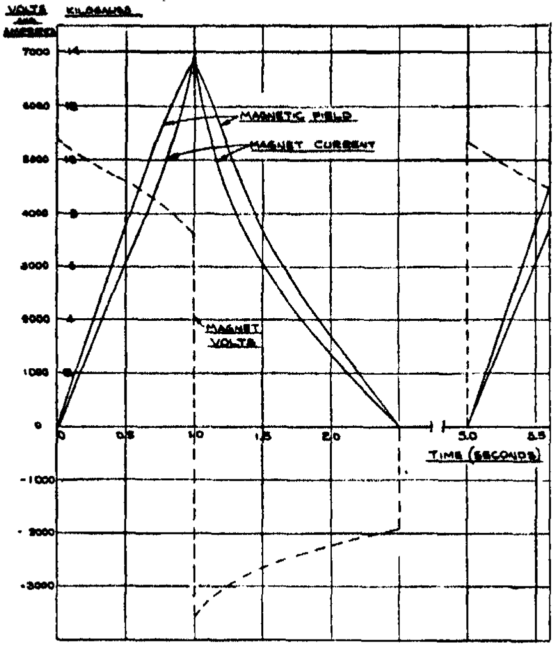

FIG. 5. Time cycle of applied voltage and current in magnet exciting coils, and of magnetic field at the proton orbit.

conditions the magnet windings have adequate thermal capacity and cooling to discharge the peak stored energy for one cycle. Frequency of arc-backs or other faults in the ignitrons is estimated at 1 to 2 per week under full power operation.

The peak current rating of 7000 amperes provides 3.36×10^6 ampere turns, permitting operation to fields of about 14,000 gauss. The magnetic field rise will be non-linear, starting at 16.5 kg/sec. and falling to 9.8 kg/sec. at 1 sec. The time cycle for V and I has been derived from model measurements and is illustrated in Fig. 5, and the variation of dB/dt along with the resulting curve of volts-per-turn required for acceleration at constant radius is shown in Fig. 6.

7. APERTURE DIMENSIONS

Most theoretical studies of particle oscillations in the magnetic field of a synchrotron have been applied only to electrons. At the Massachusetts Institute of Technology Frank and Twiss,[7] in collaboration with the Brookhaven design group, have studied orbital stability specifically for a proton synchrotron. The equations of motion were analyzed to determine frequency, amplitude and damping of phase oscillations and the necessary conditions for stability. Similar calculations were made by the British investigators.[2] As in the electron synchrotron, the oscillations have their maximum amplitude near the start of the motion when the particles are injected and are damped as the energy and magnetic field increase. The limits of stable phase oscillation during injection establish a "phase acceptance angle." For protons of 3-Mev energy, injected in a narrow bundle at the position of the equilibrium orbit for particles of this energy, the phase acceptance angle is approximately 180°. This means that for a beam of constant intensity 50 percent of the ions will be bunched and accelerated synchronously; the remainder will be phase unstable and will be lost to the walls. As the particles oscillate in phase they also oscillate in energy, and so traverse orbits of varied radius. Those ions which are injected at the extremes of the acceptance phase angle will deviate most from the equilibrium energy and will have the maximum amplitude of about ±8 inches; this will be reduced to a fraction of an inch by the time the ions have reached a few hundred million volts energy.

Ions which are injected at an angle to the equilibrium orbit will oscillate about this orbit with the familiar "betatron" type oscillations. The same is true of ions injected parallel to the orbit but displaced from it, such as would result from mistiming of injection. The frequency and amplitude of the betatron oscillations are determined by the "shape" of the focusing magnetic field.

The magnetic index "n" used to define the shaping of the field is given by:

$$B = B_0(r_0/r)^n \tag{10}$$

where B_0 is the field at the central orbit of radius r_0, and B is the field at radius r. By differentiation:

$$n = -r_0/B_0 dB/dr. \tag{11}$$

For circular machines the range of values of n for stability of both vertical and radial oscillations has been shown[10] to be: $0<n<1$, and the angular frequency

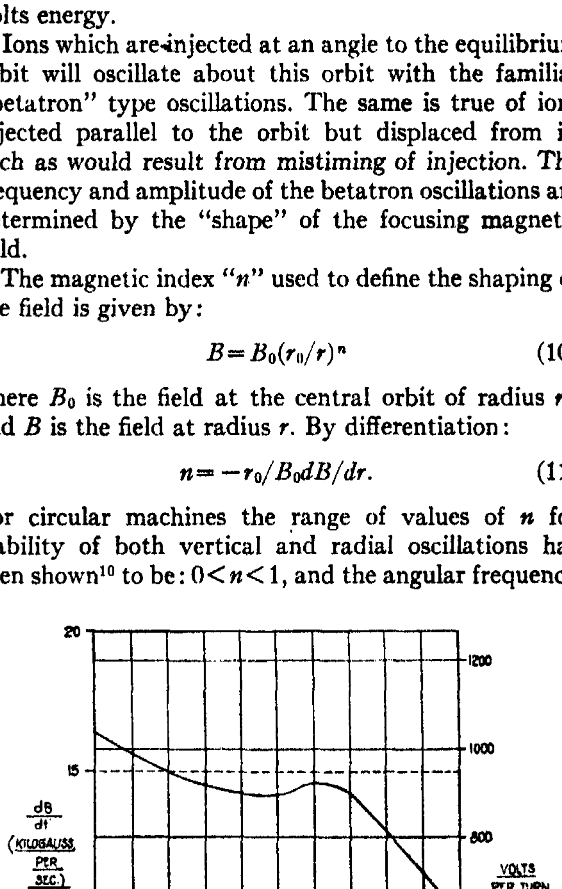

FIG. 6. Rate of change of magnetic field, and accelerating voltage per turn required during acceleration.

---

[10] D. W. Kerst, Phys. Rev. 60, 47 (1941).

of vertical and radial oscillations is a simple function of n:

$$\left.\begin{aligned}\omega_z &= (n)^{\frac{1}{2}}\omega\\ \omega_r &= (1-n)^{\frac{1}{2}}\omega\end{aligned}\right\} \tag{12}$$

where ω is the particle angular rotation frequency. Amplitudes are determined by the initial conditions of displacement and also are affected by the value of n. For large n (near unity) when the decrease of field with radius is greatest, the vertical restoring forces are a maximum and vertical oscillation frequency is essentially equal to ω; the converse is true for small n. Economy in magnet design demands the minimum practical air gap (vertical coordinate) and so a high value of n. A reasonable choice from such simple considerations would be in the range: $0.5<n<1$.

With four straight sections each of length L, the magnet quadrants of radius R, the betatron frequencies are to a first approximation:

$$\begin{aligned}\omega_z &= [1+L/(\pi R)](n)^{\frac{1}{2}}\omega,\\ \omega_r &= [1+L/(\pi R)](1-n)^{\frac{1}{2}}\omega.\end{aligned} \tag{13}$$

The corrective factor, $L/(\pi R)$ is about 10 percent for 10-ft. straight sections and 30-ft. radius. The limits of betatron oscillation stability are unchanged. However, the change in frequency is significant in the analysis of ion orbits at injection, in determining whether the ions will be intercepted by the injector electrodes in the first few revolutions.

Other limitations on choice of n involve possible resonances which might feed excessive energy into one mode of oscillation. The most familiar is the resonance between radial and vertical betatron oscillation frequencies at $n=0.2$ which has been observed in the synchro-cyclotron. For circular machines other possible resonances exist of which the most significant are at $n=0.5$, 0.75, and 0.80 and 1.0. With our racetrack design these same resonances occur at $n=0.5$, 0.80, 0.80 and 0.81. The resonance at $n=0.81$ is for $\omega_z=\omega$ and will cause large amplitude vertical betatron oscillations.

Damping of synchrotron phase oscillations is a slowly varying function of n. With protons the damping becomes positive only for $n>0.67$ (circular) or $n>0.72$ (racetrack) so this would appear to set a lower limit to n. However, the anti-damping for n smaller than this limit is not serious, and results in only a 5 percent increase in amplitude for n as small as 0.4. It may also be compensated by other techniques such as increasing the amplitude of the radiofrequency accelerating voltage.

Eddy current distortion of the magnetic field at the time of injection and saturation effects near the end of the cycle are treated in detail in Section 13. However, the general conclusion can be drawn that such effects will tend to produce an anomalously high value of n. This suggests an n value as low as is compatible with other limitations such as the vertical aperture. From the above considerations a figure of $n=0.6$ has been chosen, with an acceptable range: $0.50<n<0.80$. A certain amount of fluctuation in n may be desirable, to avoid dwelling too long on a specific value characteristic of a high order resonance.

A detailed analysis of the oscillations during injection is given in Section 8. It is shown that the energy spread, angular divergence, pulse length of the injected ions, and gas scattering result in a flattened sausage-shaped envelope for the accelerated ions soon after injection, of about 180° angular length, ±10 inch radial width and ±3.5 inch height. This envelope would be centered about an equilibrium orbit, ideally at the center of the chamber. Errors in frequency of 0.1 percent will cause radial displacements of the equilibrium orbit of about 1 inch at injection, decreasing to smaller displacements at later times. Control of frequency to 0.3 percent is considered to be straightforward, and a precision of 0.1 percent is possible with further development. The radial aperture taken up by the ion envelope might thus be increased to 23 inches for frequency errors of ±0.15 percent.

The gross radial aperture chosen is 36 inches, which is 10 percent of the orbit radius. The net aperture inside the vacuum chamber and within the useful region of magnetic field ($n<0.80$) is about 30 inches. Vertical clearance between magnet poles is 9.35 inches, resulting in a usable vertical aperture of more than 7 inches. A direct comparison with the apertures used for betatrons and electron synchrotrons is difficult, since in these machines injection is at much lower magnetic field, the electron beam from the gun is poorly collimated and injection efficiency depends on betatron acceleration at the start. Radial apertures used in such machines vary from 25 percent of the orbit radius in early designs to 10–15 percent in more recent designs. Most of the difficulties experienced with electron accelerators are associated with the very low magnetic fields at injection, as low as 7 gauss in some instances. The much higher injection energy of the Cosmotron, resulting in fields of about 300 gauss at injection, and the improved collimation available from an electrostatic generator source, justify the choice of a minimum size aperture. The savings in size and cost of magnet iron and the reduction of power demands with the small aperture, were the influencing factors in making the decision.

The discussion above illustrates the difficulty of defining a minimum aperture. Injection pulse length will be adjusted in practice to give maximum intensity, in which case the ions at the extremes will be lost to the walls. Oscillation amplitudes may be greater than those estimated in this study, due to factors such as high order resonances, gas scattering or magnetic inhomogeneities which cannot be anticipated. However, the consequence will be loss in intensity due to ions on the periphery of the envelope striking the walls. Our best estimate is that the final intensity will not be reduced below 10 percent of the number accepted into resonant orbits at injection.

8. INJECTION

All considerations point to the desire for high injection energy. The initial frequency increases with injection energy, thereby reducing the range of frequency sweep required; uniformity of magnetic field at injection improves with increasing field; gas scattering decreases with increasing energy. These factors indicate an injection energy of a few million volts. However, there are practical limits on the energy available from existing types of low energy accelerators which are adaptable to this purpose. The electrostatic generator seems to us to fill the requirements for a source of ions more adequately than other types; it has already been developed to provide the voltage uniformity and small divergence required and the ion source can be pulsed if desired. The cyclotron is a possible alternate which would give higher energies but the focusing of the emergent beam is notoriously poor and its energy uniformity cannot be made comparable with the electrostatic generator except by serious reduction of intensity.

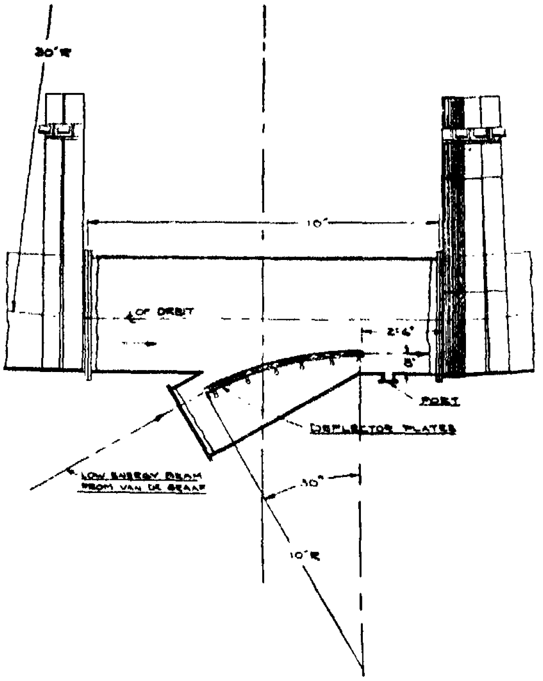

FIG. 7. Electrostatic deflecting system for injection at periphery of vacuum chamber.

Electrostatic generators in the 3–4-Mev range have been developed in several laboratories, with difficulties increasing rapidly toward the top of this range. We have chosen to utilize proven designs and existing knowledge rather than attempt new designs for still higher energy. A "4 Mev" generator will operate reliably at 3 Mev, but usually requires considerable conditioning to operated at its rated voltage. Accordingly, our design parameters are chosen for injection at a minimum of 3 Mev, capable of adjustment to higher injection energy when desired. These parameters are:

Injection energy	3.0 Mev	4.0 Mev
Magnetic field	271 gauss	311 gauss
Ion rotation frequency	0.35 Mc	0.40 Mc
Volts/turn (acceleration)	1040 volts	1040 volts
Time after $B=0$	0.014 sec.	0.017 sec.

Judging from past experience with electrostatic generators, the ion beam at 3 Mev will have an energy spread of less than ±10 kilovolts and an angular divergence smaller than $\frac{1}{4}$ inch in 10 ft. The synchrotron oscillations will require 50 or more revolutions to build up and so have small significance for injection. At these energies and anticipated beam intensities the effects of space charge can be neglected.

A number of methods of injection have been proposed,[7] to minimize loss of ions on subsequent revolutions by striking the injection electrodes or the chamber walls. Some of the methods involve the use of internal electrodes to provide electric fields which will damp the oscillations adiabatically; others propose rapid changes of phase of the accelerating electric fields or a distorted frequency modulation cycle.

The method chosen for injection into the Cosmotron depends on the decrease in radius of path associated with the increasing magnetic field. If particle energy remains fixed (no acceleration during the first few revolutions) the decrease in radius of the equilibrium orbit proves to be: $\Delta R=0.18$ inch/turn. Protons will be injected at one of the straight sections, parallel to the equilibrium orbit at the outer edge of the chamber, at a time when the equilibrium orbit for 3.0-Mev protons is, say, at 2 inches inside the radius of the injector. The ±10-kilovolt energy will result in a band of equilibrium orbits ±1.5 inches wide centered on the mean orbit. The radial betatron oscillations will have initial amplitudes varying between ±0.5 and ±3.5 inches. For a magnetic field index $n=0.6$, the frequency of these radial oscillations is (Eq. (13)):

$$\omega_r=[1+L/(\pi R)](1-n)^{\frac{1}{2}}\omega=0.70\omega. \qquad (14)$$

Hence the maximum positive amplitudes for subsequent revolutions are displaced in angle from the injector position by: 150°, 300°, 90°, 240°, etc. The average particle will make 5 to 10 revolutions before the phase of the maximum amplitude coincides with the location of the injector. If, during this time (15–30 μsec.) there has been no change in energy, the equilibrium orbit will have moved inward 1 to 2 inches, sufficient for a large fraction of the ions to miss the injector.

Angular divergence adds to the radial oscillation amplitudes and also introduces vertical oscillations, with a frequency (at $n=0.6$) of 0.86ω, centered on the median plane. Due to this effect alone, the maximum dimensions of the ion envelope have been computed to be ±0.5 inch vertically and ±0.75 inch radially. Vertical oscillations can be used to advantage by injecting at a position above (or below) the median plane and depending on the mismatch of frequencies to cause the ions to pass below the injector when the radial oscillations alone might cause a hit. So the number of free revolutions can be increased to 10 or 20 and the effective shift in equilibrium orbit radius doubled.

Loss of ions due to impact on the back of the injector or against the walls can be estimated from the considerations above. A short pulse lasting for only a few revolutions, timed for the optimum location of the mean equilibrium orbit (about 2 inches inside the injector), should lose no more than 10 percent during injection. In principle a long pulse could be used, timed to overlap the entire interval during which the equilibrium orbit moves from the injector radius into the center of the chamber, at which point the betatron oscillations fill the chamber. A much larger total number of ions could be thus injected, but the fraction lost would be larger. In practice a variable pulse length and variable injection timer will be used to pick the optimum conditions experimentally.

The electrostatic generator will be so located that the beam is directed at a small angle toward the straight section used for injection. The ions can then be deflected electrostatically so as to enter the first quadrant at the chosen radial position. A field of 50 kilovolts/inch is sufficient to deflect 3-Mev protons on a 10-ft. radius. This deflecting electrode is shown schematically in Fig. 7. Provisions will be made to adjust the radial and vertical location of the deflecting channel and the beam. A channel $\frac{1}{4}$ inch wide will contain the beam, so the minimum orbit shift required to miss the injector is of the order of $\frac{1}{4}$ inch.

The injection scheme described above is most efficient if the ions are not being accelerated during injection. The radiofrequency accelerator can be turned on when the mean equilibrium orbit approaches the center of the chamber, and brought up to full voltage in a few cycles. Within a few hundred cycles synchrotron oscillations will be set up and about half of the uniformly distributed protons will be accepted and trapped in stable synchrotron orbits. The maximum amplitude of the radial synchrotron oscillations is ±8 inches, and on this will be superposed the betatron oscillations whose amplitude will increase due to gas scattering to a maximum of about ±4 inches. This maximum, occurs, however, after the synchrotron oscillations have been damped to some extent. The net oscillation amplitude has, therefore, a maximum value of about ±10 inches.

The beam intensity or number of protons accepted and accelerated during each cycle, depends first on the output of the electrostatic generator. The output desired is a high intensity pulse, of about 100 μsec. pulse length (corresponding to an orbit shift of 7 inches). A development program is under way to provide an ion source for the electrostatic generator which can be pulsed (at 5-second intervals) to provide the highest possible peak intensity. The present estimate of the best peak intensity achievable is 1.0 milliampere of protons accelerated to 3.0 Mev; under these conditions the energy spread and angular divergence will probably be considerably larger than the values obtained for low intensity steady beams. If 10 percent of the protons injected during 100 μsec. are within acceptable oscillation amplitude limits, we could expect 5×10^{10} protons to be successfully injected. Consideration of the scattering due to residual gas in the chamber, and other factors causing loss of intensity, indicate a beam of the order of 10^9 protons per pulse at 3 Bev.

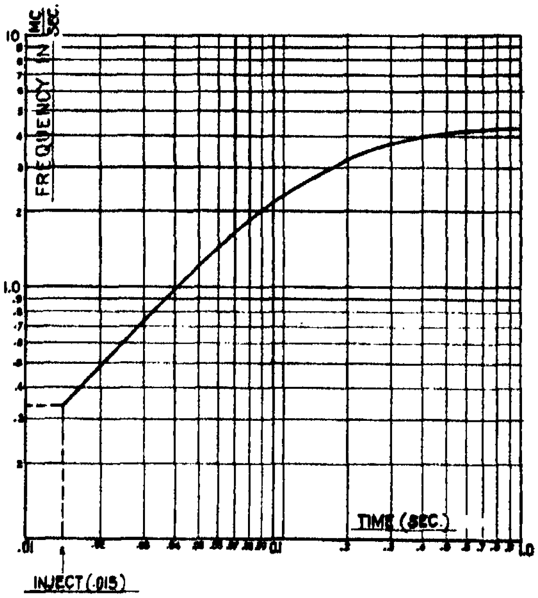

FIG. 8. Cosmotron frequency cycle.

9. RADIOFREQUENCY ACCELERATOR

Ions will rotate in a circular orbit in a uniform magnetic field at a frequency f given by:

$$f=\frac{\omega}{2\pi}=\frac{eB}{2\pi m}=\frac{c^2eB}{2\pi(E_0+T)}. \tag{15}$$

With the racetrack orbit having four straight sections each of length L and four quadrants of radius R, the frequency is decreased by the ratio:

$$\frac{f_i}{f}=\frac{2\pi R}{2\pi R+4L}=0.824. \tag{16}$$

A plot of ion rotation frequency, f_i as a function of time is given in Fig. 8 for the 1-second acceleration cycle. For protons at the injection energy of 3 Mev and the magnetic field of 271 gauss, this frequency is 0.35 Mc, rising to 4.20 Mc at the maximum energy of 3 Bev.

In order to maintain constant radius the ions must be

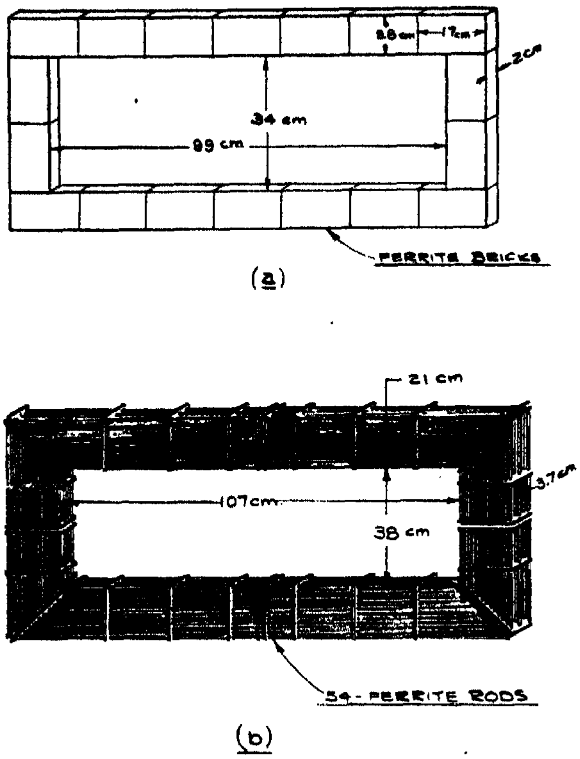

FIG. 9. Typical sections of ferrite core for accelerating transformer.

accelerated on each turn by an amount determined by the rate of change of magnetic field with time, dB/dt. This function of "volts per turn" is plotted in Fig. 6, and shows a value of 1180 volts at injection falling to 680 volts at 1.0 sec. A radiofrequency voltage synchronized with the ion rotation frequency will be applied to the accelerating gap. In order to maintain stable synchrotron oscillations over a wide range of phase and energy the peak r-f voltage should be materially higher than the average "volts per turn" required. A theoretical study[7] shows that a peak voltage double the average requirement will maintain phase oscillations of 0.86π-total amplitude. In this situation the equilibrium phase for protons of the correct energy will be displaced from the voltage peak by 60° and such particles will receive the correct "volts per turn."

The r-f accelerator must supply a potential of about 2400 volts across the accelerating gap at 0.35 Mc, dropping to 1400 volts at 4.20 Mc, following the frequency schedule illustrated in Fig. 8. The precision in frequency required to keep the orbit radius within reasonable limits is of the order of 0.3 percent. The wide frequency sweep and the requirement of following a predetermined schedule, are unique features of the proton synchrotron and pose some of the most difficult problems.

Several methods have been suggested and tested for generating the variable frequency signal. In view of the required precision of the timing and frequency control, electronic tuning appears decidedly preferable to mechanical tuning. The signal generator which has given the most promising results is an LC oscillator in which the inductance is varied by saturation of a ferromagnetic core. The core consists of two toroids of a ferromagnetic ferrite having an initial permeability of the order of 1000. The oscillator tank circuit winding threads both cores, while the control winding has a figure eight configuration around the cores so that no coupling exists between the two windings. The required tuning has been covered with some latitude with this oscillator. When the temperature of the ferrite is held constant to 0.1°C, the oscillator frequency is stable and reproducible at any control current to better than 0.1 percent.

Amplification of the output from the oscillator will proceed in a 4-Mc band width power amplifier. Amplitude control during the cycle will be provided from a pick-up on the accelerating unit.

The proton accelerating system for the Cosmotron presents several new problems. A fixed frequency resonant system, such as the resonant cavity circuit used for electron synchrotrons, would draw excessive power when off resonance. Either the accelerating system must be continuously tuned over the desired frequency sweep, or its impedance must be high enough that it can operate untuned without requiring excessively high power levels. We have chosen the latter approach and have investigated the use of ferromagnetic loading materials to give the desired high impedance accelerating system. This has led to a design which consists of a ferromagnetic core surrounding the vacuum chamber, located in one of the straight sections between magnet quadrants where the magnetic fringing field is negligible. A winding of a few turns excites the core. This winding is supplied from the r-f power amplifier. Evidently the system is a transformer in which the proton beam constitutes a one-turn high impedance secondary.

The input impedance of this system will be:

$$Z = 4\pi\omega N^2(A/d)(\mu/\mu_0)(1/Q+j)\times 10^{-7}\text{ ohm} \quad (17)$$

where $\omega = 2\pi f$, N is the number of turns in the exciting winding, A is the cross section of the core in square meters, d is the length of core in meters, μ/μ_0 is the ratio of permeability of the core material to that for free space and Q is the usual figure of merit of the exciting winding including the effects of core losses.

TABLE I. Comparative properties of magnetic core materials at 1 megacycle.

Material	μ/μ_0	Q
4-79 Mo Permalloy (1 mil lam)	600	0.6
Fe powder (80 mesh grade B)	35	2.0
81 Permalloy powder (120 mesh)	75	1.6
2-81 Mo Permalloy powder (120 mesh)	125	3.0
Typical ferrite	1000	6.0

If, for example,

$$f=1.0\text{ Mc},\quad N=1\text{ turn},\quad A=0.05m^2,\quad d=3m,\quad \mu/\mu_0=1000:$$

$$Z=133(1/Q+j)\text{ ohms.} \qquad (18)$$

The applied voltage on a one-turn winding must equal the peak r-f potential needed for accelerating the proton beam. If this is 2400 volts and Q is 5, the r-f current required would be 18 amperes peak. An alternative arrangement would be for $N=4$ turns in which case the applied r-f potential would be 9600 volts and the r-f current 3.5 amperes. Currents of this magnitude can be supplied by a conventional amplifier using commercially available transmitting tubes. The power requirements for the amplifier are of the order of 100 kw.

The primary problem in this system is the choice of the ferromagnetic core, which must have a sufficiently high permeability at 4.2 Mc to provide efficient flux linkage and which does not introduce unreasonable losses in this frequency range. If the Q of the core is greater than 0.5 up to 4.2 Mc, it will be satisfactory. Fortunately, new materials have been developed during the past few years which have the required properties. These are non-metallic ferrites which have high permeabilities at high frequencies and also have high resistivity so that fine lamination is unnecessary. The components of metallic ferrites are ground, mixed in proper proportions, formed into shapes under high pressure, and then sintered and annealed under controlled temperatures which favor re-crystallization in such a manner that the material acquires ferromagnetic properties. Ferrites having different compositions and treatment show a wide range in properties. In general, high permeability goes with a narrow frequency range and vice versa. Permeabilities of 500 or greater can be obtained with materials having $Q>0.5$ at 4.2 Mc.

A number of ferrites have been investigated and tested. Laminated sheet material such as Permalloy tape in thicknesses of less than one mil, and powdered iron and permalloy have also been tested for comparison. Comparative data on μ/μ_0 and Q for ring core samples of the several materials are given in Table I. The ferrites appear by far the most promising at these frequencies.

The resistivity and dielectric constant of the ferrites are such that eddy current effects will be rendered negligible by lamination to a maximum thickness of about 2 cm.

Two fabrication techniques have been tested, both of which appear to be satisfactory. One procedure involves stacking of "picture frames" of ferrite. The individual frames are assembled as shown in Fig. 9(a) by cementing together 18 ferrite blocks 2×17×9.8 cm. This frame will surround the vacuum envelope with sufficient clearance to allow for insertion of exciting windings. The other procedure uses round, extruded rods about 1 cm in diameter. These rods are stacked and cemented into mycalex supports. The ends of the stacks are ground flat so that, when the core is assembled as shown in Fig. 9(b), series air gaps are less than one mil. Units of both types will be employed in the final core which will have an area of cross section of about 750 sq. cm and will include about 2000 lb. of ferrite. The winding will be effectively a one-turn winding although it will consist of two physical turns so that it can be driven by a push-pull class B power amplifier.

The accelerating field will appear across a short insulating section of the vacuum chamber. The core will be enclosed, except for this gap, in a copper shield. The core sections will be separated by air spaces which will permit forced air cooling and will suppress undesired modes of oscillation. Further suppression of undesired modes can be accomplished by insertion of copper sheets between the core sections.

10. FREQUENCY CONTROL

In order to limit radial excursions of the equilibrium orbit and minimize loss of particles to the walls of the chamber, the frequency of the accelerating r-f must be held to within 0.3 percent of the scheduled value. The scheduled frequency cycle is derived from the magnetic cycle, and can only be determined with precision after magnetic field measurements on the full scale magnet are available. It is possible that the magnetic cycle will be reproducible to a precision better than the above limits. If so, the frequency variation can be programmed. It will be necessary to trigger the start of the frequency cycle from the magnetic field. A signal derived from a back-biased "peaking strip" can be used to initiate the r-f cycle. This time can be varied at will by varying the peaking strip bias. Similar peaking strips can be used to time injection of ions from the electrostatic generator, or any other synchronized operations.

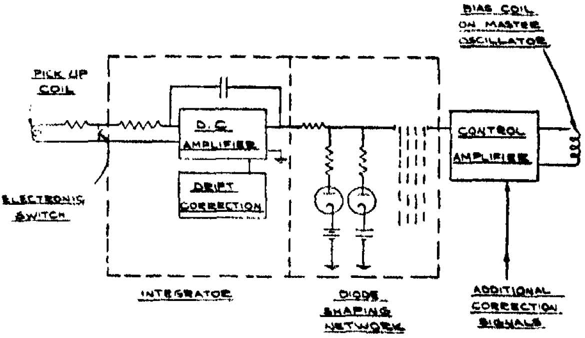

FIG. 10. Block diagram of frequency control system.

Since, in the Cosmotron, the magnetic field is the true independent variable, a preferable frequency control system would be one in which the magnetic field is measured continuously and the frequency is automatically adjusted to the correct value. This is the system which has been adopted for use in the Cosmotron. As shown in the block diagram of Fig. 10 the frequency control system has three essential components —first, an integrating circuit which converts the signal from a pick-up coil in the Cosmotron magnet to a signal directly proportional to magnetic field; second, a network which converts the magnetic field signal to the appropriate frequency control signal; and, finally, an amplifier which applies the control signal to the winding on the ferromagnetic core in the master oscillator. Prototypes of these components have been built and tested. Over periods of several weeks each component is stable and reproducible to about 0.1 percent.

The integrator is a conventional electronic integrating circuit with provision for automatic compensation of zero drift. The conversion circuit is a diode network which automatically switches in successive voltage supplies through adjustable series resistors. This circuit has the virtue that any change made in the relation between output and input at a given time in the cycle affects only the subsequent part of the cycle. This makes adjustment of the circuit a straightforward procedure. To match any possible cycle to 0.1 percent will require about 15 diodes with their associated circuits. The final control amplifier is simple in design since the signal from the control network is already at a high level of about 100 volts. Provision is made in the control amplifier for insertion of correcting signals from other possible sources. For example, an error signal can be derived from a comparison of the outputs of a proton moment magnetic field indicator and of a preset frequency discriminator.

An alternative frequency monitoring method which depends on the radial position of the proton orbit has also been considered in some detail. In principle, an error in frequency will result in a radial shift of the equilibrium orbit. For example, too high a frequency results in a phase shift of the r-f accelerating potential so that the ions get less than the theoretical acceleration per turn and the radius of the equilibrium orbit becomes steadily smaller. To observe this shift in radial location of the ions, a pair of electrodes can be mounted radially inside and outside of the chamber, and the magnitude of the voltage pulses induced on these electrodes by the passage of the bunch of ions can be compared. Electrostatic models of such "pick-up" electrodes have been studied in the laboratory, with a charged wire simulating the beam. Shapes have been developed which have a response linearly proportional to the displacement of the beam from the central orbit. Calculations of the expected induced voltage pulses indicate difference potentials of a few millivolts for a long sausage-shaped bundle containing 10^9 protons located halfway between center and edge of the chamber. It is possible to amplify this difference potential to obtain a signal capable of modulating the frequency of the oscillator so as to correct the ion beam drift. This system suffers from two draw-backs which may be serious. First, it is sensitive to stray pick-up from the main r-f system. Second, during the early stages of tuning up the machine, the beam may not be sufficiently intense to provide a signal detectable above noise and stray pick-up. However, one of the straight sections is allotted to these electrodes, and the control system can utilize this type of signal if it is available.

Another proposal involves the insertion of counters located about the tube so as to pick up a fraction of the scattered ions. In principle, the relative numbers of ions detected by counters one inside, and one outside of the orbit will give a measure of the frequency error.

The more general aspects of the controls needed for the Cosmotron need not be described in detail. All of the usual features of a cyclotron or synchrotron control system will be involved as well as the special requirements of frequency programming. Engineering is now in process on the vacuum pumps and gauges, cooling circuit indicators and interlocks, magnet power supply and time cycling, electrostatic generator (injection timing and pulsing), ion source, r-f oscillator, amplifier and power supply, ejection timing, and the many other circuits required to maintain and operate such a machine by remote control. The combination of high r-f power, a wide frequency range and the sensitive circuits needed for control will require the ultimate in electrical shielding. Personnel hazards and the requirements for remote operation are being carefully considered in designing the circuit interlocks. A large control console in the control room will bring together all of the functions required for operation. This part of the development program will be a continuing one, which cannot be considered completed until the machine is operating at full ratings.

11. VACUUM SYSTEM

Scattering by the residual gas in the vacuum chamber during the 1-second acceleration interval will result in some loss of ions. A theoretical study of this problem[11] shows that the significant scattering all occurs within the first few thousand revolutions or the first 10 milliseconds when ion energy is small and oscillation amplitudes are large. The result of the calculation is that $\mathfrak{X}^2$, the mean square angular divergence due to scattering of the ions from a true orbit is a linear function of proton energy T and gas pressure P:

$$\mathfrak{X}^2 = kP/T. \qquad (19)$$

Vacuum chamber geometry, combined with computed oscillation damping in the synchrotron, can then be used to establish a pressure corresponding to the loss to the walls of any given fracture of the ions. The numerical results are:

$P_{0.5}$ (50 percent proton loss) $= 1.8\times 10^{-6}$ mm of Hg.
$P_{0.1}$ (10 percent proton loss) $= 1.1\times 10^{-5}$ mm of Hg.

---

[11] N. M. Blachman and E. D. Courant, Phys. Rev. 74, 140 (1948).

In the design of the pumping system, the figure chosen as a maximum acceptable pressure is 1.0×10^{-5} mm of Hg. This is to be achieved with 12 or more pumping stations around the periphery of the chamber, each consisting of a 20-inch oil diffusion pump and equipped with refrigerated baffle, close-off valve, and the necessary valves and gauges. Four centrally located fore pumps will supply the rough backing vacuum for the twelve diffusion pumps. Speed at the entrance to the vacuum chamber spout will be about 2500 liters per second at 10^{-5} mm of Hg for each pump unit. The units will be interchangeable for ease in maintenance and testing. They are shown in the plan view of the Cosmotron, Fig. 3.

The method of fabrication of the vacuum envelope is the subject of an experimental program which has not yet arrived at the most satisfactory solution. To avoid induction of eddy currents in the wall of the vacuum envelope, a non-conducting vacuum wall would be preferable. The chamber must however, fit in a space roughly 9×36 inches and must waste as little as possible of this aperture. Strength tests have been made on ceramic sections of roughly elliptical cross sections having outside dimensions 34½×9 inches. The walls were one inch thick, increased to 1¼ inches at the ends of the long axis. These sections collapsed under pressure of about one atmosphere and so are obviously unsatisfactory for this application.

The elliptic cross section of the ceramic chamber was rather wasteful of space and this design has now been superseded by a chamber of rectangular cross section constructed partly of metal and partly of an insulating plastic. Metal foil will be bonded to the inside of the chamber so that no plastic is exposed to the vacuum. Mechanical strength will be obtained by supporting the chamber walls from the magnet structure. Model tests on various configurations of this type indicate that satisfactory mechanical and vacuum properties can be attained without undue disturbance of the magnetic field by eddy currents in the chamber walls.

In the straight sections where magnetic fields are low, solid metal can be used for the vacuum envelope. In the accelerating section, an insulating ring will be introduced across which the radiofrequency accelerating fields will appear.

12. EJECTION

The basic design of a "C" magnet with the slot for the vacuum chamber on the outside provides a favorable situation for obtaining an emergent beam of protons. Another advantage of the Cosmotron over electron synchrotrons is the long acceleration time after injection; during this 1-second interval ejection electrodes or magnetic peelers which might distort or interrupt the beam at injection, can be inserted. By 0.1 second the ions will have reached an energy of 300 Mev and the radial oscillations will be damped to small amplitudes around the central orbit.

A movable "peeler" or magnetic shield has been designed which can be located well outside the ion orbits at injection and then inserted to the proper radius for ejection before the ions have reached final energy. The peeler is a simple magnetic shield formed of a block of iron with a slot or channel through which the ions can travel. A similar device has been used to obtain an emergent beam of electrons from the betatron. The peeler will be located in a vacuum housing with sliding seals to allow radial motion. The external position will be determined by magnetic model tests so as not to distort the magnetic field at the orbit.

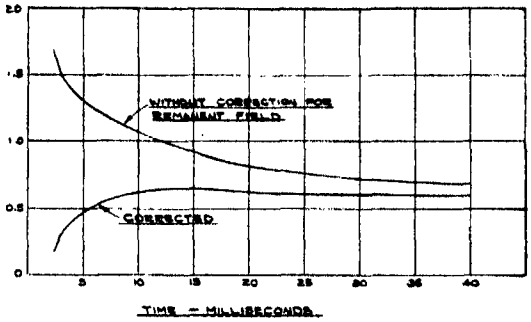

FIG. 11. Model measurement of n value (exponent for radial variation of magnetic field) for short times, showing the effect of eddy currents in the ½-inch laminations. (Injection occurs at 14 milliseconds.)

When using the peeler the ion beam, normally following a central orbit, can be expanded by changing the frequency and hence the phase of the accelerating electric field. A reduction of 1 percent below the resonant frequency will cause the orbit to expand by 9 inches, sufficient to throw the beam into the slot of the peeler. This frequency shift can be timed to eject ions at any desired energy. While passing through the weak field in the peeler channel (about 50 percent of normal) the ions will travel on a larger radius path. The azimuthal location of the peeler is chosen to eject the ions from one of the straight sections, so that a vacuum beam pipe can emerge tangentially to contain and collimate the ejected protons. Pulsed electrostatic fields can be used if necessary to excite radial oscillations and throw the ions out into the peeler channel within a few revolutions.

The efficiency of such an ejection scheme cannot be predicted. Up to the present time only a small fraction of the circulating electrons in a betatron have been ejected. The emergent beam from the Berkeley 184-inch synchro-cyclotron contains about 10 percent of the resonant ions. Assuming a similar success for the Cosmotron, we might expect as much as 10^8 protons per pulse in the ejected beam. With electrostatically pulsed ejection this number might be emitted within about 1.1 μsec.; with the magnetic peeler alone the protons would probably be distributed over a sequence of 10–20 pulses at 4.1-Mc frequency. Both forms of the ejected beam have their advantages for specific detec-

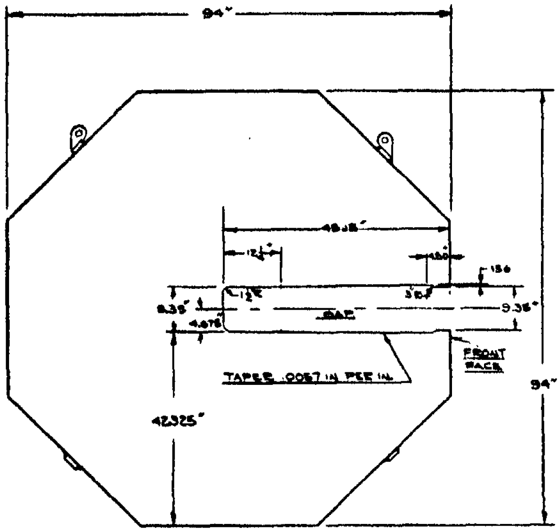

FIG. 12. Magnet lamination showing shape of gap contour.

tion instruments; the single pulse might be desirable for cloud chambers and the multiple pulses for electronic coincidence counters.

Many experimental detection techniques do not require an emergent beam. Photographic film can be mounted on probes at any position around the circumference with vacuum locks to expedite removal. High speed neutrons will emerge tangentially from the periphery, at whatever points the expanding orbits intersect probes or walls. A specific "neutron spout" has, in fact, been designed, consisting of a *T* section in which a probe target can be mounted, with a tangential spout through which the neutrons will emerge. These alternate methods of employing the high speed ions multiply the usefulness of the instrument for research.

13. MAGNETIC PROBLEMS

a. Eddy Current Effects

Dynamic measurements of magnetic field performed on a one-quarter scale model of a short sector of the magnet show that eddy current effects in the ½-inch magnet laminations will be appreciable during the first 30 or so milliseconds. Qualitatively the effect of eddy currents is to reduce the magnetic field at the mid-portion of the gap as compared with the field near the exciting windings. As a result, the rate of field decrease with radius or "n" value (see Eq. (11) above) is increased. The magnitude of this increase in n value has been measured by observing the difference in induced voltage in two coils spaced a short distance apart radially, and located at various positions across the gap. Photographic recordings of the integrated difference voltage displayed on a cathode ray tube have been analyzed to obtain the n value as a function of time. "Δn" or the increase in n over steady state conditions is found to have a large value at very short times; but to be down to about 0.4 at the time corresponding to injection, when the magnetic field is 271 gauss. In Fig. 11 a time plot of n at the central orbit position is given to illustrate the magnitude of this effect before and after injection.

A theoretical study[12] of eddy currents in the ½-inch plates checks the experimental findings and allows extrapolation beyond the extent of the experiments.

If required, this variation of n could be corrected by auxiliary windings distributed across the pole faces. A 48-turn winding (24 on each pole face) would require a current of less than 1 ampere during the first 30 milliseconds in order to compensate for the eddy current effects.

b. Remanent Field

The remanent field resulting from unidirectional operation has also been measured. It is found to have a value of about 30 gauss and to increase almost linearly by about 25 percent from the face of the inner exciting coil to a point near the outer end of the air gap.

The initial negative Δn due to the remanent field decreases with increasing field, and almost completely compensates for the positive Δn at short times due to eddy currents. The maximum resultant Δn measured as the sum of both effects at injection time and over the useful width of pole face is the order of ± 0.1. This is considered to be sufficiently small to make further corrections for eddy currents unnecessary. The variation of n after correction for remanent field effects is shown in Fig. 11.

c. Saturation Effects

At high fields, the permeability of the magnet iron decreases and an appreciable fraction of the magnetomotive force appears in the iron. Due to the *C* shape of the magnet and the resulting large difference in iron path length for flux crossing at the two ends of the gap, the effect of decreasing permeability is to cause an increase in n value at high fields. Results from model tests indicate a measurable rise in n value, starting at about 9000 gauss in the gap, increasing to a Δn of about 0.7 by the time the field reaches 14,000 gauss.

This large change in n value due to saturation effects cannot be permitted, and must be compensated by auxiliary windings. Accordingly designs are in process for a single layer winding on the surface of each pole face adequate to supply the necessary correcting field. These windings will each have 24 turns of 1×⅛-inch copper bar, wound flat with suitable insulation between turns and to the pole. The space required for these windings will probably be reduced to a minimum by imbedding them in the upper and lower walls of the vacuum chamber. To provide correction for a Δn of 1.0 at 14,000 gauss the peak current in these windings would be about 800 amperes. The corrective cycle would require zero current up to about 0.6 sec., an increase of current to a maximum at 1.0 sec., and then a reduction to zero current as rapidly as possible. The time constant of these windings is about 0.1 times that of the main windings, so this condensed time cycle should be possible with applied potentials no higher than required for the main windings. The short cycle and sharp peak call for average power levels of only a few hundred kw.

---

[12] M. H. Blewett, Phys. Rev. 75, 1288 (1949).

d. Pole Face Shaping

To attain a value of $n=0.6$ requires a taper shaping of the pole faces. The pole contour has been derived from model experiments and is shown in Fig. 12. A straight taper cut starting about 4 inches from the front of the main winding produces a 3 percent maximum increase in air gap. At the periphery a lip of iron is retained to extend the region of uniform field to the maximum possible radius. This contour yields a usable field at injection over a radial distance of about 31 inches.

e. Mechanical Problems

Magnetic forces on the coil system and on the iron laminations will be considerable and must be taken into account in the magnetic design. The force on the central winding is inward and tends to compact the coil; that on the return windings is out and away from the gap, requiring closely spaced heavy brackets. The laminations repel one another and tend to spread apart into the air spaces between blocks. This force will be retained by hardwood wedges driven between magnet blocks in the air spaces near the pole face. The laminations of the end blocks of the quadrants will be held together by several insulated bolts. Blocks will be welded together externally to make a rigid unit. Mechanical tests on models have shown these to be satisfactory procedures to prevent lamination spreading.

f. Magnetic Testing Program

The magnetic properties of each magnet block will be checked in detail in order to determine the order of their arrangement in the final magnet which gives the best azimuthal uniformity of remanent field, magnetic median plane, n value, and any other parameter which appears to be important. This will be done by measurements on a full scale three-block model in which the block under test is set between two standard guard blocks. The model will be magnetized to full field using a one-second cycle which duplicates as closely as possible the final operating cycle.

14. SHIELDING AND BUILDING

The radiations from the Cosmotron may be a serious hazard to personnel. The maximum expected beam intensity, of 10^9 protons at 3-Bev energy 12 times a minute, is equivalent to an average power output of 0.1 watt. This may be compared with the 2 microampere time average beam of 200-Mev deuterons from the Berkeley 184-inch synchro-cyclotron, equivalent to 400 watts, or the 4 kilowatt beams for 60-inch standard cyclotrons. After the high energy radiation has been scattered and distributed among secondary radiations, the intensity is to a good approximation proportional to the beam power. On this basis the intensity of scattered radiation from the Cosmotron should be about 2.5×10^{-4} that from the synchro-cyclotron or 2.5×10^{-5} that of a 60-inch cyclotron. The shielding for scattered radiation adequate for the 184-inch machine is 2 ft. of concrete (overhead), providing an attenuation of 10^{-2}; that for a 60-inch cyclotron is 3 ft. for an attenuation of 10^{-3}. On this basis the overhead scattered radiation from the Cosmotron without overhead shielding is $0.025=1/40$ the intensity from these two machines with shielding. Conclusions from this analogy may not be legitimate, however, since the initial energies involved are materially higher than those produced by cyclotrons. An interpretation has been attempted of available data on cosmic-ray absorption and the results, based on several reasonable but uncertain assumptions, indicate the possibility of a dangerously high level of scattered radiation. Moreover, the possibility exists that a higher beam intensity than that mentioned above may follow from ion source developments. The Cosmotron building has, therefore, been designed so that the machine can be enclosed in a concrete housing having walls ten feet thick and a roof four feet thick. This housing will not be set up until the machine has been operated and the intensity of the scattered radiation has been measured.

The penetrating 3-Bev protons and their high energy

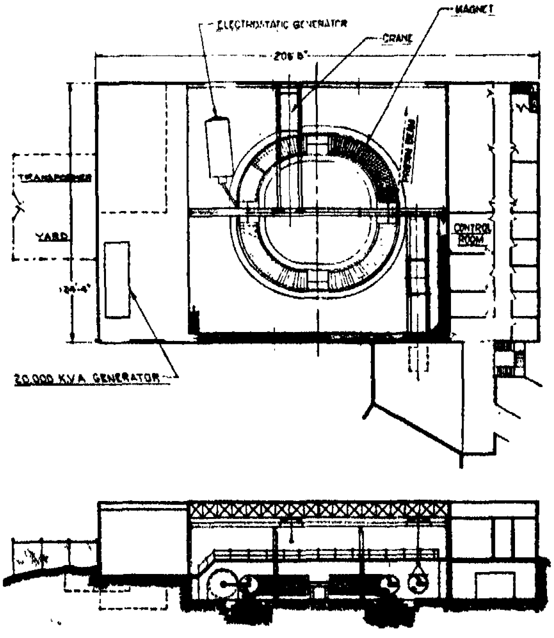

FIG. 13. Building plan and elevation for the laboratory to house the Cosmotron.

secondaries will be severely collimated in the horizontal plane. In this narrow band 4½ feet off the floor, the intensity will be dangerous. The Cosmotron is to be located in an excavation so that this radiation impinges on earth on three sides. The fourth side, in the direction of the ejected beam, is left open so the beam can shoot out across a flat area for experimentation at a distance from the machine, if desired. This area is unoccupied and fenced so that personnel cannot gain access during operation. Operators and maintenance personnel are located on an upper floor, overlooking the Cosmotron pit.

Build-up of contaminating radioactivities will also be approximately proportional to the average power level, and so will be negligible as compared with cyclotrons.

The building design is based on the shielding requirements described above, with control rooms, laboratories, offices and power house on the upper level. Two 10-ton traveling cranes will cover the working floor area. The power house for the magnet power supplies and auxiliaries occupies another large area. Control rooms, both for Cosmotron operation and for experiments, overlook the ejection quadrant and emergent beam run. A plan view of the building is shown in Fig. 13. Construction has started and the laboratory should be ready for occupancy early in 1950. Schedules for erection of the iron, winding the exciting coils, installing power equipment, and assembly of the vacuum chamber and auxiliary equipment indicate that the machine should be assembled late in 1950.

This design study represents the collaborative efforts of some 30 members of the Accelerator Project of the Brookhaven National Laboratory and also of several consultants. Each member has assisted in the progress of the design, but it is impractical to attempt to identify the individual contributions. The authors wish to recognize and credit these contributions to the joint effort. The present stage could not have been attained without the wholehearted assistance of many members of the Brookhaven Laboratory Staff and their Scientific Advisors.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

A Simple Pressure Balance

C. A. Swenson*
The Clarendon Laboratory, Oxford University, England

(Received August 1, 1949)

Precise pressure measurement in the range from 5 to 100 atmos. is quite a difficult problem. A set of high pressure mercury manometers is very unwieldy and difficult to use, while Bourdon gauges require frequent recalibration and are inherently inaccurate. The most likely solution for this problem is to use a simple piston-in-cylinder pressure balance, which, for these pressures and for accuracies of the order of 0.05 percent, can be relatively crude, and does not require excessively precise machining or care in use. A simple pressure balance was constructed for use in the pressure range from 25 to 35 atmos., and used for both pressure measurements and density change determinations. It proved perfectly satisfactory, giving pressures reproducible from day to day to about 0.01 atmos.

THE accurate measurement of pressure in the range from 5 to 100 atmos. offers quite a serious problem. For low pressures, quite accurate and reproducible pressure measurements can be obtained by means of a mercury manometer of sufficient length. However, above roughly 5 atmos. the mercury column becomes rather long (well over ten feet) and the set-up becomes unwieldy and difficult to use.

An alternative is to use a Bourdon gauge. Here, while the instrument is compact and easy to use, it is accurate at best to only one-half percent of its full-scale reading, unless the gauge is specially built and calibrated against a standard over the range of pressures in which it is to be used. There is always the danger of drift, and frequent recalibration is necessary.

The usual method used for the calibration of a Bourdon gauge is to compare it with a pressure balance. A pressure balance is essentially a piston which fits closely into a cylinder filled with oil, and a schematic diagram of a very simple model is shown in Fig. 1. Since the pressure on the oil is given by the weight of the piston (W) divided by its area (A), this is an absolute rather than secondary means for measuring pressure. In practice, the weight, W, is slowly increased (or, preferably, decreased) until the unknown pressure, P, is "balanced" by W/A, and the piston "floats" at some intermediate position between the top and bottom of the cylinder. Less weight would cause it to rise out of the cylinder, while more weight would cause it to sink to the bottom.

While this forms a very convenient method for calibrating a gauge, there is no reason why a pressure balance should not be used to measure an unknown pressure directly, instead of using an intermediate secondary standard. Pressure balances have been used directly at very high pressures and to very great accuracies, particularly by Michels of Amsterdam, and for this work a great deal of skill and experience is necessary.[1]

---

* Now at Harvard University.

However, for moderate accuracies, say 0.05 to 0.1 percent, and for pressures up to 100 atmos., the set-up need not be complicated at all. The weight can be of moderate size, and the piston large enough so that sufficient accuracy in the machining and the measurement of the diameter is easily obtained. For these accuracies and pressures, most of the difficulties, such as thermal expansions, deformations of the cylinder with pressure, etc., encountered in the more accurate and high pressure work, are negligible. While the above-mentioned accuracies are easily obtained, if another factor of five or ten were desired in the accuracy, a great deal of skill, patience and hard work would be required to produce a satisfactory instrument. Above 100 atmos. the weight becomes quite large for moderate sized pistons, and the balance either becomes very clumsy, or very precise machining is necessary.

The pressure balance can also be used as a means for measuring changes in density at constant pressure, while, for instance, the temperature of a substance is varied. Variations of density are shown by the rise or fall of the pressure balance piston as it increases or decreases the volume of the system to maintain the pressure at its constant value. Thus, direct measurements of density changes can be obtained by observing the change in the height of the piston. Probably the most elementary application of this would be to measure the change in volume of a gas upon liquefaction under pressure.

These conclusions led to the construction of a very simple pressure balance at this laboratory for use in some experiments on the melting curve of helium, and it has proved so satisfactory, both as a pressure measuring device and as a means for determining density changes, that it was thought worth describing in some detail.

DESCRIPTION OF THE APPARATUS

A sketch of the pressure balance cross section and set-up is given in Fig. 2. The pressure balance consists of a silver steel piston, *A*, 1.152 cm in diameter, which has been lapped into a mild steel cylinder, *B*. The piston is about 15 cm long to allow for volume changes of the order of 10 cc. The piston is set into a re-entrant cavity in the mild steel weight, *C*, to make the center of gravity of the weight as low as possible. This is quite important when it is realized that by using this size piston to produce an absolute pressure of 24 atmos. (which was used as a minimum pressure for this work), a weight of about 25 kg is needed. It probably would have been better to place the center of gravity of the weight below the end of the piston; however, the present set-up seems quite satisfactory.

The pressure is transmitted to the gas through vacuum pump oil to an oil reservoir, *D*, of about 200 cc capacity. This oil also acts as a lubricant between the piston and cylinder walls, and the oil that escapes through the separation between the walls is replenished periodically through an opening not shown. This leakage oil is collected in the flask, *E*. The space above the oil surface in *D* is filled with helium under pressure—the pressure determined by the weight and cross section of the piston. The valve, *F*, is a needle valve to either high pressure helium (to raise the piston) or to the atmosphere (to drop the piston). The valve, *G*, goes to the cryostat. A large Bourdon manometer is also in the system to indicate the pressure roughly, although all pressures are calculated from the diameter of the piston and the weight.

To insure that there is a continuous film of oil between the piston and the cylinder walls, the piston is rotated at about 30 r.p.m. by a small electric motor, *H*. The contact, *J*, is made as frictionless as possible by having a roller on the arm attached to the weight and a roller on the arm from the motor. While it is considered very desirable to have the pressure balance rotating freely while taking a reading, often the density changes that were measured took place in a half-hour, while the system would rotate freely for only five minutes or so. To give a semi-free rotation the center of rotation of the arm on the motor is placed slightly off the center of rotation of the piston-cylinder combination. This gives the motor arm a variable speed relative to the weight, and contact at *J* is made only for a short interval during each revolution; that is, when the motor arm is closest to the weight. The rest of the time the weight is rotating freely. A circular disk is placed on the motor arm to prevent the piston from rising out of the cylinder.

The pressure is changed by adding weights to the top of *C*, and, roughly, 10 g=0.01 atmos. Changes in height

are measured by a stationary centimeter scale placed beside a pointer on the rotating weight.

PERFORMANCE

Since a more standard means of measuring pressure was not available in the laboratory, the absolute pressures determined by the pressure balance are not known to better than 0.2 percent. However, no special effort was made to obtain exact absolute pressures, since for this work the main interest was in dp/dT and the important factors were reproducibility and sensitivity to pressure differences. Thus, in all calculations, it has been assumed that the pressure generated is that obtained by dividing the weight of the piston-weight combination by the area of the piston as calculated from its measured diameter. Absolute pressures are obtained in any given instance by adding barometric pressure to this value, plus the additional pressure due to any weights placed on the top of the piston.

Because there was some possible inaccuracy in the measured value for the piston diameter, the area of the piston was roughly checked by replacing the large weight by a much smaller one and calibrating the result against a two-meter open mercury manometer. The resulting effective area (1.042 cm^2) agreed with the calculated one to 0.1 percent. The final uncertainty was determined by the reproducibility of the pressure balance at these low pressures and the accuracy to which the difference in oil level between the reservoir and cylinder could be determined. This shows that there is little deformation of the cylinder with pressure, as would be expected at these relatively low pressures. Since the weight was known to about 0.05 percent, absolute pressures are known to approximately 0.2 percent.

The reproducibility of the pressure balance, however, is much greater than this, and was checked by repeating melting point determinations on different days for the same cryostat temperature. These results have shown that the pressures are reproducible to ±0.01 atmos. at 25 atmos. The same criterion shows that no variation of pressure with height greater than this exists, so that the balance seems to be working as well as had been hoped.

No precautions need be taken to insure this accuracy, except that a supply of oil be present, and that the rotation is continuous. Thermostating is not necessary, since any error introduced into the effective area and hence into the pressure by thermal expansion is less than 0.01 percent for temperature changes of the order of five degrees centigrade. While it is desirable to have the weight placed as symmetrically as possible, asymmetries seem to have no noticeable effect.

For density changes this pressure balance is not quite as satisfactory, although it does everything that is required of it in our experiments. While the normal rate of fall of the piston is a direct function of the viscosity of the oil, the speed of response of the setup depends inversely on the viscosity. Since the instrument is used in a dynamic manner, this is quite important. So, a compromise was made between oil leak (which should be very small) and speed of response. Shell Box Pump Oil was found to be quite satisfactory, with the piston dropping rather slowly (about 2 cm/hour), and responding to changes in pressure fairly rapidly. This correction to the observed data for normal rate of fall is usually about ten percent for our work, so if the leakage rate is known to 20 percent (changes in room temperature, length of time the balance has been running, height of piston, all seem to have slight effects), the results should be good to about 2 percent. They are definitely as reproducible as this. It has been found that the pressure balance must rotate for an hour or so before it will give reproducible rates of fall, and this is probably the time necessary to insure proper lubrication. In using the balance to measure density changes, however, care must be taken to insure that room temperature does not change during a run, or that the reservoir, *D*, and other large volumes are thermostated.

I wish to thank Professor F. E. Simon for his interest and advice. I also wish to express my appreciation to Mr. A. Charters for his technical assistance. This work was made possible in part by a Parker Fellowship in Physics from Harvard University, and in part by a grant from the Carnegie Fund for Overseas Students.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

A Versatile Pneumatic Instrument Based on Critical Flow

W. A. Wildhack
National Bureau of Standards, Washington, D. C.

(Received June 20, 1949)

Gas flows through two restrictions in series, the second one or both being a nozzle operating with sonic throat velocity so that discharge is independent of the downstream pressure. For fixed restrictions, the ratio of entrance pressures at the two restrictions depends on their relative sizes and the ratio of entrance temperatures. After calibration, the pressure ratio may be used to measure temperature with a sensitivity of 1°C or better over a range of 2000°C. With the same arrangement, the temperature being constant, the intermediate pressure is a direct measure of mass flow. A sensitivity of better than 0.1 percent is possible in this measurement. For given temperatures, the device can be used as a "pressure divider," with the intermediate pressure controlled by adjusting the restrictions, or as a pneumatic micrometer. Gas analysis is accomplished by removing one component of the gas flow between nozzles. A vacuum pump is used, if necessary, to ensure critical discharge through one or both nozzles; divergent cones on nozzles may be used to minimize pressure drop.

WHEN gas flows through a properly shaped restriction (a nozzle) with the ratio of throat or exit pressure to the entrance or upstream pressure being less than a so-called critical value (roughly 0.5 for air), sonic velocity is attained at the throat, and the mass discharge no longer depends on the value of the downstream pressure. If a divergent cone is used after the throat of the nozzle, a considerable recovery of pressure is obtained at the exit of the cone, although the critical ratio still obtains between the pressure at the throat of the nozzle and the entrance pressure.

These phenomena have been utilized in the design of a new instrument, or family of instruments, for measurement and control of various quantities, such as pressure, temperature, flow, humidity, gas composition, or mechanical displacement. In the simplest form, critical flow is maintained through two nozzles in series. Variations in flow through the first nozzle, occurring with changes of pressure, temperature, or size, are reflected as a change in absolute pressure at the entrance to the second nozzle. The value of this absolute pressure serves as a measure of the variable causing the change. Similarly, a change in composition of the gas stream occurring between the two nozzles is likewise reflected as a change in the absolute pressure at the entrance to the second nozzle.

Essentially the same results are obtained if an orifice-nozzle series is used, although the sensitivity is somewhat reduced. Fairly simple quantitative expressions may be derived relating the absolute pressures and temperatures under the various conditions of use.

FLOW THROUGH NOZZLES AND ORIFICES

The essential characteristics of gas flow through orifices and nozzles are shown graphically in Fig. 1, in which the relative flow is given as a function of pressure ratio.

For a nozzle, the volume flow, Q_e, measured at the entrance pressure, P_e, is related to the ratio, r, of throat to upstream pressure by the expression

$$Q_e=CA\left(\frac{2n}{n-1}\right)^{\frac{1}{2}}r^{1/n}(1-r^{(n-1)/n})^{\frac{1}{2}}\left(\frac{P_e}{\rho_e}\right)^{\frac{1}{2}}, \qquad (1)$$

where n is the ratio of specific heats, A is nozzle throat area, C is a discharge coefficient (between 0.95 and unity), P_e and ρ_e are upstream, or entrance, pressure and density. This holds for values of r between unity and the critical pressure ratio

$$r_c=\left(\frac{2}{n+1}\right)^{n/(n-1)}. \qquad (2)$$

Beyond the critical pressure ratio, r_c, the volume flow as measured at the entrance pressure, P_e, is independent of changes in r. Under these conditions, the *characteristic critical flow* of the nozzles, F_e, for the entrance temperature, T_e, in terms of volume at the upstream, or entrance, pressure is

$$F_e=CA\left(\frac{2n}{n+1}\right)^{\frac{1}{2}}r_c^{1/n}\left(\frac{P_e}{\rho_e}\right)^{\frac{1}{2}}=KAT_e^{\frac{1}{2}}. \qquad (3)$$

For air at 0°C and $C=1$, this *characteristic critical flow* is

$$F_0=1114\text{A}, \qquad (3a)$$

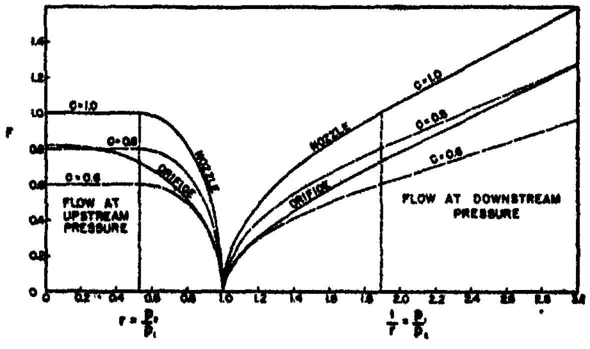

FIG. 1. Flow chart for nozzles and orifices.

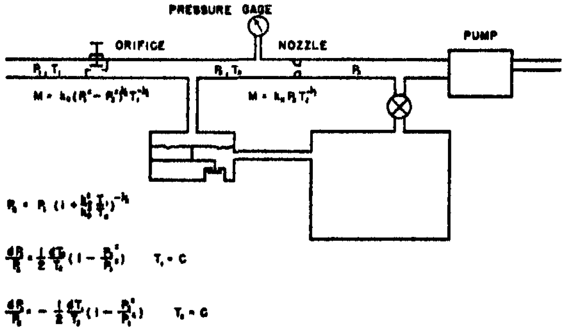
when F_0 is in liters per minute and A is in square centimeters. The mass flow through the nozzle is

$$M_N=\rho_eF_e=K_NP_eT_e^{-\frac{1}{2}}, \tag{4}$$

where the factor K_N includes the first two factors in Eq. (3), the gas constant, and appropriate conversion factors for the units chosen. There are certain corrections required to Eq. (4), particularly at high pressures or low temperature, because of deviation of gases from ideal behavior.

Careful calibration of the nozzle under the expected operating conditions can obviate much tedious computation and is, in any event, a desirable check on computed characteristics.



PRESSURE GAGE
ORIFICE
NOZZLE
PUMP
P_1, T_1
P_2, T_2
P_3
$M = K_0(P_1^2 - P_2^2)^{\frac{1}{2}}T_1^{-\frac{1}{2}}$
$M = K_N P_2 T_2^{-\frac{1}{2}}$
$P_2 = P_1\left(1+\frac{K_N^2}{K_0^2}\frac{T_1}{T_2}\right)^{-\frac{1}{2}}$
$\frac{dP_2}{P_2} = \frac{1}{2}\frac{dT_2}{T_2}\left(1-\frac{P_2^2}{P_1^2}\right)$ $T_1 = C$
$\frac{dP_2}{P_2} = -\frac{1}{2}\frac{dT_1}{T_1}\left(1-\frac{P_2^2}{P_1^2}\right)$ $T_2 = C$

FIG. 2.

The flow equation for sharp-edged orifices, in plates no thicker than the diameter and for pressure ratios near unity, is roughly approximated by the nozzle formula, Eq. (1), multiplied by a discharge coefficient of about 0.6. However, this approximation becomes worse for lower pressure ratios. The orifice discharge does not become constant but continues to increase at decreasing pressure ratios. The orifice curve shown on the chart of Fig. 1 for air, is based on the experimental work of Bachmann.[1] This curve may be fairly well approximated over the entire range by the same equation which applies closely for orifices (or tubing) at pressure ratios near unity, with the density assumed proportional to the mean pressure:

$$M_0=K_0(P_1^2-P_2^2)^{\frac{1}{2}}T_1^{-\frac{1}{2}}, \tag{5}$$

where K_0 includes the area, an "effective" discharge coefficient, and normalizing factors. M_0 is the mass discharge through the orifice, P_1 and P_2 are upstream and downstream pressures, and T_1 is upstream temperature. The actual values of C appropriate for different orifices may differ by several percent, but the form of the flow curves is presumably the same.

Both nozzle and orifice equations have corrections for velocity of approach, if the gas stream is moving at a high velocity before entering the restriction. This may be taken into account, approximately at least, by taking the entrance pressure and temperature of the gas as that which would be obtained if the gas were brought to rest at the entrance.

OPERATING PRINCIPLES OF THE INSTRUMENT

The device to be described consists basically of two restrictions in series, through which gas is drawn by suction or forced by pressure, and a pressure-measuring instrument connected to the line between the two restrictions. Figure 2 shows one embodiment of the device, in which the first restriction is a variable orifice, the second a nozzle, and the gas is drawn through the system by a vacuum pump of sufficient capacity to ensure critical discharge.

The mass flow through the two restrictions must be the same at equilibrium conditions. By equating the appropriate flow equations for the two restrictions, we may obtain expressions for the intermediate pressure (between restrictions) in terms of the geometry of the restrictions, one or both of the pressures beyond the restrictions, and the temperatures of the gas at the entrances to the restrictions. For an orifice followed by a nozzle, we equate Eqs. (4) and (5) and obtain

$$P_2=P_1\frac{K_{O_1}}{K_{N_2}}\left(\frac{T_2}{T_1}\right)^{\frac{1}{2}}\left[1-\left(\frac{P_2}{P_1}\right)^2\right]^{\frac{1}{2}}, \tag{6}$$

which may also be expressed: (after squaring, rearranging, and solving)

$$P_2=P_1\left(1+\frac{K_{N_2}^2}{K_{O_1}^2}\frac{T_1}{T_2}\right)^{-\frac{1}{2}}, \tag{6a}$$

where the sub-subscripts indicate the first or second restriction.

For a nozzle followed by an orifice:

$$P_2=P_1\frac{K_{N_1}}{K_{O_2}}\left(\frac{T_2}{T_1}\right)^{\frac{1}{2}}\left[1-\left(\frac{P_3}{P_2}\right)^2\right]^{-\frac{1}{2}}. \tag{6b}$$

For two orifices:

$$P_2=P_1\frac{K_{O_1}}{K_{O_2}}\left(\frac{T_2}{T_1}\right)^{\frac{1}{2}}\left[\frac{1-(P_2/P_1)^2}{1-(P_3/P_2)^2}\right]^{\frac{1}{2}}. \tag{6c}$$

For two nozzles:

$$P_2=P_1\frac{K_{N_1}}{K_{N_2}}\left(\frac{T_2}{T_1}\right)^{\frac{1}{2}}. \tag{6d}$$

For any of these arrangements in which the pressure ratio for a nozzle is sub-critical, the equation which applies is approximately the same as that for an orifice replacing the nozzle, except that the coefficients K_N (sub-critical) would be from 1/0.7 to 1/0.6 times the K_0 corresponding to the same diameter (as may be seen by inspection of Fig. 1).

---

[1] Bachmann, "Messung von Luffmengen," Doctoral Dissertation, (Published by C. Pfeffer, Darmstadt, 1912). Recently translated by Lyman M. Van der Pyl, Rockwell Manufacturing Industries, Pittsburgh 8, Pennsylvania.

It is clear that with these arrangements for which the absolute pressure P_2 is a function only of P_1, the temperatures T_1 and T_2, and the areas A_1 and A_2, it may be taken as a measure of any one of these quantities if the others are constant, or known.

The device can thus serve as:

(1) A wide-range, sensitive thermometer (with fixed areas, P_1 and T_1 (or T_2), known or constant, and T_2 (or T_1) variable, P_2 is a function of the variable temperature).

(2) A pressure divider (with area and temperature ratios constant, P_2 is a constant fraction of P_1).

(3) A pressure controller (with the areas of one of the restrictions adjustable, the pressure ratio changes with the area ratio).

(4) A flowmeter (with temperature T_2 and area A_2 constant, and other factors varied arbitrarily to vary the flow, P_2 is a direct measure of the mass flow).

(5) A micrometer (with temperature and P_1 constant, variation of A_1 or A_2, as by displacement of an object near the nozzle, or by a sliding or rotating valve, will cause a corresponding variation in P_2). When connected to other devices for translating various physical quantities into displacement, this gives an alternative method of measurement and control of very wide scope.

(6) A gas analyzer (with one component of the gas being removed, or changed, by chemical action between the nozzles, the change in P_2 is a measure of the fractional change in the mass flow). Using two nozzles, both operating at critical discharge, with some difference between the normal value of P_2 and its permissible upper design limit (which is set by the requirement of critical discharge through the first nozzle), some further resistance to flow may be permitted between the two nozzles without changing the "normal" value of P_2. This allows a long connecting line, or the inclusion of a chemical scrubber or reactor of one type or another.

It has been stressed that for accurate measurements, calibration is essential. The "errors" or deviations from predicted performance, particularly with both nozzles under critical flow conditions, arise mainly from the equation of state for the gas. Information may therefore be obtained on the equation of state by study of the variation of the pressure ratios from predicted values under various conditions of pressure and temperature. Studies with various gases under the same conditions should yield information on *relative* thermodynamic properties.

The schematic arrangement shown in Fig. 2 will be referred to in further describing the several different uses. The vacuum pump maintains the pressure P_3 sufficiently low for critical discharge through the nozzles at the lowest value of P_2 to be used. To decrease the pump capacity required, a nozzle with an expanding cone may be used to obtain critical discharge at higher values of P_3. The first restriction is shown as a valve, which may be regarded as a variable orifice. A nozzle here would obviously not change the operation in principle, although in practice, variable-area nozzles are rather difficult to make.

APPLICATION IN SPECIFIC MEASUREMENTS

1. As a Flowmeter

With critical discharge at the nozzle, regardless of the nature of the upstream restriction,

$$M = K_{N_2} P_2 T_2^{-\frac{1}{2}} \tag{4}$$

so that, for this condition, P_2 is a direct measure of the mass flow, T_2 being known, whether gas is drawn or forced through the nozzle and whether P_2 is below or above atmospheric. In the arrangement shown, the flow may be adjusted by varying the upper restriction, and is drawn through the nozzle by suction developed by the pump. However, if the gas to be measured is at a sufficiently high pressure upstream of the first restriction, proper choice of nozzle size may keep P_2 enough above atmospheric so that the pump may be dispensed with.

The *sensitivity* of this device as a flowmeter is just that of the associated pressure measuring instrument (approximately 1×10^{-4}), and the absolute *accuracy* is as close to this as the calibration of the nozzle. Since the characteristic *volume* flow is independent of the entrance pressure (except for compressibility corrections), a calibration at only one pressure may suffice, which may justifiably be done carefully and exactly.

The single critical-flow nozzle has been used for flow measurement for many years, but not as widely as its advantages would seem to warrant. This type of flowmeter is simply and ruggedly constructed, is easily adapted to multi-range operation, and, once calibrated, is more accurate than most rate-indicating meters now available.

2. As a Pressure Controller

It is clear that if the upstream restriction is adjusted to a given opening, P_2 will come to some corresponding equilibrium value, as given by Eq. (6a) or (6d) for the orifice-nozzle or nozzle-nozzle combinations, respectively. If the upstream pressure P_1 is constant, and if the temperatures are constant or change in the same ratio, then P_2 will remain constant, independent of variation of P_3 below the critical value. The value of P_2 may be varied by adjustment of the area of either of the restrictions (varying either K_N or K_0). Practically, it is simpler to adjust the "orifice," since any valve will usually behave like an orifice, unless specially designed to behave like a nozzle.

A chamber in which pressure is to be controlled, or pressure instruments are to be calibrated or compared, may be connected to the system between the two restrictions. The rapidity of approach to equilibrium pressure is, of course, dependent on the volume associated with this part of the system. It is therefore more practicable, if large volumes are to be controlled, to use an auxiliary pneumatic relay or admission valve as shown in Fig. 2, which regulates the flow into the chamber in which the pressure is to be controlled, from which air is drawn by the same, or a different, pump. If desired, a second relay with reversed valve action could be connected in the pump line to control outflow from the chamber as well. For minimum response time, not only the fixed volume of the line in the system associated with the pressure P_2, but also the active volume or displacement of the diaphragm in the admission valve, must be minimized.

3. As a Pressure Divider

It is seen from Eqs. (6a) and (6d) that P_2 will vary in approximately direct proportion to P_1 with either the orifice-nozzle or nozzle-nozzle combinations. When used as a reduced pressure controller, with P_1 the ambient atmospheric pressure, the variations of P_2 are only proportional to those of the barometer. These are negligible for many purposes, at least over short periods (seldom more than 0.1 percent in 10 minutes). If, however, the device is connected to a region where a variable pressure P_1 is to be measured, then the variations are reproduced proportionally over a smaller range and at the smaller pressure P_2. This is of some convenience in extending the range of utility of a standard manometer or barometer, for example. For accuracy of the degree desirable for calibrating pressure gauges at the pressure P_1 in terms of the standard barometer or manometer at P_2, the orifice, or preferably the nozzle, used between P_1 and P_2 should have been calibrated at that pressure, although for nozzles, calibration at one pressure may be sufficient if computed corrections for deviation from the gas law are applied.

When it is recalled that accuracy of the order of 10^{-4} atmosphere is easily possible in pressure measurement by mercury columns, it is clear that engineering accuracy (1 percent) can be attained in calibrating gauges up to 100 atm. by this method, using a standard of only 1 atm. range.

4. As a Thermometer

Referring again to Eqs. (6a) and (6d), it is apparent that if P_1, K_N and K_0 (or K_{N_1} and K_{N_2}) remain constant, P_2 will be a function of the ratio of the temperatures T_1 and T_2. If, then, either T_1 or T_2 is held constant, or otherwise measured, measurement of P_2 will suffice to determine the other temperature. For this application, the device is best used with a fixed orifice, or preferably a nozzle, as the upstream restriction. Obviously, the range of temperatures over which it may be used extends up to the melting point of the materials used. The sensitivity of the device as a thermometer, and therefore the possible accuracy over its calibrated range, is quite good. Differentiating Eq. (6a) (orifice-nozzle combination),

$$\frac{dP_2}{P_2}=-\frac{1}{2}\frac{dT_1}{T_1}\left(1-\frac{P_2^2}{P_1^2}\right)(T_2=C) \tag{7}$$

or

$$\frac{dP_2}{P_2}=\frac{1}{2}\frac{dT_2}{T_2}\left(1-\frac{P_2^2}{P_1^2}\right)(T_1=C). \tag{8}$$

For optimum sensitivity, using an orifice, P_2 should equal $P_1(\frac{1}{3})^{\frac{1}{2}}$, as may be seen by differentiating dP_2, as given by Eqs. (7) and (8), with respect to P_2. For this condition,

$$(dP_2)/P_2=\pm\tfrac{1}{3}[(dT)/T]. \tag{9}$$

For two nozzles, both operating under conditions of critical discharge, the corresponding equation (from differentiation of Eq. (6d)) is

$$(dP_2)/P_2=\pm\tfrac{1}{2}(dT)/T. \tag{10}$$

An accuracy of 0.1 millibar is routine in pressure measurement with mercury columns, so that with $P_1=1$ atm., P_2 approximately 0.6 atm. at the temperature of interest, the temperature variation corresponding to 0.1 mb variations in P_2 would be approximately 3/6000 by Eq. (9) or 2/6000 by Eq. (10). If the maximum sensitivity for the orifice-nozzle combination were at room temperature, this would correspond to 0.15° per 0.1 mb, and the sensitivity at 1650°C would be, by Eq. (9), 3/3000 or 1.6° per 0.1 mb. The maximum sensitivity at 1650° would be 0.9° per 0.1 mb with the relative areas of the orifice and nozzle adjusted for this condition, and the corresponding sensitivity at room temperature would be about 0.4° per 0.1 mb. Corresponding maximum sensitivities for the two-nozzle combination would be 0.6° per 0.1 mb at 1650°C, 0.1° at 300°C.

At extremely low temperatures, a sensitivity of 0.005° per 0.1 mb could theoretically be obtained, using helium, in the range 5° to 10°K.

Sensitivities of this order over such a wide range make the device of wide applicability in measuring gas temperatures in presently developing fields, such as high temperature turbines and jets. The computed sensitivity is, of course, not exact, since deviations from the gas law may either decrease or increase the sensitivity, depending on the particular gas and the range of temperature and pressure involved.

The speed of response of the dynamic thermometer, like the controller, is dependent on the line volume between the two restrictions and that associated with the pressure measuring device.

If two nozzles are used, an expression for the "characteristic time lag" of the instrument may be derived simply.

Applying Eq. (4), the difference in mass flow in and out of the intermediate volume, V, is:

$$M_{\text{in}}-M_{\text{out}}=K_{N_1}P_1T_1^{-\frac{1}{2}}-K_{N_2}P_2T_2^{-\frac{1}{2}}. \tag{11}$$

The rate of change of pressure P_2 in this volume is given by:

$$\frac{dP_2}{dt}=\frac{M_{\text{in}}-M_{\text{out}}}{V}\frac{P_0}{\rho_0}\frac{T_2}{T_0}$$

$$=\frac{K_{N_1}P_1T_1^{-\frac{1}{2}}-K_{N_2}P_2T_2^{-\frac{1}{2}}}{V}\frac{P_0}{\rho_0}\frac{T_2}{T_0}. \quad (12)$$

At equilibrium, $P_2=P_{2eq}$, so that

$$K_{N_1}P_1T_1^{-\frac{1}{2}}=K_{N_2}P_{2eq}T_2^{-\frac{1}{2}}.$$

Substituting and integrating,

$$(P_{2eq}-P_2)_t=(P_{2eq}-P_2)_0\exp-\frac{K_{N_2}P_0T_2^{\frac{1}{2}}}{\rho_0VT_0}t, \quad (13)$$

where the subscript 0 refers to the time of start of approach to equilibrium, the subscript t refers to any time t later. The approach to equilibrium is thus exponential, with a "time constant" given by

$$\frac{\rho_0V}{K_{N_2}P_0}\frac{T_0}{T_2^{\frac{1}{2}}}.$$

By Eqs. (3) and (4) this time constant is just the ratio V/F_2, where F_2 is the characteristic critical flow of the second nozzle, for the temperature T_2.

In an experimental setup, the tubing and associated pressure gauge (an aircraft altimeter) had a total equivalent volume of 250 cc, and the characteristic flow was about 1.5 liters per minute, giving a pneumatic lag constant of 10 seconds. The same arrangement with a different gauge had an effective volume of only 20 cc and a time lag of only 0.8 second. The pneumatic lag can be readily determined by closing off the inlet restriction, then suddenly opening it and noting or recording the time variation of P_2. The thermal lag of the instrument may differ slightly from the pneumatic lag, depending on how much of the gas in the intermediate volume changes in temperature. Since the downstream nozzle must be kept at a known temperature, which may require a long tube, or fins, or a water jacket for heat interchange, it may not always be possible to make the volume as small as would be desirable.

If the temperature to be measured is that of hot gases produced by combustion, the condensation of water vapor presents a problem. Under some conditions, it may be possible to design for P_2 sufficiently low so that the vapor pressure is reduced below the saturation value at room temperature. Maintaining T_2 at an elevated temperature by a thermostatted heater and insulation is another way to avoid this difficulty. With either of these arrangements, the hot gases may blow directly on, and enter, the upstream restriction, and the "thermal time lag" will be the same as the "pneumatic time lag." Alternatively, the hot gases may pass over and around the restriction and a tube leading air to it. With this arrangement, corrections must be deduced for the discrepancy between the temperature of the hot gases and that of the air entering the restriction, which will generally be lower. The thermal lag is increased, since the lead-in tube and restriction must come to equilibrium temperature.

The arrangement with two orifices, corresponding to Eq. (6c), has been used for temperature measurement as long ago as 1893.[2–4] In a recent adaptation of this arrangement,[5] ingenious means are provided for control of A_2 by T_2, and the pressure drop across the second orifice is kept constant by a suitable regulator. In all the work with two orifices, differential pressures must be measured. As far as is known, the measurement of gas temperature by absolute pressures in a dynamic system has not been done heretofore, although Stuart and Yarnell[6] have used the two-restriction arrangement with hot water under pressure for automatic control of a condensate drainage value. In this device T_1 and T_2 were equal. The variation in P_2 with T was due to changes in phase following pressure reduction through the first restriction.

5. As a Gas Analyzer

With two nozzles in series, both may operate at critical discharge if: (a) the area of the second nozzle is greater than that of the first, in a ratio greater than the critical pressure ratio for the first nozzle, and (b) the over-all pressure ratio is sufficiently large.

If the "normal" value of P_2 (under equilibrium conditions with the same mass flow through both nozzles) is, say, $0.3P_1$, and critical discharge through the first nozzle occurs with any downstream pressure less than $0.5P_1$, it is clear that additional pressure drop between the nozzles may be permitted, up to $0.2P_1$, without affecting the performance. With much less pressure drop, the gas may be forced through a liquid air trap, a chemical bubbler, a saturator, or a canister of desiccant or other reagent, to remove or modify one of the components of a gas mixture. The flow may be directed first through and then around the reactor, with the difference in P_2 indicating the fraction removed or added. Allowance must be made in calibration for changes in humidity if bubblers or desiccants are used. Also, for greatest accuracy, the calibrations should not be used with a gas mixture greatly different from the one used in calibration.

To obtain a direct indication of the difference in P_2 due to change in the gas stream, four restrictions may be arranged in two parallel circuits, somewhat analogous

to a Wheatstone bridge, with a differential manometer indicating the difference between the entrance pressures at the two downstream nozzles. Switching the reactor in and out of the circuit, or from one circuit to the other, will permit corrections for slight differences in the nozzles.

The sensitivity of the device is great enough to promise utility for humidity measurements (1 percent change in relative humidity at room temperature gives a change of about 0.04 percent P_2—between 1 and 2 mm of water). Because water vapor differs from air in density and also in the value of n, the change in P_2 on removal of water vapor is not a direct measure of the vapor pressure, but the slight corrections may be made on the basis of theory or calibration.

6. As a Micrometer or Gauge

Pneumatic gauges have come into fairly wide use in recent years, particularly in industrial inspection and automatic gauging. Gauges of this class all consist of a pneumatic circuit in which a restriction is determined, or varied, by the displacement, or clearance, to be measured. In the several types in current use, the dimension indication is related to: (a) the change in flow, with a given differential pressure across the variable restriction (gauging head); (2) the change in differential pressure, with a constant flow through the gauging head; or (3) the change in differential pressure across the gauging head (or the fixed restriction), with a constant differential pressure across the two restrictions.

When the critical flow device described here is used as a gauge, the gauging pressure is the *absolute* pressure, P_2. Referring to Fig. 2, it is clear that, after calibration, the value of P_2 is a measure of the position of the valve lid at the first restriction. Other gauging heads such as tapered plugs, needle valves, or sliding or rotating ports, or holes partially blocked by the part being gauged—all these are equally adaptable to critical-flow gauging when used with the fixed nozzle downstream. When the gas is forced, by a constant absolute pressure, first through the fixed nozzle at critical flow, then through the gauging head, true critical flow will not be obtained through the gauging head unless the geometry of the variable restriction is such that it behaves like a "nozzle."

DESIGN FEATURES

In all the various uses of this instrument, it is not necessary that a vacuum pump be used, if it is possible to maintain the pressures P_1 and P_2 at high enough values to ensure critical discharge through the nozzle, or nozzles. It may be convenient or sometimes necessary to arrange for this type of operation in metering flows of gas to be added to a process, for example, or in measuring temperature of a gas or liquid in which the nozzle is immersed and exhausts.

The dimensions of the nozzles and orifices used are, in principle, of little importance—only their ratios; but since a large flow requires a large pump and a small flow increases time lag, some compromise must be made. A nozzle of diameter 0.3 mm (No. 80 drill; 0.0135 in.) gives a characteristic flow of about one liter per minute. With this, a small vacuum pump is adequate; e.g., one of 12 liters per minute capacity, for instance. For larger sizes, a larger pump with a capacity of perhaps 100 liters per minute at 0.1 atm. is required, but the pump used need not be capable of attaining extremely low pressure. The limits of performance can be increased, or pump capacity decreased, as noted previously, by designing nozzles with a divergent exit cone to reduce over-all pressure loss.

Although the smallest nozzle so far used in this work was 0.3 mm, it is possible that even smaller ones could be successfully used under certain conditions. However, viscosity effects may be expected to cause trouble in using the smaller nozzles. A recent paper by J. W. Andersen and R. Friedman[7] reports pressure-proportional flow with small sapphire "orifices" as small as 0.05 mm in diameter at entrance pressures from 2 to 5 atmospheres when discharging at atmospheric pressure.

Since in this instrument pressure changes are associated with a change in the measured quantity, mechanical power is available for initiating control of the variable. This fits directly into automatic control systems responding to mechanical signals; pressure transducers may be used as a link when other systems are to be used.

ACKNOWLEDGMENT

This instrument was developed during the war for the Bureau of Aeronautics, Department of the Navy, mainly for experimental use in pressure measurement and control. The investigation of the other applications, and the preparation of this report were supported by the Office of Naval Research, under a project on "Basic Instrumentation for Scientific Research."

It is a pleasure to acknowledge the cooperation of present and former colleagues, especially L. W. Honea, J. M. Davis, A. S. Iberall, and D. S. Goalwin, in constructing and testing the instrument and in elucidating its behavior.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

Design and Use of Piezoelectric Gauges for Measurement of Large Transient Pressures[*]

A. B. Arons[†] and R. H. Cole[‡]
Underwater Explosives Research Laboratory, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts

(Received June 22, 1948)

This report discusses the design and use of piezoelectric gauges for the measurement of rapidly varying hydrostatic pressures of large amplitude in gaseous and liquid media. Reasons are given for the selection of tourmaline in preference to other types of crystal. Fundamental principles of design are stated, and gauge construction is described in the light of these principles. A simplified theoretical analysis of transient response characteristics is presented.

I. INTRODUCTION

THE original suggestion that transient pressure waves could be recorded as functions of time by observing the trace of a cathode-ray oscilloscope as it was deflected by the signal from a piezoelectric crystal has been credited to J. J. Thomson. Early experiments using such apparatus to record shock waves from under water explosions of TNT were described by Keys in 1921.[1] Since that time, the technique has been applied to several types of large amplitude pressure measurement, the most common being pressure-time phenomena in internal combustion engines and in shock waves due to explosions in air and water.

During World War II, a group at the Underwater Explosives Research Laboratory of the Woods Hole Oceanographic Institution made a number of contributions to the technique of shock wave measurement, utilizing tourmaline crystal gauges. A discussion of the present status of this technique will be given in this report. The type of gauge developed at the Underwater Explosives Research Laboratory will be referred to in the following as the UERL gauge.[¶]

II. BASIC REQUIREMENTS FOR A PRESSURE-SENSITIVE DEVICE

It is illuminating to outline first the criteria which an ideal electromechanical pressure-measuring device should satisfy. Although in principle these criteria should apply to any magnitude or duration of applied pressure, in practice their relative importance depends on both characteristics. In this paper, we consider primarily the measurement of transient pressures lasting a fraction of a second at most and with amplitudes from one to hundreds of atmospheres, as opposed to static pressures or acoustic waves. The requirements for such purposes can be summarized as follows: linearity, freedom from hysteresis, thermal stability, freedom from extraneous signals, adequate high and low frequency response, minimum distortion of the pressure field, ruggedness, and simplicity.

The efforts of the UERL group were directed toward the development of a gauge affording a practicable compromise among these requirements.

III. SELECTION OF THE GAUGE MATERIAL

Of the many known piezoactive crystals, those that have been used and investigated most extensively are rochelle salt, ADP, quartz, and tourmaline. More recently, crystals such as barium titanate and its various modifications, lithium sulfate, and certain tartrates have been successfully prepared and utilized.

The most sensitive of these materials are rochelle salt, barium titanate, and ADP. The first two do not appear to be suitable for measurement of fairly large pressure amplitudes owing to a relaxation or hysteresis effect which causes them to produce a rising signal upon application of a step pressure. Rochelle salt and ADP exhibit further disadvantages in that they are not hydrostatically sensitive and not sufficiently rugged for the applications here intended. The other "synthetics" present various difficulties due to their solubility or the presence of water of crystallization.

An extensive survey of piezoelectric activity of minerals has been reported by Bond.[2] It is interesting to note that after listing all the known piezoactive, naturally occurring minerals, Bond concludes that only quartz and tourmaline are practical for any extensive piezoelectric work. All the other active minerals are very rare, occur in the form of exceedingly small crystals, or are very weak mechanically.

Quartz was rejected because of its lack of hydrostatic sensitivity. Because of its ruggedness, linearity, insolubility, and hydrostatic sensitivity, tourmaline appeared to offer most promise for the construction of small, simple gauges and was selected accordingly.

IV. DESIGN AND CONSTRUCTION OF TOURMALINE GAUGES

A. Basic Considerations of Design

Since the criteria listed in Section II are not all mutually consistent, the design of a gauge for a particular application resolves itself into a search for a suitable compromise among these factors, and sometimes the final design cannot satisfy all the requirements to the extent desired. It has been established that tourmaline is satisfactory with respect to linearity, freedom from hysteresis, and stability of its pressure sensitivity, but there remains the problem of arriving at a design adequate from the points of view of sensitivity, frequency response, and ruggedness—all factors which are to some extent under the control of the designer.

Piezoelectric crystals develop polarization *charge* when subjected to pressure changes. This charge distributes itself over the capacitance which is in parallel with the gauge element, and consequently the amplitude of the voltage appearing at the amplifier input is not only directly proportional to the applied pressure change but also inversely proportional to the total capacitance parallel to the gauge element in the input circuit.

The necessary gauge sensitivity must therefore be evaluated in terms of the following controlling factors: (1) magnitude of pressure variations to be recorded, (2) total capacitance of the gauge circuit (this depends principally upon the length of cable required to connect the gauge to the amplifier or preamplifier), and (3) amplifier sensitivity.

A lower limit is sometimes placed upon the required sensitivity by the presence of spurious signal arising in the cable or the mounting of the gauge. In many applications, a piezoelectric gauge is connected to recording equipment by means of shielded cable, a certain length of which may be unavoidably exposed to the pressure wave as the latter advances from its source. Spurious signal arising in such cases is an integrated effect which generally introduces little error into the determination of initially discontinuous or rapidly changing pressures, but adds progressively more signal as the wave encounters more cable. It is evident that measurements of small pressures behind an initial high pressure region may thus become highly inaccurate and an effort to obtain reliable values of impulse by integration of the pressure-time curves may be entirely vitiated.

Experience has demonstrated that most ordinary commercial rubber microphone cables and polyethylene cables are completely inadequate since the signals they develop when subjected to pressure variations are very large and may even be, under some conditions, larger than those which would be produced by the gauge elements themselves.

A number of cables were developed which proved to be adequate, and one type—a copper tubing cable, originated at the David Taylor Model Basin—was used successfully for several years in under water studies. More recent developments have led to the production of a polyethylene cable (designated F.O. 5879 by the Simplex Wire and Cable Company) which appears to be superior to any other cables previously available and which is equally satisfactory for measurements in both gaseous and liquid media. However, even in this cable, the signal has not been completely eliminated (although it has been very greatly reduced) and one must always make sure that the gauge signal is large relative to the residual cable signal in each application.

Although much work in the past has been done with single-ended systems using coaxial cables,[3] it is well known that push-pull or balanced systems effect material reduction in residual cable signal by canceling out components which are symmetrical about ground. It seems unlikely, however, that such a system would eliminate the difficulty entirely, since there is no reason to expect the cable signal to be a perfectly symmetrical phenomenon.

The sensitivity of a piezoelectric gauge is directly proportional to the available sensitive area of crystal. In cases where spurious signal due to cable or gauge mounting is a significant factor, the permissible lower limit of sensitivity imposed by such signal places a lower limit upon the size of the gauge. On the other hand, the discussion of high frequency response and pressure-field distortion given in Section V shows that higher fidelity is obtained with *smaller* linear dimensions of the sensitive unit. Specific requirements as to accuracy with respect to high frequency response consequently put an upper limit on the linear dimensions of the gauge, particularly the dimension along the direction of propagation of the wave, and this upper limit must be reconciled with the lower limit indicated by the necessity of swamping spurious signal. In some cases the two requirements cannot be reconciled, and one or the other must be compromised in designing the gauge. This is particularly true where it is desired to measure very rapid pressure variations in liquid media. In gaseous media where the high frequency response requirements are usually less stringent, large gauges can be used and the above requirements can generally be reconciled.

In the actual construction of gauges, a given sensitivity can be obtained and the linear dimensions minimized by stacking two or more crystal plates in parallel. This feature has been utilized in all UERL gauges, but, except for a few special cases, it has not proved practicable to use gauges having more than four plates in the pile.

B. Construction of Gauges

The object of the UERL group was to develop a unit suitable for measurement of explosion-produced shock waves in air and water. Many of the basic principles, however, apply to measurement of transient pressure waves in general, and properly modified UERL-type gauges should be useful under a wide variety of circumstances.

The principal difficulties with the early gauge designs proved to be lack of stability of pressure sensitivity and prevalence of large systematic discrepancies between gauges used on the same measurement, even when the sensitivity of each gauge appeared to be stabilized. These difficulties were largely overcome by adoption of an improved construction technique, the governing principle of which was to prevent disturbance of the electrodes during the later stages of gauge assembly and during subsequent use.

---

[3] R. H. Cole, "The use of electrical cables with piezoelectric gauges." OSRD Report No. 4561.

An assembly drawing of a single-ended UERL gauge is shown in Fig. 1, and a picture of the different stages of construction is shown in Fig. 2. Properly lapped tourmaline disks receive a coat of electrode material, such as Du Pont liquid silver No. 4391, and are baked for about an hour at 550°C. Four disks are then assembled in a pile, two on each side of a steel tab as shown in Fig. 1, and the pile is sweated together into a single homogeneous unit by being placed in a spring clamp and again heated in an oven. Provision is made in this operation for electrode connection to the intermediate crystal faces.

The peripheral edges of the pile are insulated by the application of a thin layer of dielectric material such as pure latex which can be painted around the edges and cured *in situ* by baking at *ca.* 120°C. With the periphery properly insulated, contact can now be made between the outermost crystal faces and the grounded central tab. Originally this was accomplished by direct soldering to the electrodes, and the technique was revised because of the deleterious effect on the intimacy of electrode-crystal contact. The present technique is to make contact by means of a conducting silver paint which can be baked on at temperatures low enough to be compatible with the insulating material used around the edges of the unit.

In connecting a unit of this type to a length of electrical cable, it is only necessary to solder the central tab to the cable shield and spot solder the high electrode leads to the cable conductor. These connections can be made quickly, with a minimum of heating of the gauge element. In this manner the electrodes are afforded the greatest possible protection during mounting of the unit. (Elements of this type have also been mounted in threaded inserts which can be screwed into the wall of a container in which pressure variations are to be studied.)

Gauges of this design have been used to measure pressure, impulse, and energy flux in waves ranging in amplitude from 0.5 to 100,000 lb./in.^{2}.

It was originally feared that the introduction of the metal central tab might tend to introduce spurious mechanical oscillations on the pressure-time records. However, there has so far been no evidence of the presence of oscillations more serious than those ordinarily observed with gauges of earlier design which were not provided with central tabs.

The central tab principle is also vitally important because of the strength it gives the completed unit, particularly where measurements are to be made in gaseous media in which stresses caused by the exceedingly high particle velocities are capable of causing severe damage to unreinforced gauges.

The gauge design described is also well suited to the construction of push-pull units. If one pair of tourmaline disks is arranged with positive faces connected to one high potential lead while the pair on the opposite side of the central tab has negative faces connected to another high potential lead, the central tab and outer pair of faces can all be grounded to the shield of a two-conductor cable while the two high potential leads are connected to the two center conductors, respectively. This results in a perfectly symmetrical, completely shielded unit which develops signals balanced about ground. A less symmetrical, but more efficient push-pull gauge can be made by connecting a single-ended-type unit to the center conductors of a two-conductor cable without grounding any point within the gauge.

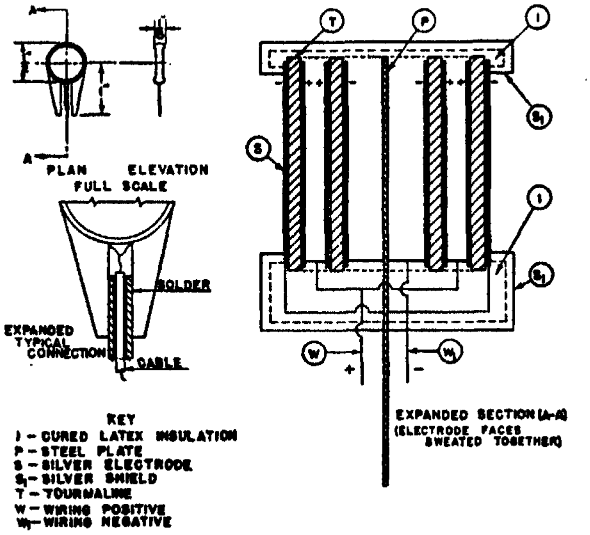

FIG. 1. Assembly drawing of UERL-type tourmaline gauge.

In the case of gauges intended for measurements in gaseous media, the serious effects of perturbation of the flow around the gauge[4] can be minimized by surrounding the gauge element with a streamlined housing or baffle of suitable shape and proportions. Various aspects of this design problem are still under investigation in several laboratories.

C. Coating of Gauges

After the gauge element is assembled and mounted, it is necessary to apply a waterproof coating, since contact with even minute quantities of moisture results in low gauge resistance with consequent impairment of the low frequency response.

Numerous coating techniques have been tested by the UERL group, and only a few have proved satisfactory. The most useful method has been the application of a

---

[4] J. K. L. MacDonald and S. A. Schaaf, "On the estimation of perturbations due to flow around blast gauges," OSRD Report No. 5639.

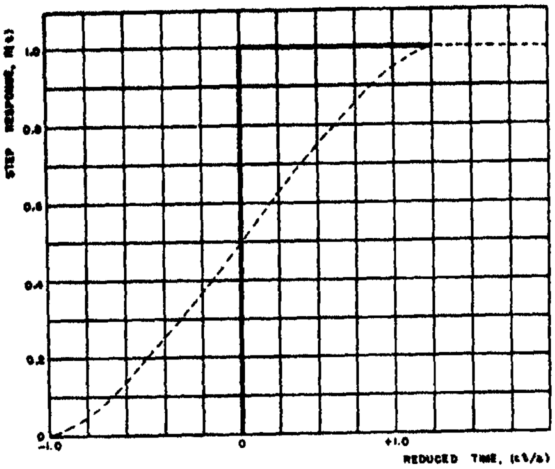

FIG. 5. Response of a gauge of radius a to a progressive step wave of velocity c.

time required for the gauge to give maximum response, this time being theoretically equal to $2a/c$.

The validity of such a correction involves the assumptions that distortion due to diffraction effects dies out sufficiently rapidly not to affect the curve after the maximum, and that the true pressure curve is sufficiently simple for a linear decay law to be a good approximation. It is reasonable, however, to expect that any diffraction effects will have the general character of damped transient oscillations about the gradual rise as the gauge is covered by the advancing wave and should not be significant after the gauge is covered. Whether or not the pressure curve is sufficiently simple to be represented by a straight line or smooth curve, depends, of course, on experimental conditions. Unless appreciable interference or reflections are combined in the resultant wave, the corrected maximum pressure may well be used as a significant measure of the wave.

This principle has been extensively applied by the UERL group in the interpretation of underwater shock wave records and the estimation of true peak pressures under conditions where the gauge size introduced appreciable error. It was found that the simplified theory provides adequate correction for amplitude effects up to about 10 to 15 percent, but then begins to show serious departures from observed values. It has also been found empirically that the gauge radius a which must be used in the theory is not the radius of the element alone, but rather the radius of the *complete* gauge *including* coating material.

B. Interference Effect

The analysis of the effect of gauge size on transient response neglected any disturbance of the pressure wave due to presence of the gauge in the field. Actually, of course, the gauge material is a medium through which sound waves can be transmitted. As a result, one can expect interference effects due to repeated internal reflections of the incident wave at the interfaces of the crystal. This would have roughly the character of a damped saw-tooth oscillation. The frequency of this oscillation cannot be calculated accurately, but it is probably of the order of 100 kc/sec. for the types of gauges described in this paper.

In order to examine the effect of interference on response of an actual gauge, we might consider a circular disk in either of two orientations: face-on and edge-on to the approaching pressure front. The Coulomb sensitivity of a disk of tourmaline depends only on the face area, not on the thickness, and, as a result, the travel time is obviously minimized and the natural frequency highest if a thin disk is oriented face-on. It is to be expected, however, that Bernoulli effects[4] will be much less if the same disk is edge-on.

To the extent that a single very thin disk is practical, the face-on orientation may appear preferable because of the inherently higher frequency characteristic. In actual practice there is a limit to the thinness possible, and in the interest of greater sensitivity, it is desirable to construct a gauge from a pile of disks; thus multiplying the effective area and sensitivity and obtaining a better electrical and mechanical design. Under such circumstances the face-on orientation would have much larger interference oscillations than the edge-on orientation and comparable transit time and flow effects.

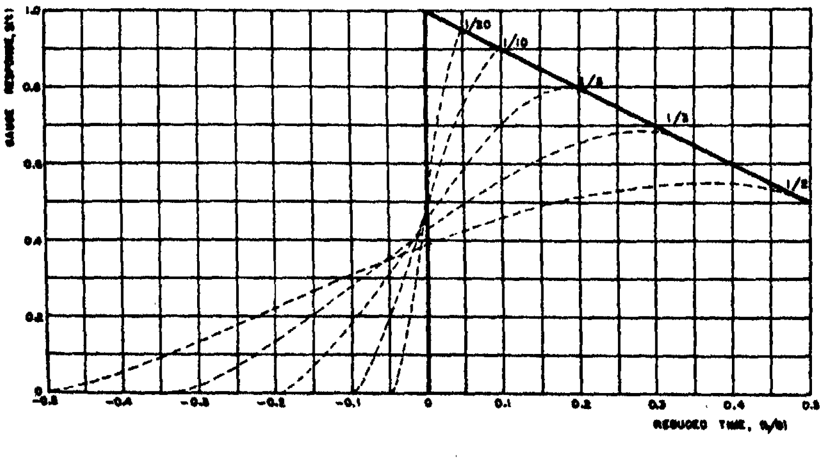

FIG. 6. Response of a gauge of radius a to a progressive saw-tooth wave of decay constant θ and velocity c. Solid line represents incident wave. Dotted curves show response for various values of $a/c\theta$.

Comparing the two possibilities, one might expect the edge-on gauge to have a much smoother rise in response to a step pressure, taking a longer time, but approaching the true curve more smoothly. Experimental tests have roughly indicated this state of affairs, and practical experience has also shown that records obtained with gauges in the edge-on orientation give about as much usable high frequency resolution as face-on gauges and are much cleaner and easier to analyze empirically.

C. Low Frequency Response

(1) Internal impedance. Although a piezoelectric crystal under ideal conditions develops a potential difference between its faces which persists as long as a force is applied to it, in practical use unavoidable leakage resistance and input resistance of recording equipment afford conducting paths by which the piezoelectric charge is gradually neutralized. As a result, the response to applied pressure falls off as the rate of change of pressure decreases. The electrical properties of a piezoelectric crystal are represented with sufficient accuracy for the present discussion by an e.m.f., V_0, proportional to applied pressure, in series with the capacitance, C_0, of the crystal. In actual use the gauge will be shunted by lead capacitance C and leakage or other resistance R.

The response of such a circuit to a step pressure P_0 is a negative exponential:

$$V_t=[KA/(C+C_0)]P_0\epsilon^{-t/\tau}, \qquad (6)$$

where V_t = terminal voltage; KA = gauge sensitivity expressed as charge developed per unit pressure change; and $\tau=R(C+C_0)$.

From Eq. (6) it is evident that the response in the limit of low frequencies or long times approaches zero. The useful lower limit is obviously increased by increasing the time constant τ. Therefore the input impedance and other resistances represented by R should be made as large as other considerations (for example, amplifier stability) permit. Likewise, the time constant can also be increased by use of larger values of C. (In practically all applications $C_0 \ll C$, and increase of crystal capacitance would have no appreciable effect on τ.)

Unfortunately, an increase in the value of the padding capacity C reduces the output voltage by the same proportion. If one is limited in allowable gauge sensitivity by high frequency considerations or by low pressure amplitudes, improvement of low frequency characteristics in this way requires increased sensitivity of the recording system. The best solution in difficult situations requires a compromise between gauge size, resistance of the circuit, and sensitivity of the recorder.

(2) Pyroelectric effect. A second factor that may affect the low frequency response of a piezoelectric gauge is the development of charge as a result of temperature changes in the crystal. Such charges can arise either directly from increased temperature due to adiabatic compression of the crystal, or, indirectly, from temperature changes in the surrounding medium or from radiation such as sunlight, explosion flashes etc.

The first effect has been shown to be negligible by Keys.[5] The second effect depends upon the amount of heat developed external to the crystal and the rate at which it can raise the crystal temperature by thermal conduction or radiation.

The pyroelectric sensitivity of tourmaline is such that a change in temperature of 1°C produces a charge equivalent to that developed by a pressure change of 200 lb./in.^{2}. In liquid media, however, the pressure wave durations are usually very short, and although the adiabatic temperature change of the liquid is appreciable, a gauge can hardly undergo more than a small fraction of the ultimately possible temperature change during such intervals, particularly in view of the thermal insulation afforded by the gauge coating.

In gaseous media, however, radiation effects, temperature changes due to adiabatic compression of the medium, and effects due to variations of ambient temperature become very much more pronounced. Special care must be taken to provide adequate thermal insulation by using coatings of sufficient thickness for the particular application. Excessive thickness of coating, however, has been found to affect the gauge properties by introducing spurious oscillations and other undesirable effects, and a suitable compromise must be found in difficult cases. Radiation effects can largely be protected against by the use of a bright coating, such as silver paint, on the outside of the gauge.

The longer the duration of the signal being measured, the more difficult it becomes to combat interference due to pyroelectric effect, and thus the applicability of the tourmaline gauge is more severely limited by its pyroelectric sensitivity than by the other natural limitations of input impedance, time constant, and piezoelectric sensitivity.

VI. REQUIREMENTS OF ASSOCIATED RECORDING EQUIPMENT

Detailed discussions relative to the design and construction of oscillographic recording equipment and cables for use with piezoelectric gauges will be found elsewhere.[5,6,7] It is the purpose here to discuss briefly only certain requirements of such equipment which are intimately associated with the selection and use of the piezoelectric gauges themselves.

From the foregoing considerations, it is obvious that the low frequency characteristics of an amplifier should be such that its over-all time constant is long relative to the duration of the phenomenon being recorded. In extreme cases this might require a d.c. amplifier. Input

impedance can generally be made sufficiently high by use of cathode follower preamplifiers.

The situation with respect to high frequency requirements is slightly more complex in that a certain amount of high frequency distortion is unavoidably present because of the geometry of the gauge. (This effect was computed for some simple wave forms in Section V.)

In general, therefore, the demand upon amplifier response will be conditioned by the gauge response, and a useful quantitative calculation can be made for the special case of steep-fronted waves, where high frequency considerations are most important.

We assume that a saw-tooth wave is incident at the gauge and that the shape of the signal reaching the amplifier can be represented to a first approximation by a linear rise to a peak value followed by a linear decay, i.e.:

$$F(t)=\begin{cases}0 & \text{when } t<0\\ t/\gamma & \text{when } 0<t<\gamma,\\ 1-(t-\gamma)/\theta & \text{when } t>\gamma\end{cases} \tag{7}$$

where θ is the decay constant of the wave and $\gamma=2a/c$, the transit time of the shock wave across the gauge.

The step response of the amplifier is assumed to have the form:

$$R(t)=1-\epsilon^{-t/\kappa}. \tag{8}$$

Expressing the above relations in terms of dimensionless parameters with θ as the scaling factor ($\alpha\equiv\gamma/\theta$, $\beta\equiv\kappa/\theta$), and applying the superposition integral, it is shown that:

$$\Delta=\beta\ln[1+(1-\epsilon^{-\alpha/\beta})/\alpha], \tag{9}$$

where Δ represents the fractional error introduced by the amplifier in reproducing the peak of the applied function, $F(t)$. $F(t)$, however, already contains an error $\alpha/2$, with respect to the peak pressure of the incident shock wave. Thus the total error introduced by the combined effects of gauge size and amplifier high frequency response is:

$$E=\Delta+\alpha/2 \tag{10}$$

with respect to the incident shock wave peak pressure.

Figure 7 is a representation of Eq. (9) which should prove useful in estimating error due to a given frequency response for various gauge conditions or for design purposes where one seeks to find the frequency response necessary to keep the error below a certain selected limit.

The problem of calibrating piezoelectric gauges is a vital one, involving rather highly specialized instruments and techniques. Owing to fairly recent developments in the field, calibration will be discussed in a separate paper at some future date.

VII. ACKNOWLEDGMENTS

The knowledge and experience upon which this report is based could not have been accumulated were it not for the cooperative effort of a large number of individuals who participated in the work of the Underwater Explosives Research Laboratory. The authors are pleased to acknowledge in particular the significant contributions of Professor E. B. Wilson, Jr., Dr. W. D. Kennedy, Dr. W. G. Schneider, Dr. A. M. Shanes, and Dr. W. E. Gordon, and regret that space does not permit a more adequate identification of the contributions of each individual to the fundamental understanding of the use and design of piezoelectric gauges. Much credit for development of techniques of construction of the present gauge design is due Professor C. Frondel of the Department of Mineralogy, Harvard University. Earlier construction techniques were developed by Dr. D. Silverman and Mr. H. M. Lang of the Stanolind Oil and Gas Company.

Background Eradication in Thick-Layered Nuclear Emulsions

MARTIN WIENER
National Bureau of Standards, Washington, D. C.

AND

HERMAN YAGODA
National Institute of Health, Bethesda, Maryland

(Received August 1, 1949)

A method for eradication of accumulated background on Ilford C-2 plates, 100–200μ thick, without reducing their sensitivity to medium ionizing particles, is described. The method involves a mild oxidation of the emulsion by air saturated with water vapor at 35°C for a period of about 16 hr. The plates are then dried and are ready for experimental exposure. Analysis of grain counts shows no loss of sensitivity in proton tracks over their last 200μ range when the plates are developed with a mild hydroquinone developer. Complete eradication of background alpha-tracks and stars is secured as well as destruction of latent images of the less ionizing proton recoils instigated by external neutron bombardment. Grain density studies on proton tracks located at different depths in the emulsion indicate substantially uniform sensitivity after eradication except for the uppermost 50μ which develop with about a 10 percent reduction in mean grain density as compared with tracks deep within the recording medium.

IN recording the tracks of ionizing particles arising from feeble radioactive sources or induced nuclear reactions of low cross section, it is advantageous to destroy the accumulated background of latent images originating from internal radioactive impurities and incident cosmic radiation. This is particularly important in recording the trajectories of low energy protons that originate from photo-disintegration processes in deuterium-loaded emulsions, as old latent images of alpha-particles develop with a reduced grain density and may be confused with protons of equal range.

Yagoda and Kaplan[1] have demonstrated that the background can be destroyed by exposing the plates above three percent hydrogen peroxide at 25°C. With plates having coatings 25–50μ thick, the process is completed in about 4 hr. When this method is applied to thicker emulsions (100–200μ), however, the oxidation process must be extended in order that the vapor has the opportunity to diffuse through the entire layer. The prolonged oxidation (about 16 hr.) causes a reduction in sensitivity as evidenced by tracks of alpha-particles subsequently produced in the dry emulsion which develop with reduced grain density.

This partial desensitization can be avoided by eradicating the plates with a milder oxidant, such as moist air, and conducting the operation at 35±2°C to accelerate the process. To test the efficiency of this procedure, an old (134 days) Ilford C plate, coated 200μ thick, was cut into three portions, A, B, and C. All three were exposed simultaneously to fast neutrons from a 5-mc Po-Be source. Portion A was then developed so that a record would be had of the knock-on protons and background alpha-tracks in an uneradicated portion of the plate. Portions B and C were exposed to air saturated with water vapor at 35±2°C for 16 hr. After drying the eradicated portions for 1 hr. over anhydrous calcium chloride, Plate B was re-exposed to fast neutrons and then developed, together with the control plate, C. Development was identical with that given Plate A. In this manner, Plate B would give us proton tracks, free of alpha-background, whose grain density could be checked against the proton tracks in Plate A, and Plate C could be examined for the efficiency of the eradication of both the proton tracks and the background.

The development consisted essentially of a 1-hr. immersion in a freshly prepared solution composed of: 2 g hydroquinone, 20 g Na_2SO_3, 1 g KBr, and 10 g Na_2CO_3 per liter of distilled water chilled to 8°C, followed by dilution with an equal volume of water at 25°C, warming the mixture to 22°C, and maintaining, without subsequent agitation, at 22±1°C for 1 hr. Studies of this method[2] indicate that the procedure

[2] H. Yagoda, Nucleonics 4, 5, 134 (1949). The processes of fixation and washing are essentially the same as those described in

produces uniform depth development in emulsions 100 to 250μ thick. More powerful elon-hydroquinone developers such as D19 cannot be employed, as the long development time necessary in processing thick emulsions causes the reappearance of eradicated alpha-tracks with, however, greatly reduced grain density.

The apparatus used for eradication consists of a water bath controlled at 35°C, an enamelware pot containing a layer of wet sand, a rack for supporting the plates horizontally, and an asbestos insulating shield as shown in Fig. 1. It is important to avoid metals, particularly aluminum, inside the eradicator vessel, as moist air acting on freshly abraded metallic surfaces produces traces of hydrogen peroxide.[3] The wooden rack employed as a support for the plates should be well aged and impregnated with hard paraffin wax. The alternate layers of blotting paper prevent droplets of condensed water from falling onto the emulsion surface. The paper should be examined periodically for mold growth and replaced as needed.

Microscopic examination of the control plate, C, showed complete absence of proton recoil tracks, demonstrating that the treatment caused total destruction of latent images formed by 0.4 to 11 Mev proton tracks. Background alpha-tracks were observed only in the non-eradicated piece. A count of the alpha-stars on this plate, A, showed a population of about 2800 alpha-stars per cc of emulsion of which 1300 originated in the emulsion itself, the remainder starting in the glass backing. As the emulsions were 134 days old at time of development, this indicated an approximate rate of formation of 10 stars per cc per day originating in the emulsion layer. Only the stars (two to five alpha-branches) were counted, not single alpha-tracks. The latter are about six times as numerous as stars so that about 70 alpha-stars and -tracks were formed per cc per day in this particular Ilford C-2 plate. The population is dependent chiefly on the quantity of thorium and radium present as variable impurities in the components of the plate.

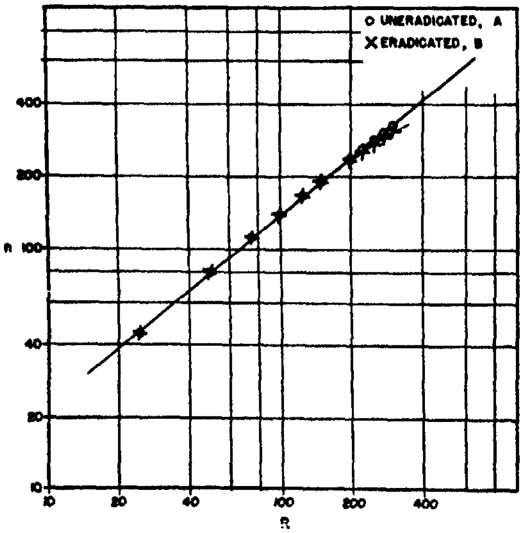

FIG. 2. Comparison of grain development before and after eradication, based on all tracks measured.

In order to detect any small variations in sensitivity produced by the eradication process, grain counts (n) were made along 25μ portions of the proton tracks recorded in Plates A and B, selecting tracks in all levels of the emulsion with a maximum slope of 30° with the plane of the emulsion, and with a range of about 200μ or greater.

The resultant data was evaluated by plotting $\log n$ against the residual range, $\log R$ (Fig. 2) as this function is essentially linear and independent of particle energy. The plot shows no noticeable variation in sensitivity between the eradicated and uneradicated plates over the first 200μ of range from the slow end. Beyond 200μ, the eradicated plate exhibits a slight, but increasing, desensitization. The graph was drawn from the average of 32 tracks on Plate A and 35 tracks on Plate B. The majority of the tracks were about 200μ long, the maximum range in which we were interested for purposes of subsequent photo-disintegration studies, so that the average for the range beyond 200μ is based on fewer grain counts than for the range below.

A further breakdown was made of the tracks in each plate into groups of tracks at different levels in the emulsion. Tracks were chosen at 10–69μ from the top of the emulsion (Group 1), 70–139μ (Group 2), and at depths greater than 139μ (Group 3). Figure 3 shows that

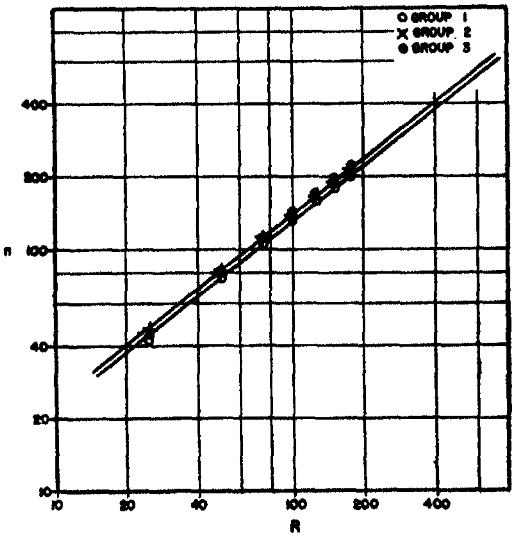

FIG. 3. Variation of grain count with residual range for knock-on protons resident in different layers of an old non-eradicated emulsion (A).

Method VII (reference 3, p. 62–63). When old plates are fixed, the tendency toward emulsion frilling can be minimized by washing the developed plate in five percent sodium sulfate for 20 min. The residual alkali is then neutralized by a 5-min. rinse in two percent boric acid prior to immersion in the 30 percent sodium thiosulfate bath.

[3] H. Yagoda, *Radioactive Measurements with Nuclear Emulsions* (John Wiley and Sons, Inc., New York, 1949), p. 9–12.

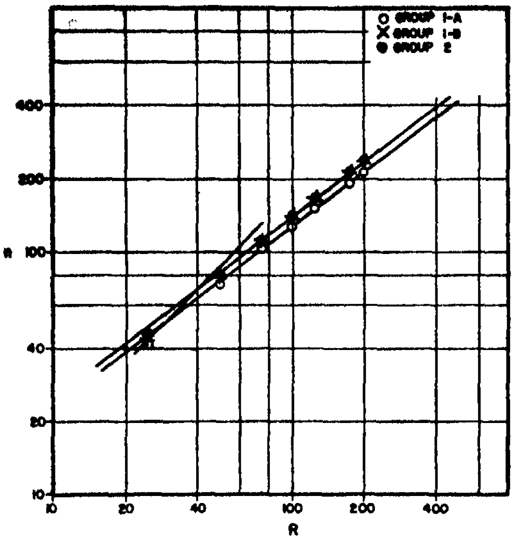

FIG. 4. Breakdown of Group 1 tracks in Plate A exhibiting large reduction in developed grain density in the emulsion layer in contact with air.

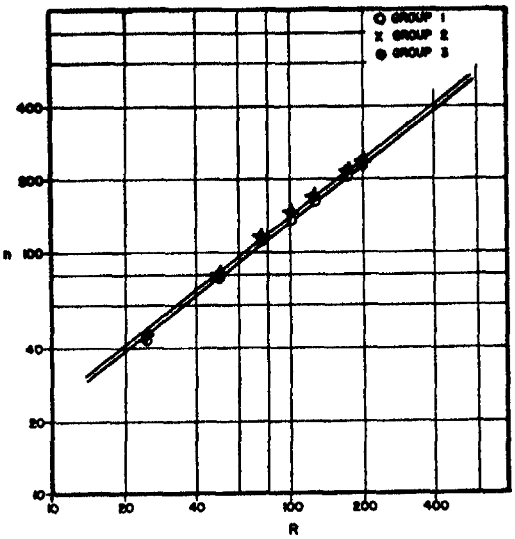

FIG. 5. Variation of grain count with residual range for knock-on protons resident in different layers of an old, but eradicated emulsion (B).

in Plate A (uneradicated) there is a definite desensitization of the upper portion of the emulsion, Group 1, with practically no variation in sensitivity between Groups 2 and 3, indicating, incidentally, uniform depth development at those levels. The reduction in grain density exhibited by Group 1 is caused almost entirely by the tracks in the uppermost 35μ of the emulsion as shown by subdividing Group 1 into 1A (10–35μ) and 1B (36–69μ), as shown in Fig. 4. These two subsections are compared with Group 2, and it is seen that Group 1B is practically coincident with Group 2.

Two possible explanations for this phenomenon present themselves. One is that the surface of the plates lost some sensitivity due to oxidation by the air enclosed in the package. The other is that the plates were not uniformly developed at the upper surface due to the mechanism of development. The portion of the development procedure in question is the dilution of the chilled developer with distilled water. Very little development occurs during the diffusion period at low temperature. The subsequent dilution with water may tend to reduce the rate of development at the surface as compared to the rest of the emulsion after the developer is warmed. Possibly both the oxidation and development factors are involved. Figure 5 shows the same effect for the eradicated plate, B, but to a lesser extent due to the fact that the majority of the tracks in Group 1, in Plate B, occurred below 35μ from the surface.

The eradication procedure appears practical for use in unloaded, Ilford C-2 plates, recording tracks of medium ionizing particles in the absence of background accumulated since time of manufacture. For lightly ionizing particles, loss of sensitivity will be encountered. While the behavior of the process was not investigated for very fast protons or meson particles, the study indicates that the initial portion of the trajectory would probably either not record at all or would be outlined by a smaller number of grains. The eradication method is entirely suitable for recording tracks of alpha-particles and low energy protons without appreciable change in track structure. The investigation also indicates the importance of carefully noting the level of the plate in which the track is found if mass determinations are to be made by grain counts. As indicated by Fig. 4, a proton track recorded in the upper layer of an old emulsion might be confused with a heavy meson particle of about 1300 m_e on the basis of grain counts.* If the plate is old, as it is of necessity in prolonged cosmic-ray exposure, care must be taken in mass estimates that the unknown and comparator tracks are resident at about the same depth.

---

* The 45° line intersects the curves at points of equal grain density. In evaluating the masses of nuclear particles of the same charge by grain counts it is well known that the masses are directly proportional to the residual ranges measured from the points of common grain density. The same method is here employed to evaluate the apparent changes of mass actually due to desensitization of the emulsion.

The Choice of Suitable Gap Forms for the Study of Corona Breakdown and the Fiel Along the Axis of a Hemispherically Capped Cylindrical Point-to-Plane Gap*

LEONARD B. LOEB, JAMES H. PARKER, E. E. DODD, AND WILLIAM N. ENGLISH†
Department of Physics, University of California, Berkeley, California

(Received August 1, 1949)

The various corona gap forms suitable for the convenient investigation of corona phenomena of both signs in the laboratory that are capable of yielding quantitative data involving the Townsend integral for the thresholds of the manifold phenomena are discussed. For laboratory study the most convenient form of gap is the hemispherically capped cylindrical point-to-plane system. Analysis of the potential fall along the axis in such gaps by means of electrolytic model studies indicates that the essential parameter is L/r, the ratio of gap length, L, from point surface to plane relative to the point radius, r. The model study potentials are, however, incapable of giving accurate values of the field strength. These fields must be obtained by computation. Laboratory studies of corona indicate the desirability of relatively large values of L/r. Practical considerations based on studies at atmospheric pressure indicate point radii r of 0.025 and 0.05 cm with a ratio $L/r=160$ to be those giving the greatest flexibility and most widely separated thresholds at convenient potentials. The use of such point systems to standardize data is recommended. On this basis the field along the axis for the hemispherically capped cylindrical point-to-plane gap as computed by E. E. Dodd is given and here applied to the calculation of the point-to-plane Townsend integral for pre-onset burst pulse thresholds in air as observed by H. W. Bandel. The value is compared with the values obtained by W. N. English for confocal paraboloids where the fields are accurately known. The results are satisfactorily consistent. Discrepancies in the fixing of burst pulse thresholds by various observers are discussed.

THE investigation of gaseous discharges using asymmetrical electrode arrangement offers exceptional opportunities for a study of breakdown phenomena. The reason for this lies in the high field concentration at one electrode which, coupled with space-charge accumulations in the lower field regions of the gap, permits one to extend over a considerable voltage range the phenomena leading to breakdown. The discharges with asymmetrical electrodes initiate with the appearance of luminous glows and brushes of diverse forms which can be characterized by the general term coronas. Corona discharges, aside from their scientific interest, have importance in industry in generators for ions of unique sign, in "noiseless" electrical discharges, in electrical valves and control circuits, and as an important source of power loss on high voltage lines.

Laboratory study has now reached the stage where quantitative data in testing basic theory are urgently required and it is important that future studies be made under appropriate conditions. Past investigations have been carried on with the most diverse assortment of electrode systems, and correlation of data has been impossible. The work to be reported here eliminates certain geometries and sets limitations which will assist future workers and lead to better coordination of data.

Modern *basic* corona mechanism studies have shown the desirability of obtaining the data listed:

1. Knowledge of the potential and field distribution across the gap. Such knowledge permits evaluation of the first Townsend coefficient, α, as a function of distance, x, from the point surface, which permits quantitative studies of onset conditions.
2. Convenience for visual, photographic, and oscillographic study. This includes opportunity for direct photographic, telemicroscopic, and spectroscopic observation without distorting the field. Such study is facilitated by concentration of phenomena at one point so that oscillographic records are not complicated by several independent localized coronas on the same system, or by the spread and diffusion of phenomena.
3. Mechanical convenience and simplicity as well as accuracy and ease of adjustment.
4. Uniformity in dimensions to facilitate comparison of data.
5. Proper dimensioning to permit observations of large ranges of pressure and potential change without introducing difficulty with achievable potential supplies or inordinately large dimensions for convenient study.

Possible geometries that have been used are:

1. Concentric cylindrical electrodes.[1]
2. Hyperboloid against plane.[2]
3. Confocal paraboloids.[3,4]
4. Hemispherically capped cylindrical point-to-plane.[5]

All of these, except the hyperboloids, have been used by the Berkeley Laboratory at some time. Hyperboloids were used by Bennett.[2] It is of interest to discuss these geometries in regard to their convenience for basic corona studies.

1. The coaxial cylindrical systems permit accurate knowledge of the fields, especially if equipped with guard rings. They are inconvenient for observation in that discharges may vary from radially symmetrica

[1] This geometry has been used in countless studies and is use currently in Geiger counter studies. Until recently, no one has attempted a comprehensive survey of the various threshold mechanisms and a complete accumulation of data for a wide range of pressures and gases compared to other gap types. This has recently been achieved in a Ph.D. thesis by C. G. Miller, University of California, July, 1948, which is now being prepared for publication.

[2] W. H. Bennett, Phys. Rev. 60, 714 (1941).

[3] A. F. Kip, Phys. Rev. 54, 139 (1938), and W. N. English reported here.

[4] K. E. Fitzsimmons, Phys. Rev. 61, 175 (1942).

[5] G. W. Trichel, Phys. Rev. 54, 1078 (1938); 55, 382 (1939). W. N. English, Phys. Rev. 74, 170 (1948).

fans to sectors of such fans and are often diffused down the length of the wire. The regions adjoining the axial wire are usually obscured by supports such that visual observation is difficult. Luminosities at the outer cylinder are hard to see. Several corona events may simultaneously appear at different points on the same inner electrode and the discharge spreads and wanders along the electrode, complicating oscillographic study. The outer cylinder walls play a very important role with the positive wire discharge, especially if the outer radius is small, since the system conserves photons and carriers that are lost in other systems. Such a system is fairly convenient mechanically, adjustment is simple, and outgassing easy. Visual observation is hampered by diffusion and visual aspects appear only at higher currents. Properties of concentric cylindrical coronas must in any case be studied since they furnish important instrumentation such as Geiger counters and other devices, even though they obscure phenomena.

2. Hyperboloids have not been used extensively.[5] It is probably difficult to achieve sufficient field uniformity to permit accurate calculations without using hyperboloid points extensive in space, shorter gaps, and large planes. Fabrication is difficult, especially for sharper points.

3. Confocal paraboloids give accurately calculable fields, if extensive enough. Observation is obscured. They are not easy to fabricate and are awkward to adjust.

4. The fields along the axis for hemispherically capped cylindrical point-to-plane gaps have not to the present been amenable to theoretical calculation. Laborious calculations made on the basis of various studies to be indicated yield a satisfactory solution for the field along the axis near the point for only one ratio of point radius to gap length. The point-to-plane gaps, once the fields are known, are ideal for observation. Localization and observation are excellent. The convenience of fabrication and the accuracy of adjustment are ideal for quick studies. The plane electrode interferes less with the point discharge than any other arrangement. In fact, no marked effect has been noted even in outgassed systems. To date, no studies have been made to indicate the best dimensioning of these systems for laboratory study, and a wide diversity of gaps have been used making comparison difficult. It has been owing to the properties of these gaps that observations of most of the phenomena leading to a knowledge of the basic mechanisms such as burst pulses, streamers, and Trichel pulses were made.

In view of the advantages of the point-to-plane system, it is the purpose of this investigation to study it in order to indicate the most suitable dimensions for experimental application on a laboratory scale, to evaluate the fields along the axis, and to compare corona threshold data for such a system with that for other systems. The cumulative results of these investigations allow of positive recommendations to be made for the future conduct of corona investigations in the laboratory.

The experimental model studies used a tank of wood lined with painted canvas 109 cm along the direction of the axis, 122 cm perpendicular to the axis, and 55 cm deep. The plane was a semicircular disk of Duralumin fastened vertically with its diameter of 116‡ cm along the surface of the electrolyte at one end of the tank. Various hemispherically capped cylindrical brass rod points were used. They emerged from the opposite end of the tank parallel to the water surface with one-half the rod immersed in the electrolyte. The meniscus of the capillary film produced no severe distortions except very close to the point. The rod projected at least 20 cm from the end of the tank. The range of point and gap diameters was limited by the size of the tank. The electrolyte was a 0.02 molal solution of NH_4Cl in water. Later only tap water was used with a higher potential. The potential source consisted of a 1000-cycle oscillator giving 10 v. Later 100 v from a 500-cycle generator was used. The measurements used the conventional potentiometer arrangement common to such studies. A cathode-ray oscillograph was used as null indicator. Potentials along the point axis were determined with a 0.3- and a 0.1-mm diameter probe projecting 1 mm into the liquid. Positioning was achieved by micrometer screw and guide. The observed potentials are shown in column 5 of Table VI, while those calculated are shown in column 4 of Table VI. In view of the inaccuracies of the fields derived from differentiating the curves for potential relative to distance from the point, such fields were not used in calculation. However, the data on potentials and fields led to important considerations in regard to the suitable geometry for use in point-to-plane discharge studies.

The preliminary measurements indicated, as one would suspect, that the principle of similitude was applicable and that the important parameter in the gap was L/r, the ratio of L the gap length from the point surface to the plane, relative to the point radius r. Data obtained for L equal to 76.4 cm, 50.8 cm, and 31.8 cm with point diameters of 0.953 cm, 0.635 cm, and 0.397 cm, gave identical curves for the ratio of potential V at any distance x from the point surface to the total applied potential V_0, when V/V_0 was plotted against the ratio x/L, of x to gap length L within the limits of accuracy of measurement.

Having established the importance of the L/r ratio in such gaps, it was next desirable to indicate the favorable values for corona studies. The work with various corona gaps in this laboratory indicates that the point phenomena are more prominent and the various thresholds are more widely separated in potential the larger the ratio of L/r. These studies also indicate that relatively lower potential gradients at the point surface are needed to start corona at larger point radius, since the critical Townsend integral $\int_{a+r}^{r} \alpha dx$ requires lower values of α

---

‡ In order that the diameter of the disk should lie in the surface of the electrolyte, 4 cm were cut off the curved end of the disk at the bottom.

if the distance $x=a$ from the point radius where ionization ceases can be increased. The larger the point radius the larger the value of a. Thus, except for studies whose specific purpose is to investigate coronas with decreasing point radius, the choice of a conveniently large point radius r within the limitations of available potential sources is indicated.

These factors impose physical limitations of other sorts on the desirable gap radii to be used, as well as fixing the ratio L/r. For example, if it is desired to study the whole range of corona phenomena with one point from onset to spark breakdown, the available high voltage supply becomes important. For $r=0.025$ cm, the threshold in air begins at about 5000 v and ranges to about 40,000 v at breakdown. For $r=0.05$ cm, the threshold is of the order of 8000 v with breakdown correspondingly higher. If potential sources are limited, then smaller values of r are required. In general, the two values given set a limit for comfortable and accurate laboratory control of stabilized potential sources. Thus for convenient work, a value of r given by $0.025\text{ cm}<r<0.05$ cm is indicated if the higher surface fields are to be avoided. Again, since large values of L/r are desirable, further limitations are set by practical considerations in laboratory study. If $L/r=160$ and $r=0.05$ cm, then $L=8$ cm. Now such studies as have been made in this laboratory indicate that if the ratio of plane radius R to gap length L is greater than $R/L=1$, the variation of the plane radius produced no serious change in onset potentials. Theoretical studies further indicate that the length of the point should likewise be at least of the order of the gap length for best results. If $R=8$ cm, the chamber for corona studies must have a diameter in excess of 24 cm so that its electrically screened and grounded walls shall not materially influence the field. This sets an upper limit on values of L/R of 160 for the largest point. The gain obtained by increasing L/r with the $r=0.025$-cm point to 320 with an 8-cm gap is not sufficient to warrant using the longer gap. It is thus recommended that point-to-plane gaps, being used for study in general, be either gaps with $r=0.025$ cm and $L=4$ cm, or $r=0.05$ cm and $L=8$ cm, in order to standardize data. If available potential sources are low, smaller values of r must be used. In any case, irrespective of the value of r chosen, *the ratio of $L/r=160$ appears to present a convenient value.* Accordingly, in setting up the computations for the point-to-plane gap, this ratio of L/r was chosen.

The calculation of the field along the axis and near the point for such a gap is as follows:

The axial electrostatic field intensity at and near the point electrode is expressed in cylindrical coordinates, (r, z), with the plane electrode grounded and at $(z=0)$. Letting $\Phi(r, z)$ be the electrostatic potential for a point electrode of unit radius starting at $(z=160)$ with unit potential difference across the gap, the axial field intensity is:

$$\begin{aligned} X(0, z) &= (\Delta V/\rho)d\Phi(0, z)/dz \\ &= (\Delta V/\rho)E_z, \end{aligned} \tag{1}$$

where ΔV and ρ are, respectively, the actual gap potential and point radius used. E_z will be referred to as the axial field intensity factor.

$\Phi(r, z)$ is approximated by the potential of an axial point charge at (0, 161) followed by an axial charge distribution in $(0, z\geq 161)$ which along with their images in the $(z=0)$ plane produce a unit equipotential surface suitably close to the point electrode boundary. (The $(z=0)$ plane will be at zero potential due to the image charge, but the point electrode boundary cannot exactly be obtained.) Then the axial charge distribution is represented[6] as a step function by a combination of semi-infinite constant axial line charges starting at various values $(z=a)$ so that

$$\Phi(r, z)\approx A_pP(r, z)+\sum_a A_aV(r, z; a), \tag{2}$$

where

$$P(r, z)=([r^2+(161-z)^2]^{-\frac{1}{2}}-[r^2+(161+z)^2]^{-\frac{1}{2}}), \tag{3}$$

and

$$V(r, z; a)=\text{const.}\cdot\int_a^\infty ([r^2+(\xi-z)^2]^{-\frac{1}{2}} - [r^2+(\xi+z)^2]^{-\frac{1}{2}})d\xi,$$

or

$$V(r, z; a)=\log_{10}\frac{a+z+[r^2+(a+z)^2]^{\frac{1}{2}}}{a-z+[r^2+(a-z)^2]^{\frac{1}{2}}}. \tag{4}$$

The total point charge, A_p, and the charge per unit length of any line change, A_a, also contain all necessary proportionality constants and are evaluated by selecting values for $(z=a)$ and imposing upon Eq. (2) the following conditions, which will establish a set of linear simultaneous equations in A_p and the A_a:

On the cylindrical portion of the boundary,

$$\Phi(1, z_i)=1, \tag{5}$$

where z_i are selected values of $z\geq 161$. On the hemispherical portion of the boundary, letting $\Phi(r, z)\rightarrow\Phi(c)$, where c is the great circle displacement from $(c=0)$ at (0, 160),

$$\Phi(0)=\Phi(0, 160)=1 \tag{6}$$

and

$$\Phi_{nc}(0)=d^n\Phi(0)/dc^n=0, \tag{7}$$

where

$$n=2, 4, \cdots.$$

Conditions (5) and (6) make the resulting unit equipotential surface coincide with the point electrode boundary at the points $(1, z_i)$ and (0, 160). The deviation between these points is small and in alternate directions and its effect is neglected. Conditions (7) make the resulting unit equipotential surface have unit curvature at (0, 160) and lie close to the hemispherical portion of the point electrode boundary.

---

[6] This procedure is illustrated for polynomial representations by Crout, J. Math. and Phys. 19, 34 (1940), with general ideas contained in Sections 4A, C, E, F, 5, and 8C. The present representation of the charge distribution is made to simplify the integration and admit a semi-infinite range of (z).

TABLE I. Values of $V(r, z; a)$ from Eq. (4).

According to Eqs. (2) and (7), $V_{nc}(0; a)$ and $P_{nc}(0)$ are needed. $V(r, z; a) \rightarrow V(c; a)$ and $P(r, z) \rightarrow P(c)$ by $r = \sin c$ and $z = (161 - \cos c)$, whence, after some calculation,

$$\left.\begin{aligned} V_{2c}(0; a) &= M(-0.5[(a-160)^{-2}-(a+160)^{-2}] \\ &\qquad +[(a-160)^{-1}+(a+160)^{-1}]), \\ V_{4c}(0; a) &= M(+2.25[(a-160)^{-4}-(a+160)^{-4}] \\ &\qquad -6[(a-160)^{-3}+(a+160)^{-3}] \\ &\qquad +5[(a-160)^{-2}-(a+160)^{-2}] \\ &\qquad -[(a-160)^{-1}+(a+160)^{-1}]), \\ &\text{etc., where} \\ M &= \log_{10}e = 0.43429\cdots, \end{aligned}\right\} \quad (8)$$

and

$$\left.\begin{aligned} P_{2c}(0) &= -[(161-160)^{-3}-(161+160)^{-3}] \\ &\qquad +[(161-160)^{-2}+(161+160)^{-2}], \\ P_{4c}(0) &= +9[(161-160)^{-5}-(161+160)^{-5}] \\ &\qquad -18[(161-160)^{-4}+(161+160)^{-4}] \\ &\qquad +10[(161-160)^{-3}-(161+160)^{-3}] \\ &\qquad -[(161-160)^{-2}+(161+160)^{-2}], \end{aligned}\right\} \quad (9)$$

etc.

The set of equations in A_p and A_a obtained from Eqs. (2), and (5)–(7) is

$$\left.\begin{aligned} & A_pP(0, 160)+\sum_a A_aV(0, 160; a)=1 \\ & A_pP(1, z_i)+\sum_a A_aV(1, z_i; a)=1, \quad z_i \geq 161 \\ & A_pP_{nc}(0)+\sum_a A_aV_{nc}(0; a)=0, \\ & \qquad\qquad n=2, 4, \cdots. \end{aligned}\right\} \quad (10)$$

Values of $V(r, z; a)$, $P(r, z)$, $V_{nc}(0; a)$, and $P_{nc}(0)$ as calculated, respectively, from Eqs. (4), (3), (8), and (9) for various values of (r, z) and $(z = a)$ and for $n = 2$ and 4 are listed, respectively, in Tables I–IV. A solution for A_p and A_a obtained by substituting any of these values into Eqs. (10) establishes an expression for $\Phi(r, z)$ by Eqs. (2)–(4) which is compatible with the conditions used, and the axial field intensity factor of Eq. (1) is then

$$\left.\begin{aligned} E_z &= d\Phi(0, z)/dz \\ &= A_p[(161-z)^{-2}+(161+z)^{-2}] \\ &\qquad +\sum_a A_a[2Ma/(a^2-z^2)]. \end{aligned}\right\} \quad (11)$$

An examination of various solutions indicates that the resulting unit equipotential surface fits the point electrode boundary best with one of the arbitrary values $(z = a)$ somewhere between two successive values of z_i with the remaining values of $(z = a)$ close to $(z = 161)$, a variation in the exact values of $(z = a)$ varying E_z by only about ±0.2 percent. Increasing n from 2 to 4 for a given set of z_i varies E_z by only about 0.02 percent, and n greater than 4 are not used.

The solution of Eqs. (10) for the conditions $n = 2$ and 4; $z_i = 161$, 162, 165, 175, and 200; and $a = 161$, 161.1, 161.2, 161.5, 162, 170, and 185 is listed in Table V, column 1, along with the resulting axial field intensity factor at the point surface, E_{160}. Adding $z_i = 300$ and $a = 250$ yields the solution listed in Table V, column 2.

Beyond the last value of z_i used, the resulting unit equipotential surface diverges from the cylindrical boundary due to the axial charge distribution remaining constant beyond the last value $(z = a)$ used, and the resulting axial field intensity factor will be too small. Table V, columns 1 and 2, show how using larger values of z_i increases the resulting axial field intensity factor. An examination of various solutions indicates that one might obtain E_z quite accurately by adding about two more values of z_i and a, extending the conditions to the region of $(z_i \approx 600)$. But since the solution of Eqs. (10) becomes increasingly difficult with additional values of z_i and a, the following approximation is made:

Adding the condition that the axial charge distribution is to be zero beyond an additional value of $(z = a)$ modifies any solution so that the resulting unit equipotential surface converges within the cylindrical boundary beyond the last value of z_i used, and the resulting axial field intensity factor will be too large. In this manner the solutions listed in Table V, columns 1

and 2, become, respectively, those listed in columns 3 and 4.

The solutions listed in Table V, columns 2 and 4, establish fields which provide limits for the true potential and field intensity values, which are represented approximately by the intersection of the linear extrapolations of the values established by these four solutions. For example,

$$E_{160}\approx\frac{0.59788(0.66869-0.63371)+0.63371(0.59788-0.58875)}{(0.59788-0.58875)+(0.66869-0.63371)}=0.60530.$$

Values of E_z and $\Phi(0, z)$ obtained in this way for various values* of (z) are listed in Table VI.

The unit equipotential surfaces resulting from the solutions listed in Table V fit the boundary to within about 0.02 unit up to the last point of coincidence, which is comparable to usual fabrication tolerances for laboratory scale electrodes. The major source of error is the deviation from the boundary at large distances from the point. The results of the solution listed in Table V, column 2, are probably accurate to within two percent (field intensity values too small, potential values too large), and the approximations listed in Table VI are probably accurate to within ±1 percent. Further accuracy is not obtained here since in practice the field may vary somewhat from that of the isolated infinite plane and semi-infinite point electrode system.

A check on the reliability of the result comes from an evaluation of the Townsend integral for the appearance of the positive burst pulse corona in room air at atmospheric pressure and temperature 22°C, with the relative humidity about 50 percent. Measurements were made for this purpose by W. N. English and give the data for the threshold of pre-onset burst pulses and streamers for the nine different confocal paraboloid combinations shown in Table VII. For hemispherically capped cylindrical points of 0.0125, 0.025, and 0.050 cm radius and gap lengths of 2, 4, and 8 cm to the plane, the pre-onset burst pulse threshold observed by H. W. Bandel under the same conditions were 3540, 5280, and 7910 volts, respectively. The theory of Loeb[7] for the threshold of pre-onset burst pulses leads to the relation of $\beta f \exp\int_{a+r}^{r}\alpha dx=1$. Here f is the fraction of the avalanche electrons which collide to give photons capable of photo-ionizing the gas before they enter the anode point. The quantity β is a geometrical factor which gives the fraction of these photons that are absorbed beyond a region of radius at $r+a$ that will produce avalanches equal in magnitude to the first one and so sustain the burst pulse. In gaps as similar as those

studied, βf should be nearly constant so that the threshold set by $\beta f \exp\int \alpha dx = 1$ should yield sensibly the same value of $\int \alpha dx$ for the three paraboloids and the capped cylinder if the theory is correct. Calculating the field as a function of distance x from the expression

$$E_x = \frac{V}{\log_e(f/F)} \frac{1}{x+f}$$

for the confocal paraboloids with focal lengths f and F for the small and large paraboloids used, respectively, and for the point-to-plane by Table VI, it is possible to evaluate Townsend's α as a function of x from the data of Sanders.[8] Plotting α as a function of distance x, $\int_{a+r}^{r} \alpha dx$ can be evaluated by graphical integration or numerical quadrature. Combinations of focal lengths $f = 0.009$ cm, 0.019 cm, and 0.028 cm, with $F = 1.1$ cm, 3 cm, and 5 cm, showed that as theory demands, E_x is independent of F but varies critically with f. The values of the integral obtained were 11.3, 10.4, and 10.0 for focal lengths $f = 0.009$, 0.019, and 0.028 cm, respectively, while the point-to-plane data gave 10.2, 10.3, and 9.1, respectively. It will be noted that the paraboloid and point-to-plane integrals are in relatively good agreement. The agreement is the more remarkable because of the extreme sensitivity of the integral to the shape of the potential curve. Thus one can have some confidence in the accuracy of the point-to-plane field calculations. The collective results yield an average value of the integral of 10.2 so that the avalanche consists of 2.7×10^4 ions. This makes $\beta f = 3.7 \times 10^{-5}$. It will be noted that the integrals seem higher for the smaller radii or focal lengths. In some measure, this may be accidental and not a real variation, since aside from uncertainties in measuring thresholds which may be in the order of two or three percent, the accurate shaping of small points and measurements of radii on these is not easy, even under the microscope. It is also possible that the low values for the larger points may follow from inadequate lengths of the point and plate diameter or paraboloid depths and thus from improper dimensioning of the apparatus. Dodd observed a strong influence of the shank of the point in his calculations of point-to-plane. If this is correct, care must be exercised in future measurements with points of 0.05 cm radius or larger to insure proper point length as well as plate radius. This effect of point length was not investigated experimentally. If Dodd's inferences are correct, it may make use of the smaller point radii desirable under most conditions, since the larger point radii may require inconveniently large chambers.

TABLE VII. f in cm.

		0.009		0.019		0.028

The values of the potentials and fields marking the burst pulse threshold as given here, and hence the values of the $\int \alpha dx$ here given, are at variance with the values reported by Fitzsimmons[4] for pre-onset burst pulses using the same paraboloids and air of the same character. Fitzsimmons reports the appearance of what *he calls burst pulses* at potentials about half those given here, even for dry air. For moist air, he got values still 20 percent lower. The values of $\exp\int \alpha dx$ in those cases corresponded to 4.46 and 1.86 for a 0.009-cm point. It is clear that such small avalanches could not possibly have been creating self-perpetuating pre-onset burst pulses. Observed on the oscilloscope were *pulses* of some amplitude and it is unlikely that avalanches of five electrons could trigger the observed pulses. The only explanation is that in the large volume available, Fitzsimmons must have used such a strong source of triggering ionization (10 μg of $RaBr_2$ at 3 cm) that he observed pulses caused by the statistical fluctuations of many unresolved avalanches of the magnitude observed. This conclusion is justified in the light of the present work in that Fitzsimmons observed pre-onset *streamers* to begin at values of the potentials yielding $\int \alpha dx$ of around 11 to 12.6. Since, as seen from Table VII, pre-onset streamer thresholds occur at potentials about three percent above burst pulse onset, this would place the values of $\int \alpha dx$ for Fitzsimmons' real burst pulses very close to the values computed from English's data. Thus, Fitzsimmons' results are really in relatively satisfactory agreement with those of English.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

Coincidence Experiments for Noise Reduction in Scintillation Counting

HARTMUT KALLMANN* AND CARL A. ACCARDO
Signal Corps Engineering Laboratories, Fort Monmouth, New Jersey

(Received August 1, 1949)

A method is described which permits discrimination between noise pulses and pulses of small light flashes. The arrangement consists of three multipliers facing the three faces of one and the same crystal. One multiplier acts on the "Y" axis, another on the X axis and the third one on the Z (intensity) axis of an oscilloscope. Light flashes induce pulses in all multipliers simultaneously, whereas noise-pulses occur at random and produce triple-coincidence pulses only very rarely. Triple coincidences are easily recorded with the scope. Pictures are presented illustrating the operation of the arrangement. The original noise being of the order of three thousand per second was dropped to one noise pulse in three seconds.

THE main difficulty in scintillation work is that when light flashes of small intensity are recorded, the counting rate is limited by the number of noise pulses of comparable size occurring in the multiplier tube itself. These pulses are caused by single electrons released from the photo-cathode by thermal collisions; their multiplication in the tube creates a pulse. It has been found by Morton and Mitchell[1] that these single electron pulses are not of equal size but exhibit a whole distribution of pulse sizes. Thus, it may occur that pulses produced by a single electron are even ten times larger than the average pulse size produced by single electrons. On the other hand, a pulse induced by the simultaneous emission of ten electrons from the photo-cathode by a light flash undergoes fluctuations, and it may be that its actual pulse height is considerably less than its medium pulse height; therefore, even pulses originating in the simultaneous emission of several electrons cannot be distinguished with certainty from noise pulses.

I. DISCRIMINATION BETWEEN NOISE PULSES AND LIGHT FLASHES

In this paper, two methods are described which make it possible to distinguish between noise pulses and pulses produced by light flashes from a crystal. For this purpose a crystal was used which emitted its light to three multipliers simultaneously as illustrated in Fig. 1. The faces of the crystal are chosen so that all light proceeding from them can geometrically enter the multiplier window. The multipliers of Type 931A are operated as shown in Fig. 1. One multiplier, called the "Y" multiplier, is connected to the Y axis of the scope and causes deflections of the cathode-ray beam in this direction. The second, the X multiplier, is connected to the X axis of the scope and causes deflections in this direction. This deflection may be produced by the pulse itself which is directly fed into the X plates through an amplifier; then the X deflections are proportional to the pulse intensity (arrangement B) or the pulse may be used to trigger a sweep in this direction giving deflections independent of the pulse intensity (arrangement A). The third, the Z multiplier, is connected to the Z axis amplifier of the scope and regulates the cathode-ray beam intensity according to the size of its pulses.

The cathode-ray beam operates simultaneously in all three directions only if all three multipliers produce a pulse at the same time and only then a deflection of the beam in the Y direction is to be seen when using method A. Noise pulses occurring in the multipliers are entirely distributed at random and are independent of each other. If the duration of a pulse is given by τ, and if the number of noise pulses per second is described by n, the probability of noise pulses occurring in two multipliers simultaneously is given by $n\tau$ and that of noise pulses coinciding in all three multipliers is given by $(n\tau)^2$.

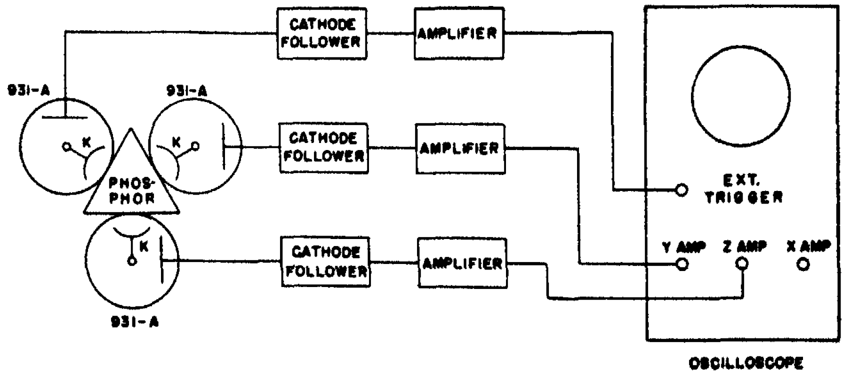

FIG. 1.

[1] G. A. Morton and J. A. Mitchell, Nucleonics 4, 16 (1949).

FIG. 2. 1/100 sec. exposure of noise pulses from a single photomultiplier.

From this it follows that the number of accidental triple coincidences or the number of events caused by noise pulses in which all three multipliers operate simultaneously is given by $n\cdot(n\tau)^2$, with $n\tau$ sufficiently small, as is usually the case. The number of triple coincidences caused by noise pulses is therefore much smaller than the noise number in one single tube.

If, however, some exterior radiation induces a light flash in the crystal this will induce pulses in all multipliers at the same time, therefore the number of light flashes counted is not reduced by this device. By this method light flashes of small intensity proceeding from the crystal can easily be counted even if noise pulses are much more frequent than the light flashes. With a pulse duration of 10^{-6} second and a noise number of 1000 per second, the number of counted noise pulses is reduced by a factor of 10^{-6}. This means that only after 1000 seconds one accidental triple coincidence occurs in the device. Exterior radiation with such a small counting rate could be detected by this device.

II. EXPERIMENTAL RESULTS

Experiments were carried through according to arrangements A and B and with a small stilbene crystal operating on all three multipliers. The crystal was not very transparent but exhibited considerable light scattering, therefore, the light flashes excited within the crystal did not emit equal light intensities to all multipliers, nevertheless, the pulses of gamma-photons were always indicated by the operation of all three multipliers. Gamma-intensities which were difficult to detect with one multiplier tube since they were covered by noise pulses were easily detected with this triple coincidence arrangement. The counting of pulses was performed photographically.

A. Recording of γ-Pulses in Arrangement A

With arrangement A, the fluorescent screen of the scope was shielded and only a small strip of the screen parallel to the Y axis was visible, on which the pulses produced by light flashes occur. The film was made to run continuously parallel to the X axis. The oscilloscope used had a frequency limit of about 0.5 microsecond and a sweep duration of 5 microseconds. According to these limits the duration of the pulses was chosen of the order of half a microsecond. If, for instance, a light flash starts a sweep, a deflection of the cathode-ray beam is seen half a microsecond after the beginning of the sweep since the Y pulses were delayed by half a microsecond to make them appear fully on the scope. With a high noise rate it is possible that an accidental noise coincidence in the Y and Z multiplier will occur during the 5 microsecond duration of a sweep started by a light flash or a noise pulse in the X multiplier. Such an accidental coincidence pulse in the Y and Z multiplier is registered on the scope by a visible deflection of the cathode-ray beam, however, this deflection does not generally occur at the same position on the scope as the gamma-pulses but appears on another position since they are randomly distributed over this time interval. These pulses were canceled by the described shielding of the scope.

To begin with the noise pulses of the tube were counted by connecting one multiplier to all three axis and were found to be of the order of 3000 per second. Then this arrangement was adjusted in such a way that all pulses excited by light photons were also recorded. Figure 2 describes a "still picture" of these noise pulses with an exposure time of 1/100 of a sec. Numerous small pulses are hidden by the strong intensity at small deflections. Figure 3 demonstrates a similar experiment with an additional exterior gamma-radiation of about 10,000 absorbed quanta per minute. On the other hand Figs. 4 and 5 show still pictures with the triple coincidence arrangement A with an exposure time of $\frac{1}{10}$ of a second. Figure 4, without exterior radiation, is blank since the noise counting rate with the triple coincidence arrangement is very low. Figure 5 shows pulses induced by exterior gamma-radiation.

Visual counting and counting with a running film

FIG. 3. 1/100 sec. exposure of a single photomultiplier with a gamma-source.

FIG. 4. 1/10 exposure (without a gamma-source) (using the triple coincidence method A) (noise pulses not observable).

showed one noise pulse every 4 or 5 seconds. With a pulse duration of a microsecond and with 3000 noise pulses per second one triple coincidence would have been expected every 25 seconds according to the above described equations. The difference between the observed number of accidental triple coincidence and the calculated one may be due to a difference in the number of noise pulses occurring in the different multipliers. Besides this, the width of the visible strip on the scope was a little wider than the width of the pulses, as can be seen in Figs. 2, 3, and 5. As a result such accidental coincidences could also be seen or recorded which occurred during a time duration somewhat longer than that of the actual pulse. A part of the coincidences observed without exterior gamma-radiation are undoubtedly real light flashes from the crystal caused by contamination of the counting chamber or by cosmic-radiation particles. If the triggering of the beam intensity was switched off and if the cathode-ray beam intensity turned on so high that the beam could be permanently seen, 50 pulses per second were approximately counted. These were accidentally occurring noise pulse coincidences in the X and Y circuits.

B. Recording with Arrangement B

The investigations according to method B are described in Figs. 6 through 10. Figures 6 and 7 check the experimental arrangement. They give a picture of the screen when only one multiplier was connected to all three axis. In Fig. 7 not only the pulses produced by the exterior radiation but also the noise pulses cause deflection of the cathode-ray beam. Since the amplifiers in the Y and X axis were adjusted to equal amplification the deflection of the pulse gives straight lines in the 45° direction, in these pictures each pulse is recorded by curves with two traces, a bright trace and one not quite so bright. These two curves occur from the rise and the decay of the pulse (the latter part the bright trace.) That they do not coincide is due to a small difference in the amplifiers used. In this picture, Fig. 6, again only noise pulses of larger intensity can be seen clearly, due to strong intensities of the cathode-beam traces at small deflections. Figure 7 describes a picture in which pulses of exterior radiation as well as noise pulses are seen. It is hard to distinguish between noise or light pulses as observed in Figs. 6 and 7.

Figure 8 describes a photographic picture with the same arrangement but with a pulse running over the Y axis delayed by half a microsecond. For this reason the pulse does not start in the 45° direction but starts from the X axis and then exhibits a sharp deflection in the Y direction corresponding to the sharp rise of the pulse, and then the pulse decays not in a 45° direction but in the direction the tangent of which is given by $e^{\Delta/\tau}$ where τ is the decay time of the pulses and Δ describes the time delay impressed on the Y axis. These curves show how easily coincidence or small time differences between pulses can be determined by this method.

Figures 9 and 10 describe the same operation with the triple coincidence arrangement B; in this case in all three directions different multipliers are operating. It is seen from the photographic pictures that the rise curve and the decay curve do not even nearly coincide in this case; this is due to the fact that the preamplifiers used for this work were not identical but exhibited a little difference in rise times. It is further noted that the decay curve is not represented by a straight line but by an inflected curve and the tangent of the angle of inclination varies along the curve. But it is found that the curves start from the same point; this means that there is no time delay between the X and Y pulses. The inflection of the curve is completely due to small difference in time constants of the multiplier and preamplifier circuits used. If this difference in time constants is given by Δ the tangent varies as $e^{-t/\Delta}$.

These pictures, Fig. 9 and Fig. 10, further indicate that the intensity ratio between the Y and the X pulses is not the same for different pulses but varies from pulse to pulse proving that the intensity of the light flashes proceeding from the crystal to the different multipliers is not the same. This intensity ratio can be determined by connecting the point of largest deflection with the origin. If the same pictures were taken without exterior radiation, they were again completely blank, all noise pulses were eliminated, since noise pulses coinciding in the Y and Z circuit or the X and Z circuit respectively

FIG. 5. 1/10 sec. exposure (with a gamma-source) (using the triple coincidence method A).

are generally deflected only in the Y or X direction but not under a definite angle between the Y and X axis. The method developed makes it possible to compare the light emission of a crystal through the different faces of this crystal.

III. CONCLUSIONS

These methods are not only operable with one single crystal but also with different crystals excited by the same radiation. In this case each multiplier is excited by a different crystal. The noise pulses are eliminated in the same ratio as previously described since only pulses are recorded in which all multipliers operate simultaneously. In this case not only three but a great number of crystals may be used and connected to the Y axis over delay lines with different time delay. Using arrangement A all these multipliers excite deflection in the Y direction which are seen on the screen with different fixed distances on the driven sweep. In this way one photographic picture of the light emission of different crystals energized, for instance, by one event of cosmic radiation can be taken. A similar arrangement can be used for many crystals in case of arrangement B; the pulses of different crystals are then fed to the plus and minus Y and plus and minus X axis with equal time delays. In this way the light flashes proceeding from nine crystals can be recorded simultaneously on one picture.

The limit of this method is given by the intensity of the light which hits the photo-cathode of the different multipliers. If the light intensity hitting the photo-cathodes from one light flash is so small that each light flash does not release one electron, then the number of counted light flashes will decrease. Only when the light flashes release at an average at least one electron is there no decrease in the number of counted light flashes. If the probability that one light flash releases one electron is given by P and if this number is smaller than one, then the number of counted light flashes is diminished by a factor of P^2. Nevertheless, this method of triple coincidence will be advantageous as long as the factor P which diminishes the number of counted light flashes is larger than the factor $n\tau$ which diminishes the number of noise pulses.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

Note on the Detection of Coincidences and Short Time Intervals

ROBERT HOFSTADTER AND JOHN A. MCINTYRE*
Palmer Physical Laboratory, Princeton University, Princeton, New Jersey

(Received August 1, 1949)

A flexible method of detecting coincidences and short time intervals has been devised in which a photo-multiplier tube views the screen of a cathode-ray tube. By using one pulse as initiator of a sweep and the other in vertical presentation, coincidences can be observed in a fixed portion of the screen while the remainder of the screen is masked off. In present use the method is limited only by the pulses available (5×10^{-9} sec.). The method appears to be capable of extension to time intervals of the order of 9×10^{-10} second or smaller.

A METHOD has been briefly reported by which coincidences in the Compton effect have been studied both visually and photographically on the screen of a cathode-ray oscilloscope.[1] The purpose of this note is to describe how this method can be extended to resolving times of the order of 10^{-9} or 10^{-10} second and otherwise improved by employing a photo-multiplier tube to view the screen of the cathode-ray tube.

The new method for detecting and counting coincidences is described below where we shall make reference to the schematic drawing of Fig. 1.

Pulse I of the coincidence pair is used to trigger the sweep and intensifier gate of the oscilloscope.[2] Pulse II is delayed by a coaxial line B, amplified and brought to the vertical plates of the cathode-ray tube. A mask, having the shape shown in Fig. 1, cuts from view the horizontal sweep trace. Therefore only a vertical pip, appearing in the unobstructed portion C of the mask, illuminates the visible portion of the cathode-ray screen. A camera lens throws a real image of the pip on the window of "viewing" photo-multiplier tube A, which is placed behind an opening in a small light tight box D. This photo-multiplier observes a light pulse only when both a triggered sweep and a vertical pulse are correlated together in time so that the pip appears in region C of the screen. If the length of the delay line B is adjusted to match the time lag required for the triggered sweep to start and run the spot to the region C, each light pulse observed by photo-multiplier A corresponds to a true coincidence. It can be seen that (a) the horizontal position of the vertical pulse will, in general, be correlated with its delay (±) with respect to the triggering pulse and (b) the width of region C determines the resolving time of the coincidence method.

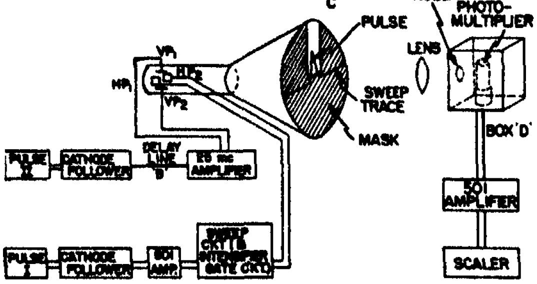

FIG. 1. Schematic diagram for detecting coincidences.

Any pulse II, regardless of shape, which fills the entire width of the open space of the mask above its lower edge, is associated with the same production of light on the screen. Therefore the photo-multiplier light pulse is constant and independent of pulse shape. It is implied that the upper part of the trace does not escape beyond the photo-multiplier's field of view and that the normal statistical spread of photo-multiplier pulse size is small. Both conditions are readily met in practice.

Table I lists typical operating conditions which we have used in detecting coincidences by this method. The coincidence pair has been: I—Compton scattered photon, II—Compton recoil electron pulses in separate luminescent stilbene crystals.[1]

From Table I it may be seen that the method offers the following advantages: (a) The allowable range of pulse sizes is very large for either pulse I or II. (b) The output pulse is constant. (c) The resolving time may be made quite small. (d) One large pulse by itself cannot possibly produce a (spurious) coincidence. We have been unable to employ a coincidence scheme offering an equivalent performance. In recent work we have detected triple coincidences by employing the third pulse as a trigger for the intensifier grid of the oscilloscope tube, as in the accompanying paper by Kallmann and Accardo.

With regard to point (a) the smallest pulse II we have detected above the masked-off-sweep is approximately as large as two line widths of the sweep, or somewhat less than $\frac{1}{16}$ inch. With better focus this figure can be made smaller. Since very large pulses II merely overload the amplifier there is no upper limit to the pulse size. Similarly the only limitation on pulse size I is that it be not so large that it produces two sweeps. In our experience this behavior does not occur. The lower limit of pulse size I is determined by somewhat less than the noise of the pulse source, amplifier, or trigger circuit. Items 12, 13, 14 of Table I show that considerable noise may be associated with pulse I and yet be discriminated against. Smaller resolving times will, of course, aid in cases where the noise pulses are more numerous.

[2] The general methods of high speed electronics are described by W. C. Elmore, Nucleonics Vol. 2, No. 4, 43 (1948).

Referring to item 10 of Table I, we have made a simple test to see how small the resolving time may be made with our relatively crude equipment. The open space C of the mask was made 1 mm wide; we have observed that photo-multiplier A pulse size is still 3.5 times larger than the pulses due to background illumination in the cathode-ray tube. This background is produced partially by tube filament glow and partially by scattered light due to fluctuations in phosphorescent screen glow produced by the large number of noise-triggered sweeps. The background is not the noise of photo-multiplier A, although such noise will provide the fundamental limit of resolving time of this method. Cooling of the photo-multiplier will help to remove this limitation. Using the given sweep speed, 1 mm corresponds to 3.2×10^{-9} second. The slit width may therefore be made at least 3.5 times smaller than 1 mm, or the sweep speed increased by the same factor, so that the resolving time can be made 9×10^{-10} sec. or smaller. Success in eventually employing this method for such small time intervals obviously depends on obtaining pulses of correspondingly small durations and on the accuracy, or lack of "jitter," with which all sweeps are initiated in time. The latter depends on the quality of the linear sweep generator and the triggering amplifier.

The useful resolving time of this method is affected to a small extent by the variable size of the trigger pulse. A small trigger pulse will start the sweep later than a large trigger pulse. Hence the vertical pip will appear in slightly different positions for small and large pulses. In order to avoid missing coincidences the slit should be opened up to accept such early and late pulses. In using a 501 amplifier to generate trigger pulses, the slit should be opened up to 0.1 microsecond to accept all pulses. A fast amplifier, of the type used to amplify pulse II, allows a smaller resolving time.

The ultimate resolving time of this method is probably considerably smaller than the figure given above. Several evident improvements on the method outlined are: placing the photo-multiplier directly at the screen; improvements in cathode-ray tube phosphor with respect to afterglow; obtaining a better focused spot, etc. It is conceivable that a secondary emitting surface might be placed within the cathode-ray tube. The fluorescent screen would then be unnecessary.

The repetition rate of coincidences is limited by the decay time of the phosphor of the oscilloscope screen. Although we have not examined this point in detail, the oscilloscope screen pulse appears to decay to a low value in two to three microseconds. Thus coincidence counting rates of the order of 50,000 per second appear to be possible with suitable phosphors.

A variation of the method given above may be used when it is desired to measure a small variable time interval. In this case several photo-multipliers would simultaneously view adjacent portions of the cathode-ray screen, or a single tube would be moved horizontally along the screen. In the former case each individual photo-multiplier would be associated with a given time delay.

TABLE I.

1. Pulses—Stilbene scintillation counters, 1P21 photo-multipliers; 25 megacycle (upper half-power point) amplifiers. Duration of pulses about 5×10^{-8} second; heights vary between limits of zero and 70 volts (the latter, amplifier overload).
2. Cathode-ray oscilloscope—"Laboratory Oscilloscope"[a]—5CP11A tube.
3. Electron gun accelerating voltage—900 volts.
4. Post acceleration voltage—3600 volts.
5. Sweep speed—0.08 microseconds per inch.
6. Vertical deflection sensitivity—40 volts per inch.
7. Screen—lens distance—16.5 cm.
8. Viewing lens—Biotar $f/1.4$.
9. Width of unobstructed region of screen has been varied between minimum of 1.0 mm and 50 mm corresponding to resolving times of 3.2×10^{-9} to 1.6×10^{-7} sec.
10. Smallest resolving time (see discussion)—9×10^{-10} second.
11. Smallest pulse II detected above blanked-out sweep line .... 2.5 volts.
12. Rate of random occurrence of pulse I as high as . . 1000 per sec. when using resolving time of 5×10^{-8} sec.
13. Rate of random occurrence of pulse II......... 2000 per sec. when using resolving time of 5×10^{-8} sec.
14. Rates of occurrence of true coincidences at various Compton scattering angles..................... 0.2 to 1.0 per second when using resolving time of 5×10^{-8} sec.

[a] V. Fitch and E. W. Titterton, Rev. Sci. Inst. 18, 821 (1947).

If there is a variation in triggering time, in other words if jitter is present, it is advantageous to portray the initiating pulse on the screen and register its position with one or more of the photo-multipliers. We have put both pulses I and II on the screen by bringing each to its own vertical plate. For example, the initiating pulse I is delayed by a fixed amount, amplified and finally brought to the lower vertical plate. The second, variable delayed, pulse II is delayed by a longer fixed time than I, amplified and brought to the upper vertical plate. Hence the initiating pulse I appears as a "down" trace at the left of the screen and the pulse II as an "up" trace at the right of the screen. A properly shaped mask to blank the sweep trace is employed in this method.

We may finally mention that large deflection sensitivities are possible in these methods since the electron beam of the tube need only be accelerated through a voltage drop sufficient to obtain good focus. The viewing photo-multiplier A requires a fluorescent screen pulse only as large as the light equivalent of a single beta-particle scintillation—which is quite small.

An account of a use of the coincidence method in an experimental test of the Klein-Nishina theory at 1.2 Mev has been published in *The Physical Review*.[3]

This work has been partially supported by the Joint Program of the ONR and AEC.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

A Large Dempster-Type Double-Focusing Mass Spectrograph*

HENRY E. DUCKWORTH
Scott Laboratory, Wesleyan University, Middletown, Connecticut

(Received August 1, 1949)

A description is given of a large Dempster-type double-focusing mass spectrograph. The dispersion of the instrument is 2.3 mm for one percent mass difference. The theoretical resolution for a 0.001-in. principal slit is 7000 and has been experimentally realized. The performance of the instrument is illustrated by a mass spectrum showing doublets formed by singly-charged Cu and Zn and triply-charged Pt.

INTRODUCTION

THE first double-focusing mass spectrographs,[1-3] which were completed in 1935 and 1936, were designed primarily for precision mass measurements. Since that time several other double-focusing mass spectrographs have been constructed.[4-11] Because of their velocity-focusing feature, such instruments are well suited for use with hetero-energetic ion sources. Some such sources, notably the "hot spark" type, possess unique advantages in analytical work (both isotopic and chemical), and consequently double-focusing instruments are powerful research tools in fields other than that of precision mass measurement. When plans were being made for the construction of mass spectroscopic equipment at Wesleyan University, a double-focusing design was chosen in order to secure the versatility which it offered. The completed instrument, which is a Dempster type, has been in operation for several months and it is felt that it possesses certain novel features which warrant a published description.

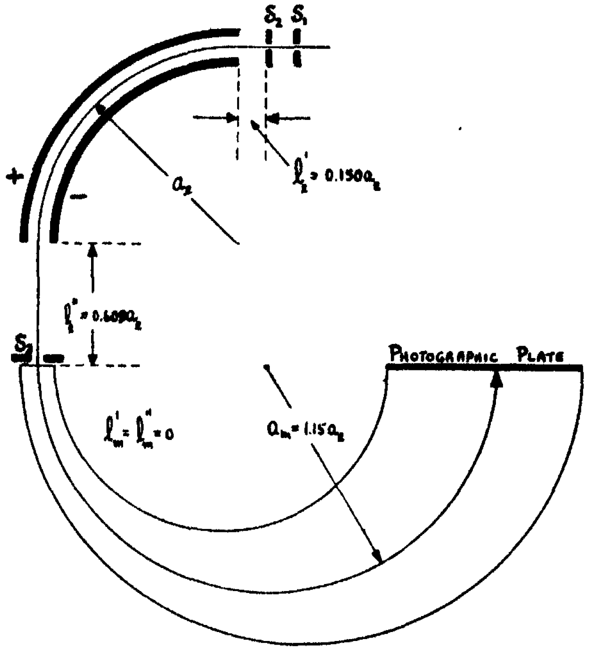

FIG. 1. The Dempster double-focusing arrangement. A $\pi/2$ radial electric field is followed by a π-homogeneous magnetic field.

GENERAL DESCRIPTION OF THE INSTRUMENT

The geometry of the instrument, shown in Fig. 1, follows Professor A. J. Dempster's well-known design.[1] The necessary theory has been worked out by Dempster and others.[12-15] The symbols in Fig. 1 are those employed by R. Herzog,[12] who first solved the problem of the focusing conditions for the general case of a steady electromagnetic field.

The mean radius of curvature of the $\pi/2$ electrostatic analyzer is 7.900 in. The principal slit, S_2, is located $0.150\times 7.900=1.185$ in. ($l_e'=0.150a_e$) in front of the effective boundary of the electric field. The image formed by the electrostatic analyzer is $0.609\times 7.900=4.811$ in. ($l_e''=0.609a_e$) beyond it, and is located at the effective boundary of the magnetic field ($l_m'=0$). For velocity-focusing, the radius of the path in the magnetic field is 9.1 in. The final image is formed at the exit boundary of the magnetic field ($l_m''=0$), at the lower surface of a photographic plate. The slit, S_3, located at the entrance to the magnetic field, allows only those ions, whose energies lie in a narrow range, to enter the magnetic analyzer.

The theoretical resolving power of the instrument, with a 0.001-in. principal slit, is calculated to be 7000. The dispersion, at the position where velocity-focusing obtains, is 2.3 mm for one percent mass difference. This position is located at the center of the 10-in. photographic plate. This plate is long enough to cover on a single exposure the mass spectrum from M to $2.6M$.

The completed instrument is shown in Fig. 2.

SOURCE AND SLIT SYSTEM

Positive ions are produced in a high frequency spark[16] between two electrodes. The spark is energized by a Tesla circuit of four megacycles frequency. In Fig. 3, which is a sketch of the source and slit region, one electrode is seen to be a rod, while the other is a cylinder inserted in a brass diaphragm. This combination of electrodes was suggested to the author by Professor Dempster. The diaphragm is positioned ⅛ in. away from the unit holding the slits by two ceramic insulators, ¼ in. in diameter and tapped at each end. These were obtained from the American Lava Corporation. The ⅛-in. space constitutes the acceleration region.

The rod electrode is adjusted and fed in by a combination bellows and Wilson[17] seal arrangement of the type described by Shaw and Rall.[9] This unit is waxed

to a male 55/50 standard taper providing a convenient ground joint to be opened when electrodes are to be changed. The ground joint, which is not vacuum-lapped, is made vacuum-tight with Celvacene Heavy, obtained from Distillation Products Incorporated. The joint is readily opened after gentle heating.

The unit holding the slits is removable to permit cleaning or adjustment. The slits are aligned by a method devised by Dr. A. E. Shaw of the Argonne National Laboratory. It is to be hoped that he will publish an account of his scheme. The distance between S_1 and S_2 is 1 cm, S_2 being the principal slit. The distance from S_2 to the front edge of the condenser plates is 1.248 in. This allows, as is Dempster's practice, for the effective electric field to extend $\frac{1}{16}$ in. beyond its physical boundary.

The slit system effectively isolates the source region from the analyzing region. This is highly desirable because of the amount of vapor released when the spark is operating. It, of course, requires that the source region be pumped separately.

THE ELECTROSTATIC ANALYZER

It is important that the curved condenser plates of the electrostatic analyzer be accurately parallel. In order to secure such parallelism, the roughed-out condenser plates were fastened in their final position before their inner surfaces were finished on a lathe. Figure 4 shows how the condenser plates are supported in their housing on ceramic insulators. These insulators, bought from the American Lava Corporation, are very uniform in size. It was possible to select a number, from among twice as many, which were interchangeable. The condenser plates were themselves made of soft iron in order to shield magnetically the ion path. The plates were nickel-plated before the final assembly.

The vacuum chamber, which houses the electrostatic analyzer, was made from a sheet of 2-in. brass. The fourth side is a close-fitting lid held in position by screws. Flanges were attached to each end of this chamber in the manner shown in Fig. 5, and the whole made vacuum-tight with Apiezon *W* wax. It is felt that the extra heavy condenser plates, vacuum chamber walls, and flanges have resulted in a precision which will be permanent.

Positive ions with charge e will acquire kinetic energy $\frac{1}{2}mv^2 = V_ae/300$ ergs in being accelerated by V_a volts. Passing into the electrostatic analyzer they will be subjected to a deflecting force $mv^2/r = Ee \doteq V_de/300b$ dynes, where V_d is the voltage across the curved con-

FIG. 6. Power supply and stabilizer for magnet current.

denser plates and b is the condenser spacing. From these one can obtain the proper ratio $V_a/V_d \doteq r/2b$. Since the condenser spacing is 0.200 in. and the mean radius is 7.900 in., the ratio $V_a/V_d \doteq 20$. In practice, when the positive ions are being accelerated by 12,000 volts, the appropriate electrostatic field is established by 550 volts, that is, the ratio V_a/V_d is experimentally 22. V_d is provided by B-batteries.

It has been found that the mass spectral lines are sharpest when the negative condenser plate is at ground potential, and they deteriorate steadily as ground is moved toward the positive plate. It is necessary to shield completely the leads to the electrostatic analyzer from the Tesla radiation.

THE MAGNETIC ANALYZER

Two pole pieces, contoured to provide a field of the shape shown in Fig. 1, are held ⅛ in. apart by a brass spacing ring and cover. These pieces, bolted and waxed together, constitute the vacuum chamber of the magnetic analyzer. This unit fits into a 3-in. gap in the large electromagnet, as can be seen in Fig. 2. The brass cover houses a Shaw and Rall[9] mechanism whereby the photographic plate can be moved laterally to allow seven exposures. The motion is got by a rack and pinion action, the rotation of the pinion being accomplished through a Wilson seal.

The magnet is made of Armco iron and has pole faces, before the insertion of the vacuum unit, 18 in.×9½ in. It is excited by approximately 220,000 turns of No. 26 heavy Formvar wire, wound on six coils by the Gramer Company of Chicago, each coil having 8500 ohms resistance. The six coils are connected in parallel and are supplied with current from the power supply and stabilizer shown in Fig. 6. A current of 100 ma establishes, in the ⅛-in. gap, a field of 12,000 oersteds, while a current of 500 ma establishes a field of 17,500 oersteds.

The circuit shown in Fig. 6 provides steady magnet current. T_6, shown in the diagram as a single tube, actually represents four 2A3's, connected identically in

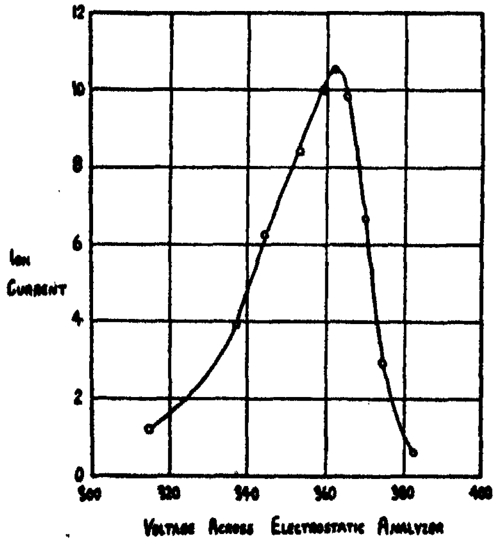

FIG. 7. Ion current emerging from the electrostatic analyzer as the voltage across the electrostatic analyzer is varied. The accelerating voltage has been kept constant.

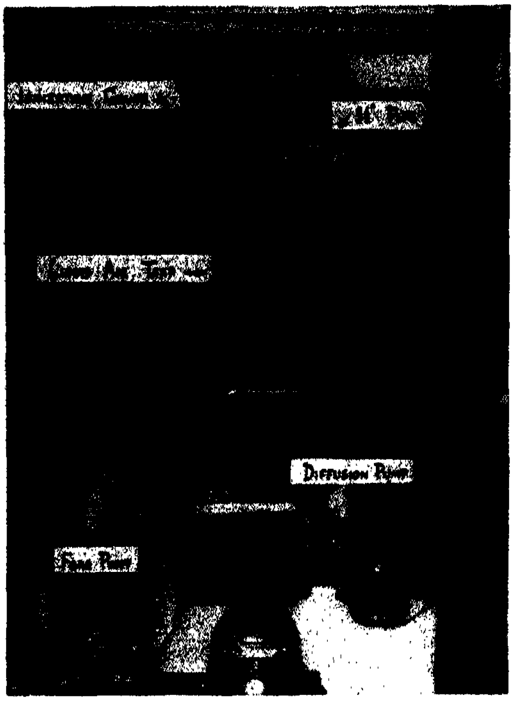

FIG. 8. View showing the vacuum system for the analyzer region. The trap is described in the text.

parallel. The 0–500 voltmeter, M_2, measures the plate voltage of these current carrying tubes. The circuit regulates when this voltage is between 60 and 140 volts. The milliammeter, M_1, measures the current through the reference resistor, R_8, which is also the magnet current. R_8 is a large wattage, low temperature drift, variable resistor. The stability of the magnet current is undoubtedly aided by the large inductance of the magnet coils, which suppresses short time fluctuations. The time constant of the magnet coils is about seven seconds.

ACCELERATING VOLTAGE

Accelerating voltage is got from a 0–40,000 V.D.C. power pack, style No. FW-D, bought from the Moss X-Ray Company of Chicago. The half-wave rectified d.c. is filtered with a 40-megohm resistor shunted by 2.25 microfarads of capacity. The high voltage lead to the source contains a 100-megohm resistor which renders the voltage relatively innocuous.

Figure 7 is a curve showing the ion current emerging from the electrostatic analyzer as the voltage across the electrostatic analyzer is varied. While the data for this curve were being obtained, the principal slit was 0.004 in. and S_3 was replaced by a collector $\frac{1}{4}$ in. wide. It can be seen that although the ratio V_a/V_d is not very critical, intensity can be gained by working with the proper value. In order to stay on the peak of this curve it has been necessary to insert a constant voltage transformer between the high voltage power pack and the a.c. line. Figure 7 shows clearly the energy spread

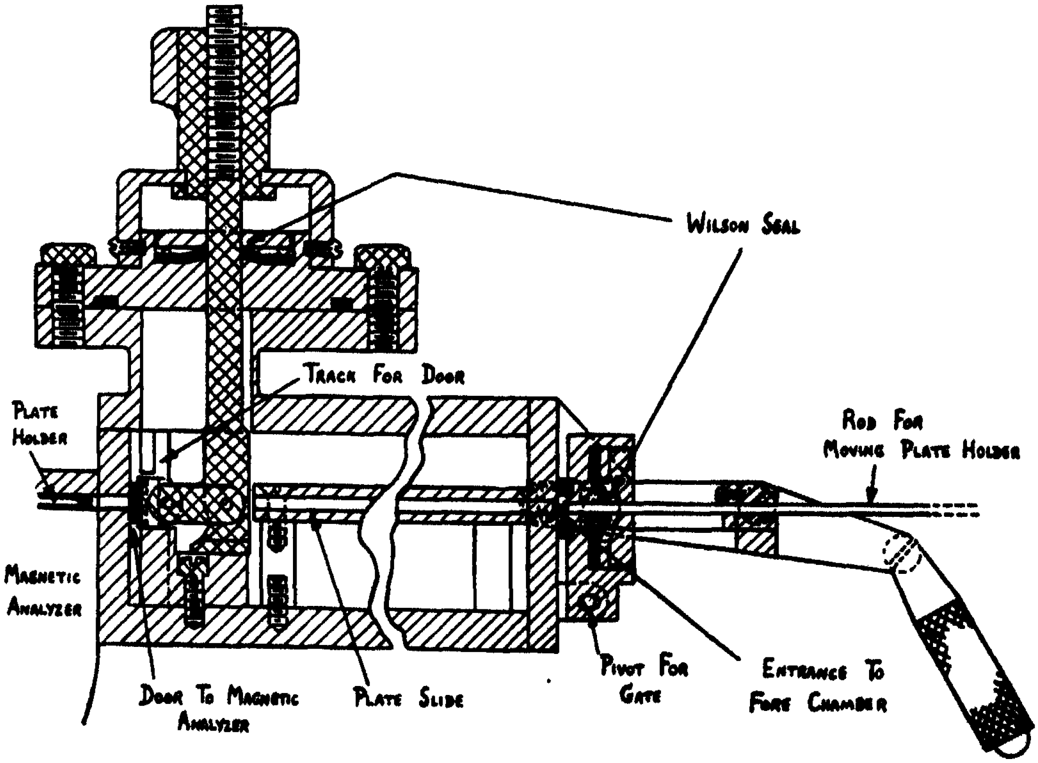

FIG. 9. Diagram of the fore chamber which permits insertion and removal of photographic plates without destroying the vacuum.

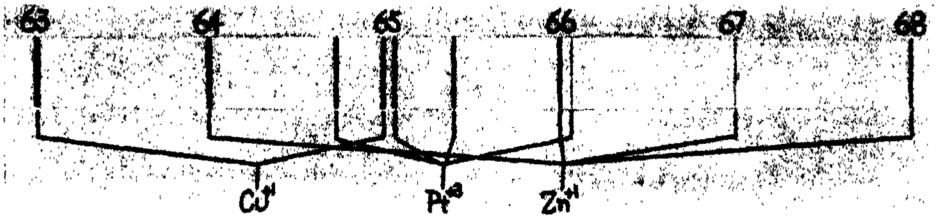

FIG. 10. Doublets formed, at mass numbers 65 and 66, by singly-charged copper and zinc and triply-charged platinum. Magnification 6×.

existing among the ions from the spark source. When ions from the spark have been allowed to enter the magnetic analyzer without first traversing the electrostatic analyzer, the resulting mass spectrum has possessed very broad and poorly defined lines.

VACUUM SYSTEM

As mentioned earlier, the source region is pumped independently of the analyzing region, the slits defining the boundary. The source is pumped by a Distillation Products VMF-10 oil diffusion pump while the analyzing region is evacuated by a Distillation Products MC-275 oil diffusion pump. Both pumps are backed by Welch Duo-Seal, Type 1405H, mechanical pumps. The recommended diffusion pump oil has been replaced with silicone pumping fluid DC 703, obtained from the Dow Corning Corporation, with splendid results. Several accidental and intentional exposures of the hot silicone to atmospheric pressure have apparently not lowered its pumping efficiency, or caused it to "crack."

In both systems liquid air traps have been inserted. These traps are simple in design and appear to be well suited for use with metal systems. As can be seen in Fig. 8, which pictures the pumping system for the analyzers, a standard sweat-fitting *T* is slotted anglewise across the throat, and a metal baffle, which extends well below the bottom end of the *T*, fitted and soldered into the slot. A glass test tube of the appropriate size, in this case $3\frac{5}{8}$ in. in diameter, is waxed into the open end of the *T*, with the metal baffle extending almost to the bottom. The glass end, which fits up into the *T*, is protected from abrasion by a cushioning lead gasket. The design offers a large pumping cross section and permits easy removal of the traps for cleaning.

Exposures are normally taken with a pressure in the analyzers of about 5×10^{-6} mm as measured with an ionization gauge. Prolonged pumping has reduced the pressure to less than 10^{-6} mm. During exposures the pressure in the source region may exceed 10^{-4} mm.

FORE CHAMBER

Figure 9 shows the scheme of the fore chamber, which permits insertion and removal of photographic plates without breaking the vacuum. When it is to be opened, the door between the fore chamber and the magnetic analyzer is raised by a rod sliding through a Wilson seal. The door is held in tracks during the raising by vertical ridges on front and back edges. When the rod is screwed down, the rubber gasket on the face of the door is firmly compressed. The plate holder is meanwhile inserted or removed by the rod which screws into the end of it. The fore chamber is evacuated, using an appropriate system of stop-cocks, by the fore pump which pumps the source end. Immediately after a plate has been inserted, the pressure in the analyzing region has been found to be 2×10^{-5} and rapidly dropping.

PERFORMANCE

With a principal slit, S_2, of width 0.001 in., and S_1 about three times as wide, the measured resolution for faint lines, in the position of sharpest focus, equals the theoretical value of 7000. Since this resolution is more than adequate for the mass comparisons which are currently being made, no attempt has been made to reduce the size of the principal slit. Figure 10 shows two typical doublets formed by singly-charged copper and zinc and triply-charged platinum. For this exposure the slit S_3, between the electrostatic and magnetic analyzer, was set at 0.75 mm. The exposure time was about fifteen minutes.

With S_1 and S_2 both equal to 0.004 in. and $S_3=2.0$ mm, mass spectra of the abundant isotopes of most elements can be got with exposures of a second or less. Ilford Q II plates have been used almost entirely.

ACKNOWLEDGMENTS

The author is grateful to Professor A. J. Dempster for his frequent advice on matters pertaining to mass spectroscopy and for many ideas which the author has unconsciously absorbed during visits to his laboratory. He also appreciates several helpful conversations with Dr. A. E. Shaw of the Argonne National Laboratory.

Thanks are due to the author's senior colleagues, Professor Karl S. Van Dyke and Professor Vernet E. Eaton, for their interest and encouragement during the construction of the instrument. Much help has been given by Benjamin G. Hogg, Robert F. Black, Richard F. Woodcock, Richard S. Preston, Howard A. Johnson, Bertram A. Calhoun, John S. Handloser, and Donald R. Little. Mr. Clifford Gieselbreth, toolmaker, has been responsible for much of the design and construction.

Most of the cost of construction was met by a special grant from the Board of Trustees of Wesleyan University. This grant is gratefully acknowledged. Also, the current support of the AEC is appreciated.

A Diaphragm Cell for Thermal Diffusion Measurements

E. S. Huse, D. J. Trevoy, and H. G. Drickamer
Department of Chemistry, University of Illinois, Urbana, Illinois

(Received August 19, 1949)

A diaphragm cell for thermal diffusion using a fritted glass disk like those used for ordinary diffusion is described. The results obtained are consistent with those obtained for other cells, and the operation of this cell is simpler and shorter than for most other methods.

NOMENCLATURE

ΔN = Normality HCl cold side minus normality HCl hot side.

$100\Delta n$ = (mole fraction benzene cold side minus mole fraction benzene hot side) × 100.

$$q=\left[\frac{\text{mole fraction hot side}}{\text{mole fraction cold side}}\right]_{\text{light component}}\times\left[\frac{\text{mole fraction cold side}}{\text{mole fraction hot side}}\right]_{\text{heavy component}}.$$

T_h = temperature of hot side.

T_c = temperature of cold side.

α = thermal diffusion ratio defined by $1_nq=\alpha 1_n(T_h/T_c)$. The sign of α was arbitrarily determined so that it was positive if the heavy component concentrated on the cold side.

A GLASS diaphragm cell for measuring thermal diffusion in liquids (the pure Soret effect) has been developed. The cell is modeled after the diaphragm cells commonly in use in ordinary diffusion experiments. The device is shown in Fig. 1. The cell is mounted in the wall between the hot and cold baths as shown in Fig. 2. The magnets proved to have considerable effect on each other during operation, therefore the pulley belt was lapped so that the magnets in rotating would always remain in phase. Temperature profiles were measured throughout the cell and over the surface of the disk both with and without stirring. Without stirring, vertical and horizontal temperature gradients within the cell and particularly along the disk were quite uniform; however, the ΔT across the disk was eight percent less than the ΔT between the thermowells. This correction was made in all calculations. Two series of runs were made, one with dilute HCl mixtures analyzed by titration, one with benzene-heptane mixtures, analyzed with the use of a Zeiss water interferometer. The results are shown in

TABLE I.

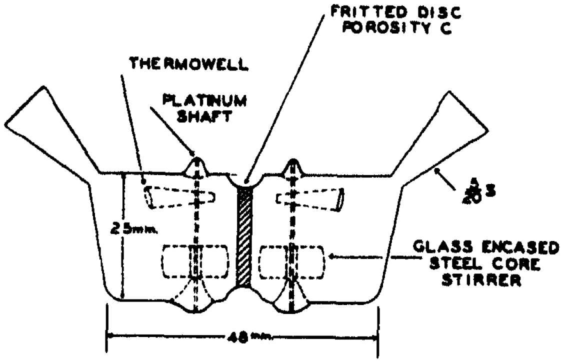

FIG. 1. Thermal diffusion cell.

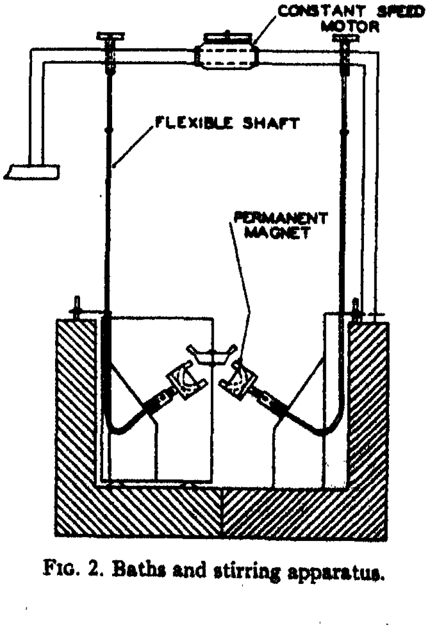

FIG. 2. Baths and stirring apparatus.

Table I, compared with the results of Chipman,[1] who used an open tube supported between two baths, and Tanner,[2] who used two flat plates and an optical method of analysis. As can be seen, the results are more nearly in agreement with Tanner's data which are generally conceded to be more reliable. Also, the time to steady state of this apparatus is less than 48 hours which is shorter by a factor of 5–10 than Chipman's. It is felt that a further substantial reduction in time is possible by using a thinner disk and a smaller cell volume.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

An Investigation of the Possible Use of the Glow Discharge as a Means for Measuring Air Flow Characteristics*

F. D. Werner
Aeronautical Laboratory, University of Minnesota, Minneapolis, Minnesota

(Received August 22, 1949)

The glow discharge in air at atmospheric pressure from a point of fine platinum wire has been experimentally investigated in its sensitivity to variations of pressure, velocity, temperature, and humidity, as well as such variables of the instrument as needle point characteristics, location and shape of the other electrode, and magnitude of the discharge current. It has been concluded that the glow current is markedly pressure sensitive, has low velocity sensitivity, is only slightly humidity sensitive, and is negligibly sensitive to ordinary temperature variations. The device offers a significant improvement over conventional pressure measuring instruments by the small size of its sensitive portion (of the order of 0.001-inch diameter wire and 0.002-inch glow diameter) and in its response to high frequency variations (more than 10^6 c.p.s. has been demonstrated experimentally). It suffers from high background noise in the present arrangement. A workable instrument is not presently described, but rather, some promising possibilities are shown to exist. The successful application to measurement of instantaneous pressures in very high frequency sound has been made, however; and the instrument will be reported as soon as possible.

INTRODUCTION

An instrument for measuring such air flow characteristics as very rapid variations in pressure and velocity should be of small size for high resolving power and for some purposes, should respond to variations as rapid as several hundred kc/sec. or higher. Considerable work on glow discharge has been done by several investigators[1–3] toward the end of measuring velocity and pressure variations. The "Diaphragmless Microphone" developed by Thomas[1] was perhaps the first effort in this direction. He made use of two relatively large, blunt end copper electrodes with a small separation between the ends. The arc was started by suitable means, and a high impedance limited the current to values between 1 and 20 ma at voltages of a few hundred to 1000. He found the device sensitive to pressure and useful as a microphone over the audible range. He reported a decrease in sensitivity with increasing frequency, and some trouble from background noise.

This type of discharge was placed in an airstream and successfully used for turbulence measurements by Lindvall.[2] He found good agreement between hot wire turbulence measurements and his glow discharge when both were subjected to the well-known turbulence behind a cylinder in subsonic flow. The two relatively large electrodes were placed normal to the airflow and were possibly interfering aerodynamically somewhat with the glow. The response to high frequency variations was probably fairly good, but apparently did not extend so high as in the case of the glow discharge from a slender point, as described here. Several other experimenters[3] have extended his work but have had generally similar results. Also, they investigated certain other electrode arrangements and other discharges as dark discharge, and experimented with radioactive pre-ionization.

It appeared that the glow discharge from a point of fine wire offers certain advantages over previous devices in the smaller size of its sensitive portion and in its response to very high frequency variations. It was decided to investigate the effects of pressure, velocity temperature humidity, and the rapidity of response. In addition, variables of the instrument itself were important, such as needle point characteristics, location and shape of the other electrode, magnitude of the discharge cur-

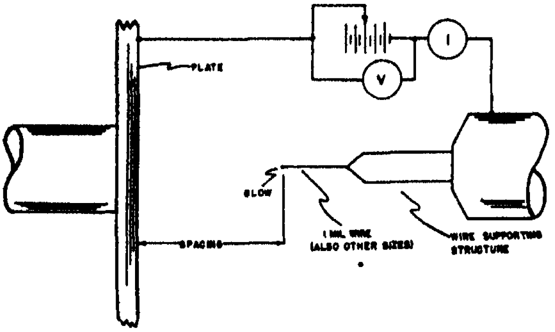

FIG. 1. Electrode arrangement for measuring pressure, temperature and humidity effects. The proportions are approximately correct. This apparatus was placed inside a glass container in the experiments. A schematic diagram of the measuring circuit is also shown. No ballast impedance was necessary due to the rising characteristic of current *versus* voltage.

rent, and polarity. The main purpose of this study was to determine if such a device held promise.

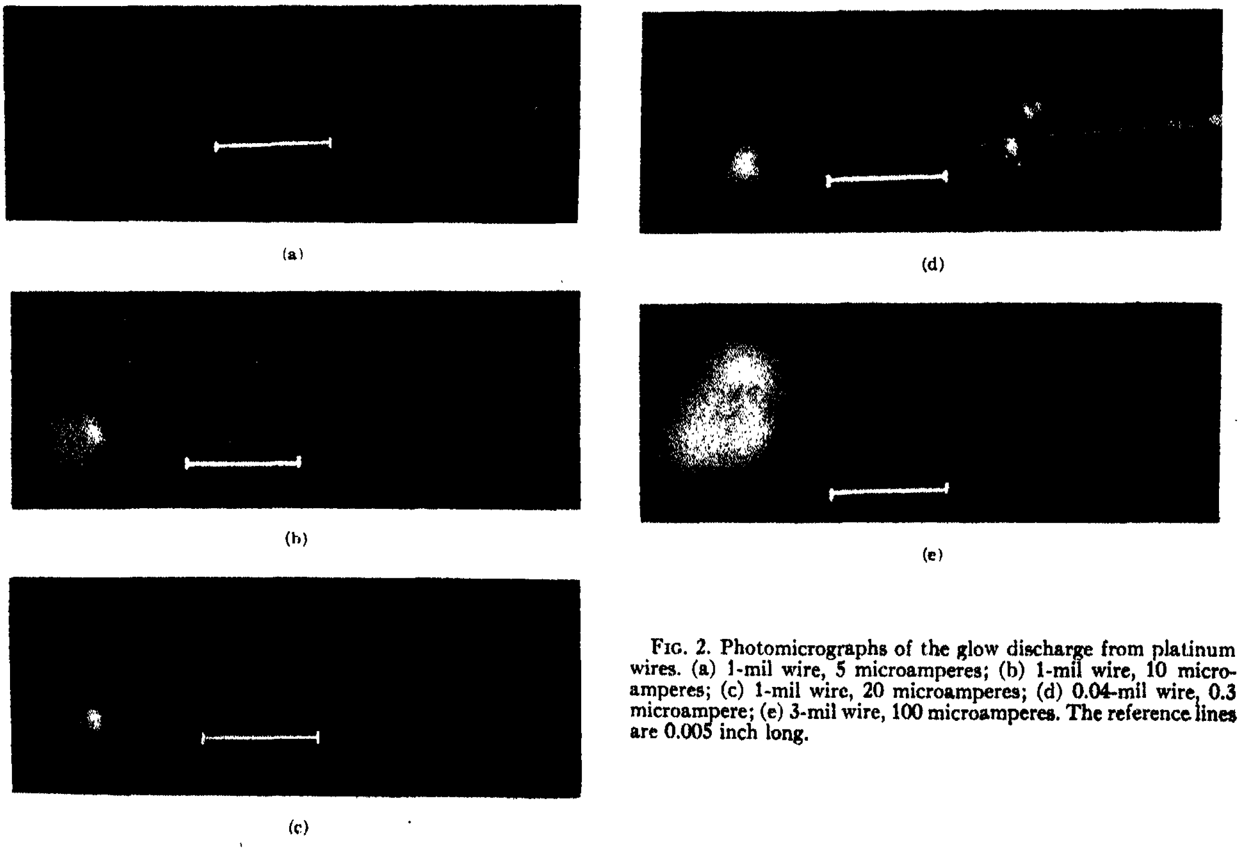
In the discussions which follow, the word, "characteristics," will refer to the curves of current *versus* voltage for the point discharge. This terminology has its origin in the literature on vacuum tubes where curves of current *versus* voltage are widely referred to as "characteristic curves." "Plate" will refer to the electrode opposite the point, even though it is not a plane in all experiments.

EXPERIMENTAL INVESTIGATIONS

Preliminary Investigations

The experimental work was begun with the idea of using as a needle point the tip of a short length of the smallest practical wire size. The smaller size should give more rapid response for reasons which will appear, and should give higher resolution, i.e., should better approximate measurements at a point. Platinum was chosen as the most promising needle material because it is not subject to oxidation and can be obtained in very small sizes. A flat plate was chosen as the plate electrode as shown in Fig. 1, with the assumption that it would give results representative of those encountered in applications requiring somewhat different plates.

In order to estimate the size of the active portion of the discharge, namely the glowing portion, the tip of the wire was examined under the microscope for various currents and wire sizes. Figure 2 presents some photomicrographs showing some of the results of this examination. In the figure are shown the glows from the tip of a negative 1-mil (0.001 inch) platinum wire for currents of 5, 10, and 20 microamperes. Also shown is the glow from a negative platinum wire of diameter 4×10^{-5} inch, for a current of 0.3 microampere. It is interesting to note that the bright glow close to the wire tip is not apparent in this case. It may be that here the wire is so small and, therefore, the electric field so high that high field emis-



(a) (b) (c) (d) (e)

FIG. 2. Photomicrographs of the glow discharge from platinum wires. (a) 1-mil wire, 5 microamperes; (b) 1-mil wire, 10 microamperes; (c) 1-mil wire, 20 microamperes; (d) 0.04-mil wire, 0.3 microampere; (e) 3-mil wire, 100 microamperes. The reference lines are 0.005 inch long.

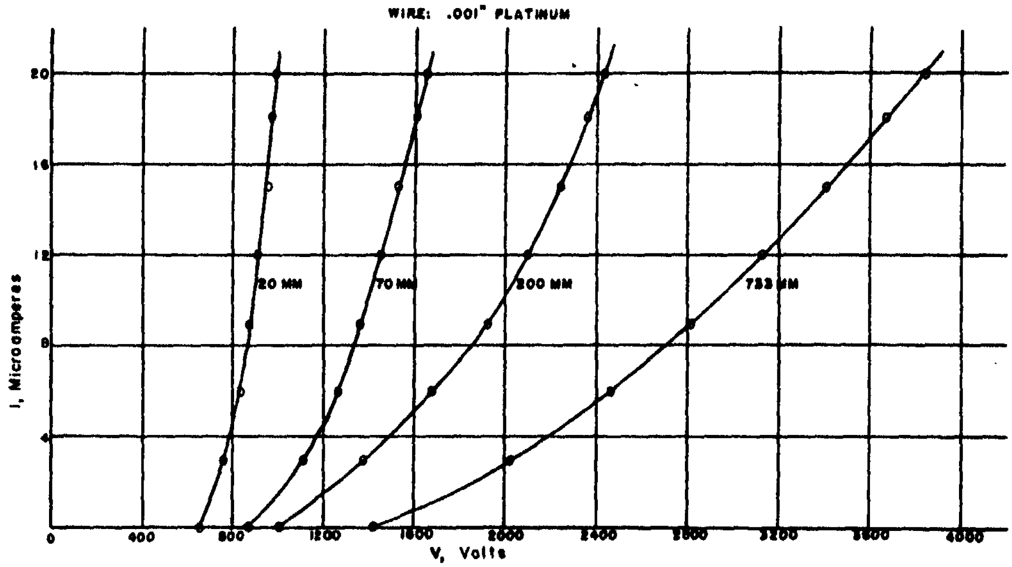


FIG. 3. General effect of pressure on the characteristics for a negative 1-mil wire in dry air for absolute pressures between 20 mm and 733 mm of mercury. These measurements were made with the apparatus of Fig. 1, with constant spacing.

sion of electrons is taking place. Also in Fig. 2 is a photomicrograph of 3-mil platinum wire and is a good example of an irregularity which occurs at a current rather low for the wire size. In this case, the glow is too small to cover the surface of the tip as it does in the other cases, as can be seen in the various photos. The result is that the glow migrates from place to place and gives unsteady characteristics. In this picture it has moved about 3 times during the exposure. This can be corrected by increasing the current. It requires more than 100 microamperes at about 5000 volts for the 3-mil wire.

When the wire is positive, the discharges are somewhat smaller, more intense and more uniformly luminous. Under certain conditions the discharge streams out toward the plate. When the wire is negative, greater pressure sensitivity has been found, so this condition has received somewhat greater emphasis.

Dust can be seen sticking to the wires in the photomicrographs. Since the dust is a poor conductor, it appears to disturb the field very little and therefore causes no noticeable effects on the characteristics unless it appears at the tip where it mechanically interferes with the glow.

The characteristics are quite sensitive to the shape of

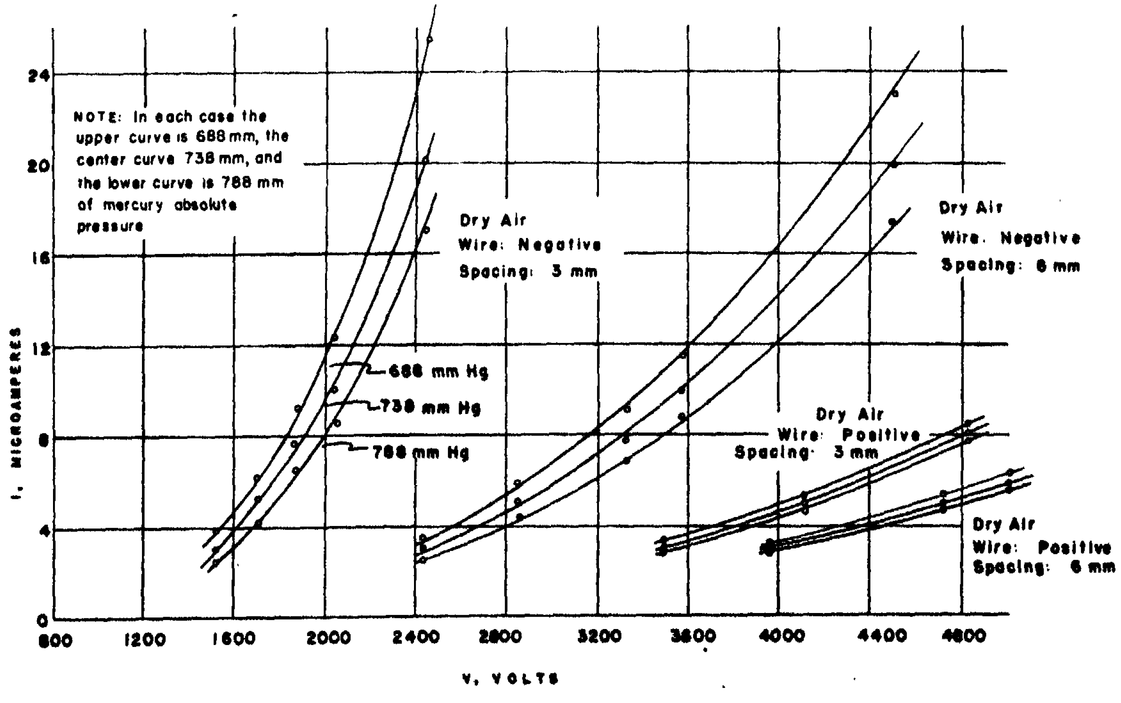

FIG. 4. Dependence of the characteristics on pressure in the vicinity of one atmosphere for 1-mil platinum wire in $CaCl_2$ dried air. Positive currents extend no higher than shown because sparking occurred.

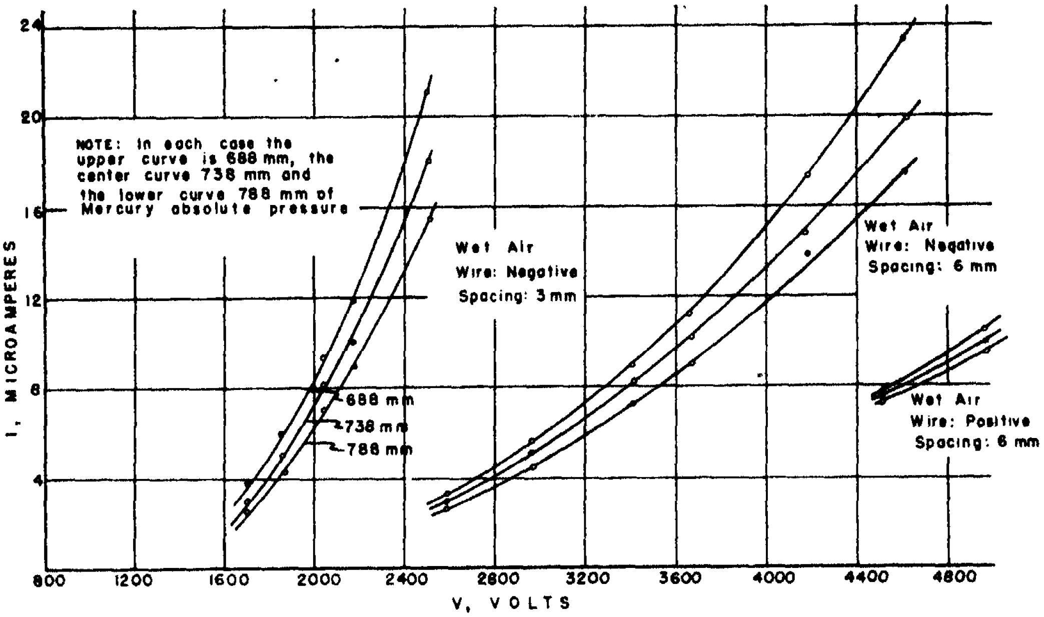

FIG. 5. Dependence of the characteristics on pressure for 1-mil wire in wet air. For positive wire, 3-mm spacing, no data could be taken because the spacing was too small for a measurable differential between onset of glow and onset of spark.

the wire tip, and for this reason it is necessary for good measurements to wait before a reading until the action of sputtering produces the equilibrium shape on the wire tip for the current under consideration before measurements are made. This can be accelerated by preliminary breaking in at somewhat higher current. It has been found desirable to make very frequent examinations of the wire under a microscope of about 100 power to detect any irregularities of the tip.

Tests made in a small glass enclosure gave results which appeared identical to those made in the open. Thus, it was considered safe to perform experiments inside the enclosure. It is believed that the immediate vicinity of the glow is normally so rich in ozone, oxides of nitrogen, and ions, that the use of an enclosure causes a negligible rise in the concentration of these materials at the glow.

The upper useful limit of current was qualitatively

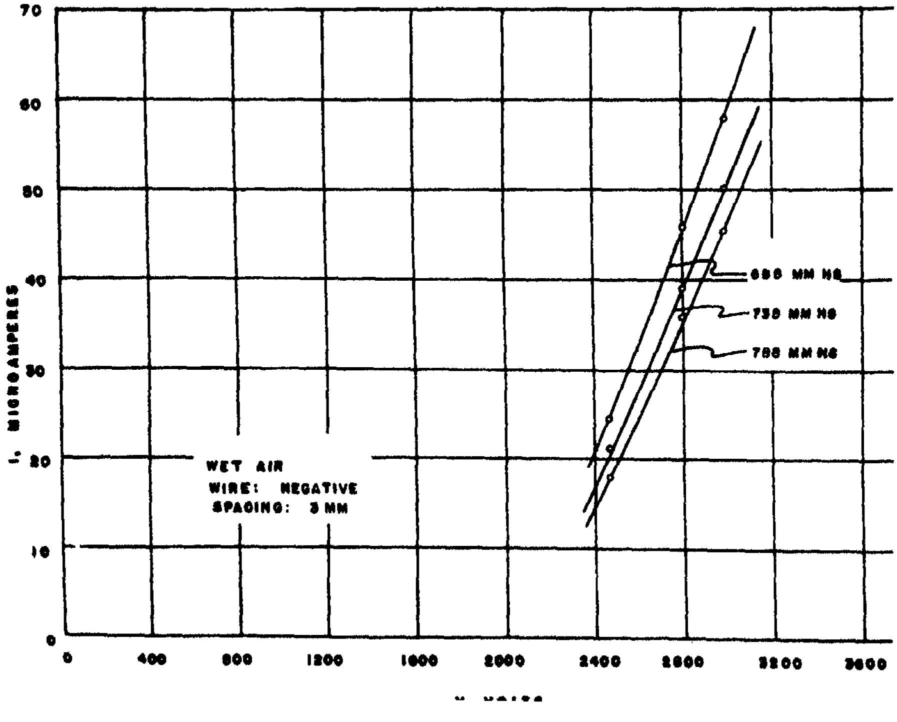

FIG. 6. Dependence of the characteristics on pressure for 3-mil wire in wet air.

determined as the current for which disintegration of the wire became objectionable. This value of current was roughly 1, 5, 40, and 300 microamperes for 0.04-, 0.1-, 1-, and 3-mil wires, respectively. If the gap is too small, a spark will occur before maximum current is reached.

Pressure Dependence

It would be expected that pressure changes would have a marked effect on the glow current if the voltage is held constant, since the mean free path is highly pressure dependent. It is not clear whether electron emission (in the case of negative point) occurs as a result of secondary emission, thermionic emission, or high field emission. Perhaps it is a combination, but in any case, the glow will be very sensitive to changes in the mean free path.

The dependence of the characteristics upon pressure was determined experimentally with electrodes arranged as shown in Fig. 1. These electrodes were mounted inside a glass container in which the pressure could be varied.

The general effect of pressure on the characteristics is shown in Fig. 3. It shows such pressure dependence as to suggest that the device could be useful as a pressure indicator. Another important feature of this discharge is that it should be able to adjust itself very rapidly to changes in pressure. This can be inferred from knowledge that the ions are present primarily in the glow where the field is very high, and that, therefore, the ion drift velocity is high. Since the glow is very small and the drift velocity is high, excess ions present when the pressure increases are quickly removed. On the other hand electron mobility is so high that electrons probably play no part in determining the limiting rapidity with which the glow can adjust itself to a change in pressure.

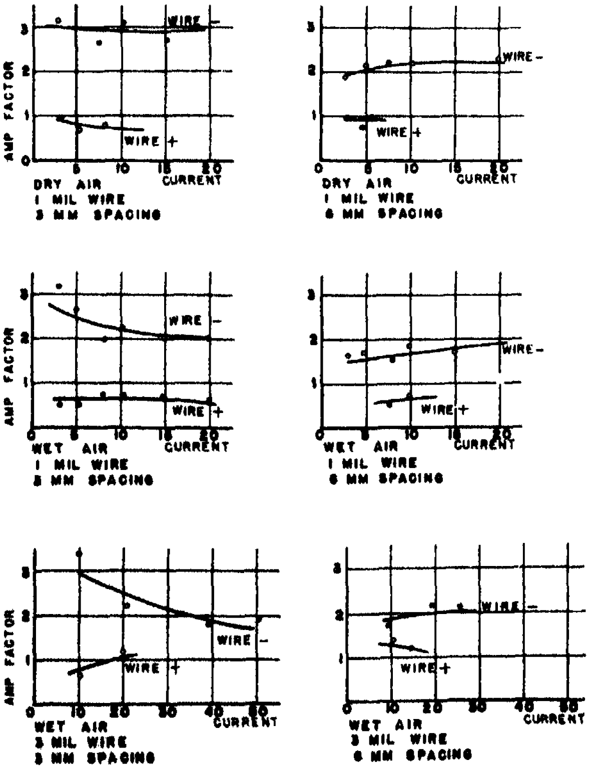

FIG. 7. Pressure sensitivity (amplification factor) of the glow discharge under various conditions. This data is taken from data like that of Figs. 4–6. The amplification factor is defined $P\partial I/I\partial P$.

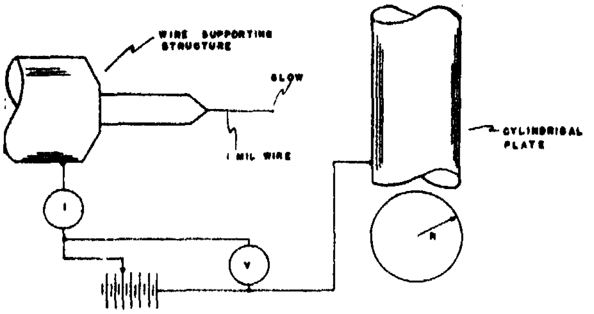

FIG. 8. Electrode arrangement for determining the effect of plate radius on the characteristics. The glow to plate spacing was 3 mm.

Together, these two features of this glow discharge, pressure sensitivity and rapidity of response, suggest that the device might be useful as a microphone for very high frequency sounds and for measuring other rapid pressure variations. Other things which make it interesting in this connection are its very small size, its lack of any mechanical resonance, and its smooth electrical impedance.

With the application of measuring very rapid pressure variations in mind, the pressure dependence in the vicinity of 1 atmosphere was examined in some detail as shown in Fig. 4. Here, the pressure was varied up and down 50 mm of mercury from atmospheric pressure and the voltage across the glow was maintained constant at various values. The various families of curves illustrate the effect of spacing and polarity on the characteristics and on the pressure dependence of the characteristics. Figure 5 shows the same measurements in air saturated with water vapor at 72°F. Apparently, humidity has only a small effect on the characteristics. Figure 6 shows the characteristics for 3-mil wire. The general character is unchanged, but there is a considerable shift to higher current and voltage as would be expected.

These graphs for various pressures bear a striking resemblance to vacuum tube characteristics for various values of grid voltage. This suggests a method for expressing the sensitivity of the device to pressure which is analogous to that used for the vacuum tube. In the case of a vacuum tube, the sensitivity is measured by the amplification factor, and is defined by $\mu=\partial e_b/\partial e_c$, where e_b is the voltage from cathode to anode and e_c is the voltage from cathode to grid. A similar dimensionless coefficient for the pressure sensitivity of the glow discharge may be written $\mu_p = p\partial I/I\partial p$, where I and p are current and gas pressure, respectively. That is, for the glow discharge, the amplification factor is the ratio of

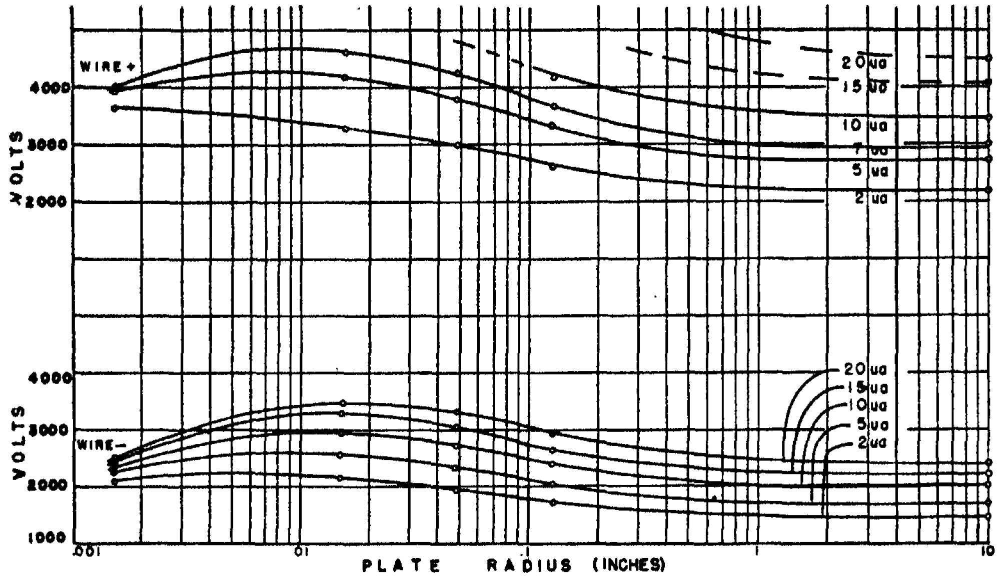

Fig. 9. Effect of variation in plate radius on the characteristics. These curves were taken from characteristic curves for the various radii. The major effect is for small diameter plates, where at high currents a small increase in voltage causes a relatively large increase in current. The upper family is for positive wire tip and the lower is for negative.

the percentage change in current to the percentage change in pressure at constant voltage. Figure 7 gives the relationship between this amplification factor and current as affected by spacing, wire size, humidity, and polarity. This figure was prepared from such data as that in Figs. 4, 5, and 6. The points on these curves depend on the differences between large quantities, and the quantities were not measured with high precision, so considerable scatter results. Nevertheless, they suffice to show that the sensitivity is consistently less for positive than negative wires. Also, there appears to be a small reduction in sensitivity with increasing humidity, and a decrease of sensitivity with increasing spacing. These conclusions must be regarded as tentative until careful quantitative measurements are undertaken.

The current measurements were made with a galvanometer having a 3-sec. period and considerable unsteadiness was evident at low currents. At high currents, the galvanometer stabilized, but radiofrequency noise was generated. It is expected that much of this noise is due to Trichel pulses which are of frequency proportional to the current. Starr[4] reported that no radiofrequency noise was present for discharges from sharp slender points, but this has been observed only for the 4×10^{-5}-inch wire and then only intermittently. Work is being done to reduce this background noise. One interesting possibility is the use of radiofrequency voltage of period shorter than the deionization time instead of d.c. This would appear to eliminate the mechanism for formation of the troublesome Trichel pulses. The signal would appear as amplitude modulation in this case. More will be reported about the background noise later.

Effect of Plate Shape and Size

The effect of changes in the shape of the plate was investigated by using long cylinders of various radii as plates. Figure 8 shows the electrode arrangement for

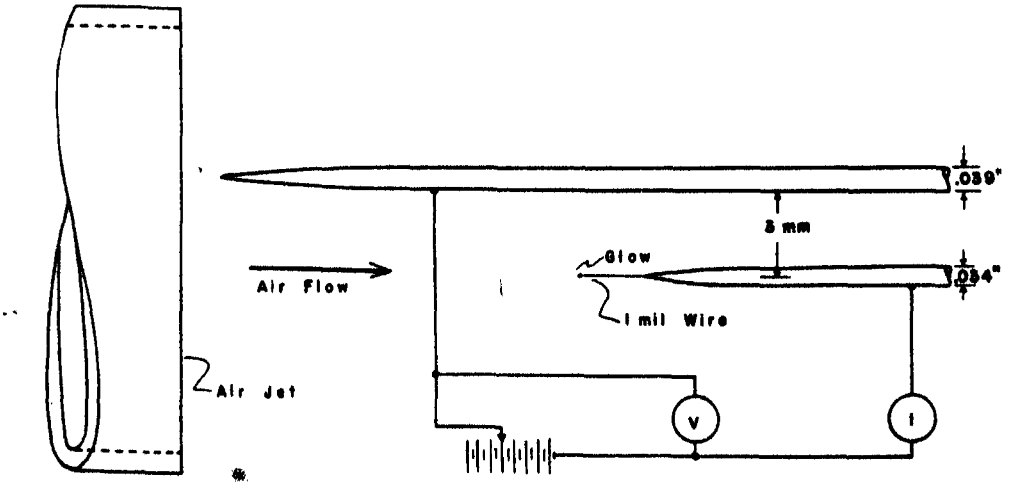

Fig. 10. Electrode and air jet arrangement for determining the velocity sensitivity of the glow discharge. The proportions are approximately correct.

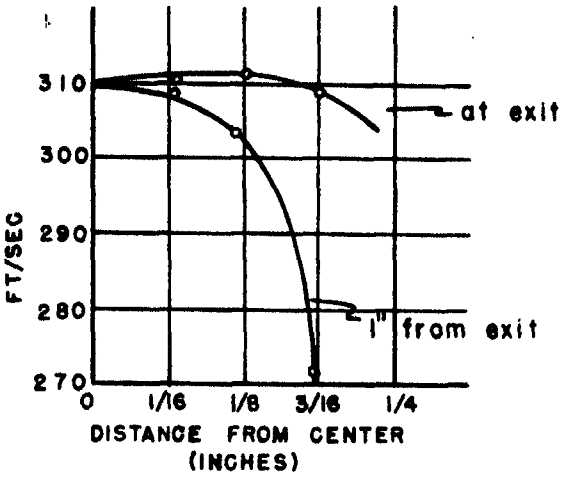

FIG. 11. Velocity distribution for the jet of Fig. 10.

this test. The radius of the cylinder was varied from ∞ to 0.0015 inch. A cross plot of the characteristics for each radius yielded the results of Fig. 9. It shows that for plates of radius greater than about 0.2 inch the radius is insignificant. No great change occurs for radii greater than about 0.03 inch, and for smaller radii the change is not noticeable at low currents, but becomes very marked at high currents. It was noted that a glow appeared at the surface of the plate in this case of small radius and high currents.

The size of the flat plate was found to be immaterial provided the plate was wider than about $\frac{3}{2}$ times the spacing and the edges of the plate were well rounded.

Velocity Dependence

Dependence of the characteristics on velocity might be expected because the wire tip is cooled by the air flow and thermionic emission would be reduced. An effect due to velocity might be partly due to the increase in pressure at the surface of the upstream side of the wire tip caused by impact of the air flow. Probably only a very small portion of the glow is in this region of elevated pressure. It was noted in analyzing the experimental results that the velocity dependence was much less than would have been accounted for by the effect of the impact pressure on the entire glow, and also, when the wire was changed from pointing upstream to a position normal to the airflow, almost no change in the characteristics resulted. When air at the needle point is in motion, a few ions on the downstream side may be carried out of the influence of the electrodes and so cannot contribute to the current, resulting in a decrease in current as constant voltage. At very high velocity, it might be expected that the velocity dependence might become quite marked for this reason.

The effect of velocity was investigated with electrodes arranged as shown in Fig. 10. The 1-mil platinum wire was soldered to the end of a common sewing needle as is the practice and another sewing needle was chosen as the plate, since the data of Fig. 9 indicates characteristics generally similar to those of a flat plate. This arrangement of electrodes is nicely streamlined for air flowing as shown and it is expected that no appreciable change in the air flow in the immediate vicinity of the glow resulted from the presence of these electrodes. A jet of air $\frac{1}{2}$ inch in diameter was used as shown in Fig. 10. The velocity distribution for this jet is shown in Fig. 11, and since it was fairly good near the center of the jet at distances up to 2 diameters, the glow was inserted at one diameter.

The velocity dependence was determined by taking characteristic curves at 0, 255, and 411 feet per second. The results are given in Fig. 12. It is seen that velocity has a definite effect on the glow. If an amplification factor is defined in this case as for pressure dependence, as $\mu_v = V\partial I/I\partial V$, it is found that the velocity sensitivity is about one-twenty-fifth as great as the pressure sensitivity at 255 ft. per sec.

The glow at the tip of the wire was observed under the microscope in this experiment. At zero velocity, it had the same appearance as the photomicrographs of Fig. 2. As the velocity increased at constant voltage, the glow was observed to shrink slightly in size and intensity as would be expected for a decrease in current, without air flow. The tentative conclusion is that the appearance of the glow is not affected by air flow of these velocities, other things being constant. This seems to disprove the idea that the reduction in current with increasing velocity, is due ions being "blown" out of the glow region because in this case the glow intensity would have

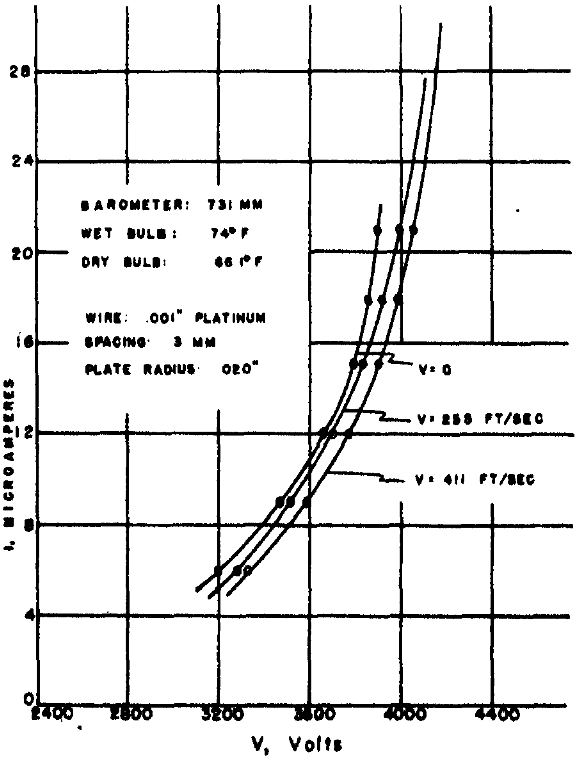

FIG. 12. Velocity dependence for room air at atmospheric pressure for a negative 1-mil wire.

been unchanged, and there would have been a slight distortion of the shape of the glow. While the distortion might escape detection, the change in over-all intensity seems to be a real clue, since this always occurs when the current decreases, whether air is flowing or not. It therefore appears that the effect of reduction of thermionic emission by the cooling effect of the wind, probably plays the most important role in the velocity effect. It is suggested that the voltage for starting the discharge may be very nearly independent of the velocity.

Effect of Humidity

The presence of water vapor can be expected to have an effect on the characteristics, because water molecules have different weight and affinity for electrons than the various molecules making up air. The effect of humidity has been observed by other experimenters for various types of discharges. The findings are similar to those reported here, even though the types of discharge investigated were somewhat different. Generally, the effect is to shift the characteristics to somewhat higher voltages, as seen by comparing Figs. 4 and 5. The effect of humidity on pressure sensitivity is tentatively believed to a reduction of sensitivity with increasing humidity as shown in Fig. 7.

Rapidity of Response

The rapidity with which the glow can adjust itself to new values of pressure or velocity may be roughly estimated theoretically. Consider for example, a small increase in pressure (negative needle). As long as the time for the change to take place is much greater than the time required for the few excess positive ions to migrate to the cathode, the pressure change will be faithfully reproduced by a corresponding current change. This assumes that the excess of electrons can as quickly reach the anode and that negative ions are present in negligible concentration. Considering the 1-mil wire with about 20 microamperes current, the outermost positive ions must move at most only about 0.005 cm to reach the cathode. Since the field is highest at the needle tip, it is reasonable, perhaps, to estimate 500 volts drop over this distance, giving a field of 10^5 volts per cm. Taking the mobility for ions in air as 1.6, the transit time would be about 3×10^{-8} sec. On this basis, pressure or velocity changes having frequency components as high as 10 megacycles or more would be faithfully reproduced by current changes. This estimate neglects the transit time for any negative ions near the outer border of the glow to reach the anode. An estimate for this time would give about 10^{-6} sec. Since the population of negative ions is probably small compared to positive ions, it may be reasonable to neglect the effect of this relatively long transit time.

The velocity dependence experiment gives some experimental support to the belief that very rapid response exists. At an air velocity of 411 ft./sec., a molecule of air moves through the glow region (about 0.002 inch in diameter) in about ½ microsecond. Since the glow was not appreciably distorted in shape, the time of transit for positive ions appears to be short compared with the time for a molecule or ion to be transported by the air flow.

The use of this device as a very high frequency microphone will be reported soon, but at present it might be stated that response to a 1-megacycle acoustic signal has been observed.

Temperature Sensitivity

The ambient temperature was elevated from 74°F to 158°F at constant pressure and no noticeable change in the characteristics was observed. Also there was no change in the pressure sensitivity.

It is concluded that the ionic temperatures are much higher than the ambient temperatures of the experiment, and therefore no appreciable change in the mean free path in the glow resulted. This is evidence that the glow is the only sensitive region of the discharge.

Comparison Between Pressure and Velocity Sensitivity

Consider the equations which define μ_p and μ_v, the "amplification factors" for pressure and velocity, respectively. It is apparent that μ_v decreases smoothly to zero as the mean velocity approaches zero. This condition is readily obtainable in practice. On the other hand, μ_p as can be determined from Fig. 3, changes but little as the mean pressure is reduced. The value of μ_p is, of course, indeterminate as the mean pressure approaches zero, because the glow ceases to exist at moderately low pressures. Summing up, μ_v varies with velocity, decreasing to zero, with decreasing velocity, and μ_p is roughly independent of pressure within the limit studied. Also μ_v is much smaller than μ_p even for rather high velocity.

In any specific application of this glow discharge to measurements where both velocity and pressure are subject to variation, the mean values and amount of fluctuation expected of each must be known before the problem can be solved of determining whether glow current fluctuations represent essentially pressure or velocity variations, or a mixture. For the general case where effects of both pressure and velocity are felt, no generally valid means of distinguishing the effects has yet been found. A specific example of this problem is the application to measurements of instantaneous pressures in a sound wave as mentioned above. Here velocity effects have been found negligible.

This glow discharge is receiving considerable attention at present in the author's laboratory in the application of sound measurements.

A Small Milligaussmeter

G. D. Adams, R. W. Dressel, and F. E. Towsley*
Physics Department, University of Illinois, Urbana, Illinois

(Received September 2, 1949)

Means are described for measuring magnetostatic fields from the order of one milligauss to 100 gauss. The operation consists of measuring the second harmonic content of the exciting current for a ferromagnetic strip which is normally excited to partial saturation. The second harmonic component appears when the strip is biased by an external magnetic field and the amount is directly proportional to this field over the bulk of the useful range. Methods of use are described.

During the course of the model work leading toward the construction of the 300-Mev betatron at Illinois, it became apparent that an instrument capable of making measurements in the milligauss range would be needed. The following is an account of an instrument developed to fill this need.

During the development of this device, the existence of a similar unit designed for the Navy during the war was called to our attention. The physical size of this instrument was prohibitive for model work.

The operation of this instrument depends on the saturation characteristics of the hysteresis loop for a ferromagnetic material. If the magnetic material is field free in the absence of exciting current and if a given sine wave voltage per turn of exciting coil is impressed, then the hysteresis loop will be similar to Fig. 1(a) and the exciting current will be peaked with respect to the sine wave voltage as in Fig. 1(b). Now, if the material be placed in an external field, it will be biased by an amount ΔB. Impressing the same voltage per turn, as in Fig. 1(b), requires the same swing with respect to the unbiased H axis, the loop having been displaced by the amount of the bias, ΔB. This means that the loop has become asymmetrical, as in Fig. 1(c), and changes the exciting current accordingly, as in Fig. 1(d). A Fourier analysis of the unbiased current wave form shows fundamental and odd harmonics. The wave form in the biased case also contains even harmonics. The instrument discussed here measures the second harmonic content of the current wave.

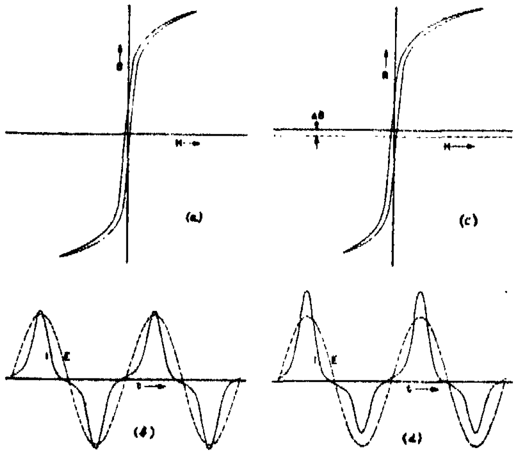

Fig. 1. (a) Hysteresis loop for unbiased ferromagnetic material. (b) Current and voltage wave forms from the hysteresis curve in (a). (c) Hysteresis loop for a biased ferromagnetic material. (d) Current and voltage wave forms from the hysteresis curve in (c).

The magnetic material used in the probe unit is a strip of Hypernik, $0.005\times\frac{1}{16}\times1\frac{1}{2}$ in. The strip is threaded through the center of a spool on which are wound 1000 turns of No. 40 enameled copper wire. The ends of the strip are then overlapped about $\frac{1}{4}$ in. and separated $\frac{1}{16}$ in. with paper. The gap reluctance so formed is about 10 times the strip reluctance. A cross section through a probe is shown in Fig. 2.

In practice, two probes are used in a bridge circuit (Fig. 3), P_1 being the search probe and P_2 the comparison probe. The comparison probe is housed in a thick magnetic shield. The function of the d.c. loop including P_1 is to bias the strip in that probe. How this bias may be used will be described. The capacitors C

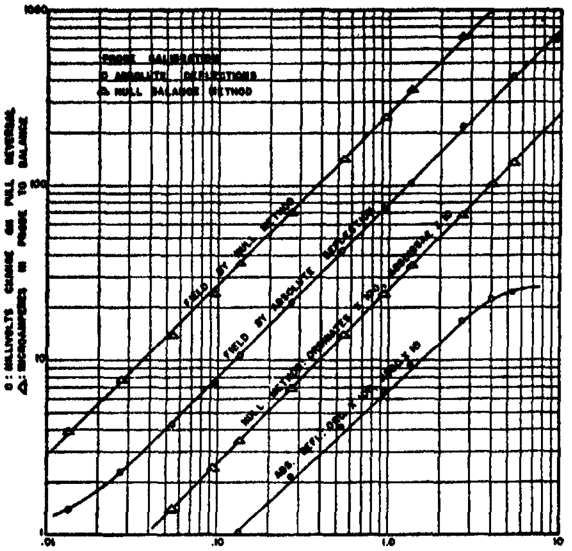

FIG. 4. Calibration of a typical probe unit.

isolate this d.c. from the remainder of the bridge. Each probe is loaded with a close-fitting copper shield to make the loading independent of surroundings.

The bridge excitation is derived from an oscillator (*BFO*) and amounts to 40 ma (M_1) at 5000 c.p.s. The operation of the instrument is sensitive to the excitation and nearly insensitive to frequency, providing this is in the kilocycle range. At 5000 c.p.s., the impedance of the probes is about 500 ohms; the whole circuit is designed around this impedance. F_1 and F_2 are *m*-derived filters with a characteristic impedance of 500 ohms. F_1 is low pass with maximum attenuation frequencies at 10 and 15 kc.p.s.; cut-off is between 7 and 8 kc.p.s. F_2 is band pass with maximum attenuation frequencies at 5 and 15 kc.p.s. and cut-off frequencies near 7 and 12 kc.p.s. The purpose of these filters is to minimize distortion in the input and output wave forms by attenuation of undesirable frequencies which are known to be present. The output detector (*D*) is an harmonic wave analyzer.

In a typical wave analyzer, a few stages of amplification occur before the frequency selection is made. Balancing the fundamental frequency voltage by using a bridge eliminates early stage saturation in the analyzer. The optimum bridge adjustment is made by R_3, the adjustment being for a minimum second harmonic indication when P_1 is in zero magnetic field.

The unit may be used in two ways to measure magnetic fields. The more rapid of these is to use the millivolt indication of the wave analyzer when calibrated against the field of a standard solenoid. It happens that the response is nearly linear up to 40 gauss. The second method is slower but more precise. In this method a null balance is used, the null being achieved by biasing the strip of P_1 with d.c. in the proper direction from the bias supply of Fig. 3. This bias current must also be calibrated against a standard solenoid. Figure 4 shows a set of typical calibration curves. The calibration has varied less than ±5 percent over two years and four different search probes.

It is seen that the null method gives better linearity over a larger range. The device is probably not useful above 100 gauss. On the other hand, the lower limit depends on the sensitivity of the wave analyzer. The analyzer used most in this work had a maximum sensitivity of 0.3 mv full scale which is about 4 milligauss by absolute deflection.

If one desires to measure small detail on a relatively large field, the bulk of the field can be biased out and the remaining detail examined by absolute deflection. In this case, the detail can be examined more precisely than with the null method alone although absolute field value is not known as accurately. This method has proved very valuable in evaluating radial and azimuthal variations of magnetostatic fields.

The probe strip can retain permanent magnetism after exposure to fields appreciably above 10 gauss. This results in an apparent second harmonic unbalance in the bridge. This balance may be restored by increasing the 5000-c.p.s. excitation typically to 150 ma and reducing slowly. In our case, it was necessary to remove F_1 to obtain this much current.

This instrument has also been used for tracing magnetomotive force demand lines at an air-iron interface. In our case the iron was the betatron yoke which is biased during operation. To minimize the leakage flux, it was desired to place the bias winding wires as required by the iron. From the air, the *mmf* surfaces plunge into iron nearly normally. Thus, if a probe of the kind described above be used to measure fields parallel to the iron surface, the direction of the *mmf* surface intersection is indicated by a null reading. This can be made quite sensitive. Following this direction completely around the iron body affords means of evaluating and correcting index errors in direction. For a magnetic circuit containing a window, the relative density of bias ampere-turns required anywhere in the window can be estimated from the indicated peak value of B when measuring parallel to the iron surface.

A High Speed Synchroscope*

G. G. Kelley
Oak Ridge National Laboratory, Oak Ridge, Tennessee

(Received October 4, 1949)

Described is an instrument for observing or photographing fast voltage transients. It consists of a sweep generator with sweep speeds ranging from 30 cm per microsecond to 0.05 cm per microsecond, a vertical deflection amplifier having a rise time of 0.005 microseconds and a preamplifier which, when used with the deflection amplifier, produces an over-all rise time of 0.0063 microseconds with a gain of about 1,000. These units are used in conjunction with a type 5XP cathode-ray tube using 20 kilovolts accelerating voltage.

INTRODUCTION

RECENT work at the Oak Ridge National Laboratory on several phases of the problem of nuclear instrumentation, e.g., the study of scintillation phosphors, Geiger discharge, and the use of high speed coincidence circuits, has led to the need for a synchroscope with features not found in present commercial instruments. The synchroscope to be described was developed to meet this need. The problem in general is the study of randomly occurring events, manifested as voltage variations, practically always of less than 200 microseconds total duration, but with significant fluctuations occurring sometimes in less than 0.01 microseconds; thus a vertical amplifier having a rise time considerably better than 0.01 microseconds is required and since each event is unique the intensity of individual traces should be great enough to be recorded photographically. The signal itself must be used to initiate the sweep, then delayed before presentation upon the cathode-ray tube screen. There are one or more companies developing instruments of this general type, indicating the probability that such an instrument soon may be available.

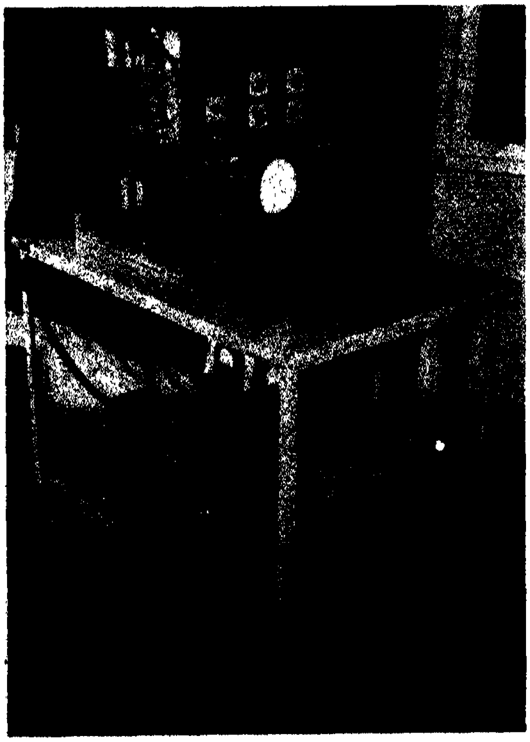

Fig. 1. A general view of the synchroscope and its associated equipment.

GENERAL DESCRIPTION

This instrument, to be called the Model S-1 Synchroscope, has been built around a Dumont type 281-A indicator and type 286-A high voltage power supply, which units house a type 5RP- or 5XP-cathode-ray tube and provide the d.c. voltage necessary for its operation. The complete assembly is shown in Fig. 1. On the shelf, to the left, is the unit which supplies the various voltages used by the sweep generator and vertical amplifier.

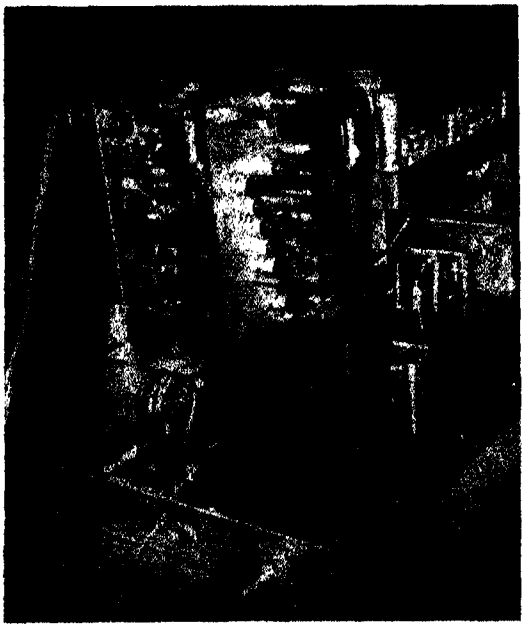

Fig. 2. The rear of the synchroscope. Part of the sweep generator is visible at the left. The delay line connecting the preamplifier, at right, to the deflection amplifier in the center of the picture is coiled in a frame under the table top.

* This document is based on work performed under Contract No. W-7405, eng. 26 for the AEC at the Oak Ridge National Laboratory.

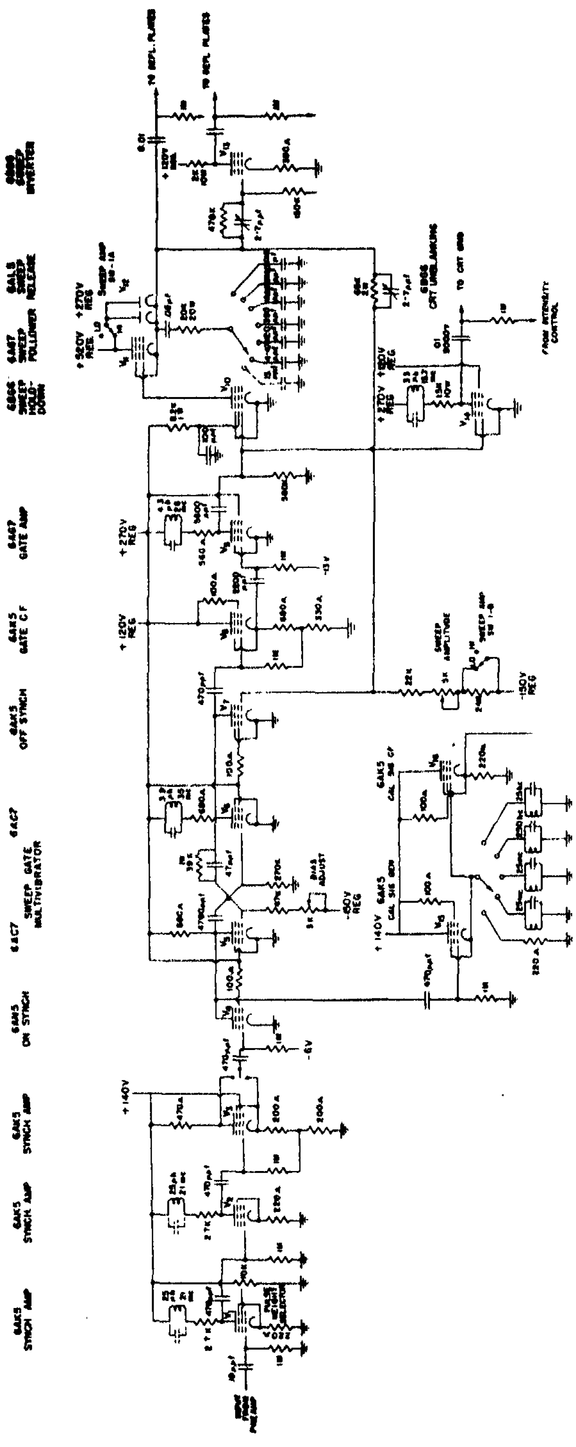

Fig. 3. The sweep generator for Model S-1 Synchroscope.

Beside it is the Dumont type 286-A high voltage power supply. Sitting above is a unit which supplies one of the voltages used in the sweep and amplifier itself. Its function will be included in the main power supply in any future models. The sweep generator, deflection amplifier, and preamplifier are mounted on and above the Dumont type 281-A indicator. Figure 2 shows the arrangement of these units. The sweep generator is on an L-shaped chassis with tubes extending toward the front and right side. At the right in the photograph, mounted vertically, is the deflection amplifier, and the long narrow chassis on the extreme right is the preamplifier. The delay line, which is 133 feet of Amphenol 72–30 coaxial cable, is coiled under the table top.

THE SWEEP GENERATOR

The sweep generator uses fairly conventional techniques and will not be described in detail. It was designed before the vertical amplifier was built, under the assumption that the vertical amplifier would have a band pass of 40 or 50 megacycles, and as a consequence the synch amplifier has a band width of only 13 megacycles. A faster synch amplifier would be advantageous where a shift in the position of the pulse on the base line, depending on its amplitude and duration, is undesirable. There is no noticeable horizontal jitter, however, when the sweep is triggered by uniform fast pulses or by random pulses whose rise time is 0.03 microseconds or greater. An input of about 0.06 volts is required to

trigger the sweep multivibrator. The trace is moving at a uniform rate and the tube is illuminated within 0.01 microseconds after the trigger has arrived. Sweep speeds range from about 0.3 microsecond to 200 microseconds in total duration. Figure 3 is a schematic diagram of this unit.

THE DEFLECTION AMPLIFIER

The deflection amplifier uses the principle of distributed amplification. This principle has been discussed in detail by Ginzton *et al.*[1] and will not be elaborated on here. The amplifier was designed to have a pass band of about 90 megacycles, corresponding to a rise time of about 0.005 microseconds. A voltage swing of at least 60 volts in either direction was desired at the output. Figure 4 is a close-up view of the inner side of the amplifier, and Fig. 5 is the schematic diagram of this unit. The delay line enters through a type "*N*" fitting and is terminated by a 195-ohm 0.5-watt carbon resistor in series with a small inductance. This inductance is very effective in reducing high frequency reflections that arise from the capacitive component of the load. The inverter tube socket may be seen just below the input jack. This type of inverter has proved to be completely satisfactory within the frequency band involved and the amplifier response is not slowed noticeably by this cir-

[1] Ginzton, Hewlett, Jasberg, and Noe, "Distributed amplification," Proc. I.R.E. 36, No. 8 (1948).

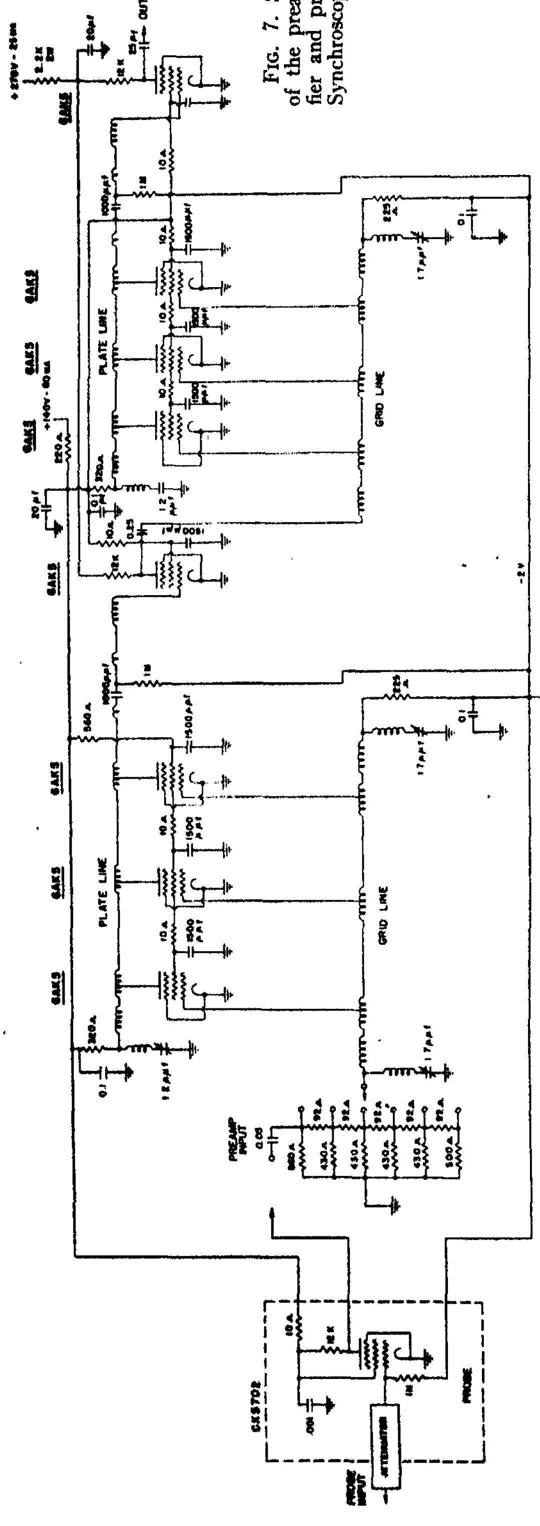

FIG. 7. Schematic diagram of the preamplifier. Preamplifier and probe for model S-1 Synchroscope.

cuit. Following the inverter are the two tubes which drive the grid lines of the eight-tube distributed stages. As may be seen from the diagram, the grid lines themselves form the load impedance for these coupling tubes and these lines are unterminated at their input ends. No termination is needed here if the output ends are sufficiently well terminated, and the gain is a factor of 2 greater. Also, the time constant involved in the low frequency response can be made satisfactorily large because it depends primarily on the current-supplying resistor from the plate of the coupling tube to $B+$. The plate lines of the output stages are terminated only on the input end. Here again only one termination is necessary and the gain is twice as great. Adjustment of the termination is more critical but it is felt that this disadvantage is greatly outweighted by the increased gain.

It will be noticed that the screen grids are paralleled and bypassed only at the center of each stage. This arrangement has proved perfectly satisfactory. The shielding between grid and plate lines was found to be necessary because of the large difference between the amplitude of the plate and grid signals near the output end, which coupled plate signal over into the grid lines.

PREAMPLIFIER

Figure 6 is a photograph of the preamplifier and Fig. 7 is its schematic diagram. Input to the unit is through a 195-ohm ladder type attenuator which may be seen at the right in the photograph. A probe is provided for high impedance input, using a type CK5702 pentode as a plate amplifier. Plug-in capacity-type attenuators are used to prevent overload of this tube. The attenuator in the main unit has a maximum attenuation of 20 db in steps of 4 db. The signal leaving the attenuator enters the grid line of a 3-tube distributed stage having a gain of about 5 and a design cut-off frequency of 118 megacycles. The plate line of this stage is coupled to a second similar stage through a buffer tube which allows the plate line to be unterminated. The second stage is coupled in like manner to the delay line and to the input of the synch amplifier.

No shielding was necessary in the preamplifier, and several components were used that had not been available when the deflection amplifier was built. These were adjustable low capacity condensors for use in the terminations, and feed-through ceramic condensors for transferring most of the wiring to the top side of the

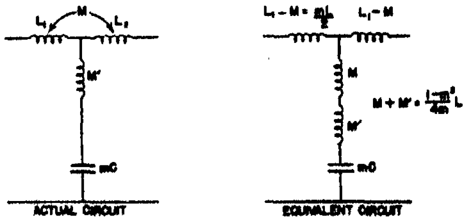

FIG. 8. See text.

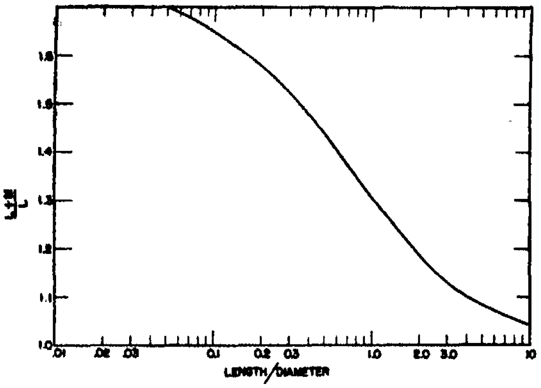

FIG. 9. See text.

chassis, reducing the clutter around the plate and grid lines.

DESIGN

All of the lines used in the amplifier are of the "*m*" derived type. Kallmann discusses this type line in connection with the construction of high fidelity delay lines.[2] He shows that best results are obtained with an "*m*" of 1.27 and points out that negative mutual inductance may be used to eliminate the need for any inductance in the shunt arm. The method of design proceeds as follows: First, a compromise is arrived at in determining the characteristic impedance of the plate line, between gain per tube and pass band desired in the amplifier. The high frequency cut-off of a delay line varies inversely with the line impedance and is given by the equation $f_c = 1/(2\pi Z_0 C)$ where Z_0 is the impedance of the line considered to be a pure resistance, and C is the unavoidable shunt capacity of each section divided by the value of "*m*." The grid line must be designed for the same cut-off frequency as the plate line because the delay per section of both lines must be equal. The required value of L and M, corrected for lead inductance, then may be calculated when Z_0, C, and the value of lead inductance M' are known.

In the equivalent circuit in Fig. 8:

$$Z_0 = 1/(\omega C),$$
$$L = \omega^2 C,$$

and in the actual circuit, setting $m = 1.27$;

$$L_1 = L_2 = 0.515L - M',$$
$$|M| = 0.121L - M'.$$

The experimentally determined values of mC and M' are 4.9 micro-microfarad and 0.021 microhenries for a 6AK5 plate line and 0.028 microhenries and 7.2 micro-microfarads for a 6AK5 grid line. M is required to be a negative mutual inductance because $1 - m^2$ is negative. L_1 and L_2 are wound as one continuous center-tapped coil which gives M the proper sign, and permits its magnitude to be controlled easily. The inductance of the two sections in series is increased by a factor $(L_1 + M)/L_1$ by the mutual inductance between them. This ratio is fixed in a continuous-wound coil by the ratio of length to diameter. It has been computed for the range of values applicable to the design of distributed amplifiers and is plotted in Fig. 9. The coils may be close wound if the proper size wire is selected to give the required length. This method was used and the coils then were checked on a "Q" meter and adjusted to the nearest half-turn. Specifications are given in Fig. 10 for the completed lines.

In every case the plate lines drive a larger capacity than their normal shunt capacity. It is always possible, however, to join two lines so long as they have the same characteristic impedance; therefore the load capacity is connected to the last regular section of a line through an inductance whose value is given by $L = \frac{1}{2}R^2C$. Wherever the capacity in a shunt leg is greater than the normal shunt capacity, the half-section involved will have a lower cut-off frequency than the rest of the line but the attenuation of one half-section is not severe and, while it does reduce the pass band, the alternative of padding all sections of the line up to the value of the maximum capacity and then reducing the line impedance to achieve the same pass band is much less economical of tubes and equipment.

ADJUSTMENT

The terminations for the grid and plate lines in the deflection amplifier were adjusted with the aid of a pulse generator using 2050 type thyratrons, and having a rise time of about 0.002 microseconds. First a negative signal was applied directly to the grids of one stage, of sufficient amplitude to cut off the tubes. The deflection plate ordinarily connected to the other stage was grounded and the observed wave form was assumed to be a function only of the plate line. With a wrong value of terminating resistors the output signal will change stepwise from a value $\Delta i_p Z_0$ to a value $\Delta i_p R$, (each step lasting for twice the delay of the line).

It was found that Sprague NIT non-inductive wire wound resistors, shunted with carbon resistors to the correct value, were very satisfactory in this application.

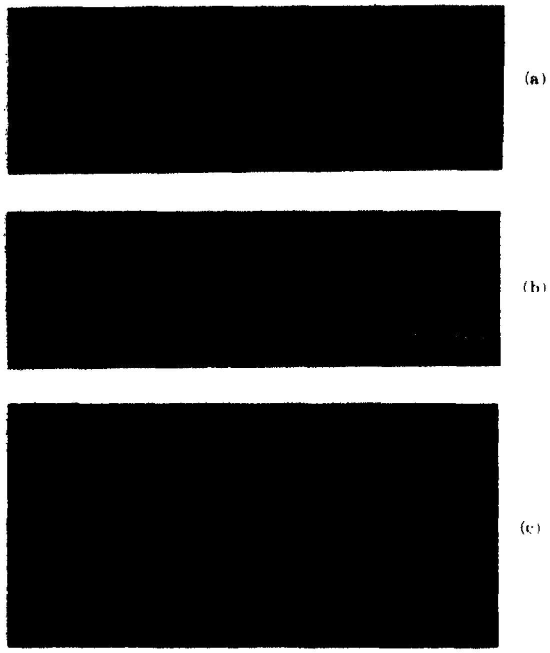

Fig. 11. Response of (a) the deflection amplifier to a step function input, and (b) the deflection amplifier and preamplifier to a 0.1 μsec. pulse. A 30 calibrating signal is given (c),

After the plate line had been adjusted, the stage was returned to normal operation and the grid termination corrected. This problem proved to be a bit more difficult because of the appreciable effect of grid loading. Dissipation along a line requires an inductive component in the termination. This fact, along with the unavoidable presence of capacitive reactance made it necessary to add a small inductance in series with the terminating resistor. Since the grid loading apparently varies with the bias, a compromise had to be made. The best value proved to be about 0.1 microhenries (11 turns of number 26 wire on a 0.1 inch form).

PERFORMANCE

Photographs of the response of the deflection amplifier alone and of the deflection amplifier plus the preamplifier are shown in Fig. 11, along with a 30-megacycle calibrating signal. The rise time as measured from these pictures is slightly less than 0.005 microseconds for the deflection amplifier alone and about 0.0063 with the preamplifier added. The pictures were obtained using about 1.2 volts of signal at the input to the deflection amplifier and 0.05 volts into the preamplifier.

Gain of the deflection amplifier is about 40 and that of the preamplifier is about 25.

All of the 6AK5 tubes used on the vertical amplifier were selected for high mutual conductance on the basis of high plate current at a given value of grid bias. About one-third of the tubes tested were accepted. The selection also gives fairly uniform inter-electrode capacities because there seems to be a rough correlation between mutual conductance and grid-to-cathode capacity.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Dr. W. H. Jordan and Mr. P. R. Bell of this laboratory for many discussions helpful in the development of this instrument.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 1 JANUARY, 1950

Design and Construction of Universal Function Generating Potentiometers*

GRANINO A. KORN
Lockheed Aircraft Corporation, Burbank, California

(Received September 2, 1949)

The design and construction of a new type of function generating potentiometer, whose output voltage may be made proportional to a wide variety of functions of the shaft rotation, is described. Voltages corresponding to the desired function values are set up at will at the taps of a linear potentiometer, which then interpolates linearly between these values. The new device combines remarkable flexibility with relatively low cost.

I. THE UNIVERSAL FUNCTION GENERATOR

A CONSIDERABLE number of industrial, research, and military applications require a voltage divider or potentiometer whose attenuation varies as a prescribed non-linear function of the shaft rotation.[1] The output voltage of an ordinary linear potentiometer is simply proportional to the shaft rotation. Several types of non-linear relationships between output voltage and shaft rotation may be approximated by various methods of resistance loading of such linear potentiometers.[1] For more exacting requirements, several manufacturers produce potentiometers with non-linear characteristics obtained through the use of tapered cards or windings of variable density. Potentiometers generating square, sine, and logarithmic functions are available on a limited production basis, and special function potentiometers for other functions are made to order in some instances. In all but a few cases, however, the delivery times are prohibitively long if quick tests involving empirically obtained functions are desirable, and the prices are often out of all proportion to those of associated equipment.

In view of these facts, it would be desirable to have a function generating potentiometer which could be easily made up in the laboratory at reasonable cost and which could be set up for a wide variety of desired functions, including functions obtained from empirical data. The following is a description of a new type of function generating potentiometer which is believed to satisfy these requirements.

An inexpensive linear potentiometer is tapped 19 to 39 times. A set of adjustment networks permits the voltages at each tap to be adjusted to correspond to the values of the desired function for the respective angular displacements. The potentiometer output voltage will be correctly set up for the desired function values at the taps. Moreover, the potentiometer will interpolate approximately linearly between the function values set up at the taps, and accuracies better than one percent are possible for reasonable gradient changes. The adjustment networks contain small variable potentiometers or rheostats, so that the function to be generated may be changed at will. If no such changes are desired, fixed resistors may be substituted for the variable ones.

The principle of the universal function generator is illustrated in Fig. 1, while Fig. 2 shows the actual circuits of the adjustment networks for a number of typical cases.[2] The "parallel" arrangement of the adjustment potentiometers shown in Fig. 2(a) is the most flexible one and permits a wide variety of functions to be set up. Its disadvantages are (1) the low impedance presented to the source by the parallel potentiometers and (2) the danger of burning out the main potentiometer winding if the full source voltage appears across a small section of the winding. Both these disadvantages are overcome by the "series-parallel" arrangement of Fig. 2(b) at the expense of flexibility. In this arrangement, the adjustment potentiometers are essentially connected in series across the source, so that each tap voltage can be varied only through a fraction of the source voltage without rewiring. This arrangement is particularly well suited for fixed function potentiometers. The arrangement of Fig. 2(c) presents an even higher impedance to the source, but it is not as easily adjusted as that of Fig. 2(b).

The following advantages of the new function potentiometers should be noted:

1. Relatively low cost potentiometers, such as General Radio potentiometers or Helipots, can be adapted. Five percent accuracy with respect to the linearity of the card and the location of the taps is ample, since the final accuracy is not seriously affected by this.
2. The effect of potentiometer loading on the taper of potentiometers is largely eliminated, since the tap voltage adjustments may be made with the load connected. This results in considerable savings and design simplifications in many cases.
3. The new function potentiometer possesses a high degree of flexibility. Different characteristics can be set into instruments, computers etc. by simply changing the tap voltage adjustments. Tables of these adjustments giving desired functions may be compiled for reference, or complete, interchangeable adjustment networks may be retained for re-use (see below).

The choice of resistance values for the tapped potentiometers and adjustment networks, as well as the effects of loading, will be discussed.

---

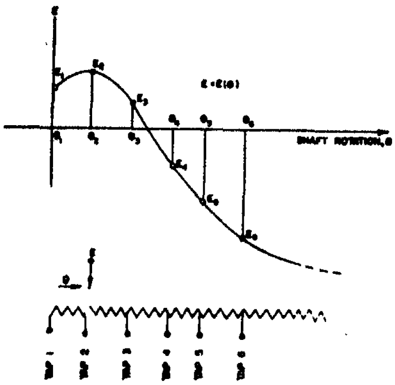

FIG. 1. Linear interpolation by means of tapped potentiometers.

II. DESIGN CONSIDERATIONS

It was seen in Section I that the choice of resistance elements for the tapped potentiometer and its associated networks must satisfy several requirements, which will be taken up in turn.

1. It must be possible to establish the desired voltages at the tap points, with the load connected and without exceeding the power ratings of any of the resistance elements. Any of the arrangements of Fig. 2 may be made to satisfy this requirement if the derivative (slope) of the function to be generated does not change too much over the interval of any one tap segment. This question may be decided very simply by drawing a rough graph of the desired function with the tap points indicated, as in Fig. 1. The points on the graph corresponding to adjacent taps may then be joined by straight line segments as in Fig. 1, and it will be easy to decide whether the interpolation error exceeds a specified percentage. It is clear that, for a given error percentage, functions with rapidly changing derivatives will require potentiometers wih greater numbers of taps than functions whose derivatives vary more slowly.

2. If, as in Fig. 3(a), the function value changes appreciably between adjacent taps (large derivative), care must be taken in order not to exceed the power rating of the potentiometer in question. It is also clear that the rate at which the output voltage can change is limited by the fact that the voltage must vary linearly over the interval of each tap segment. An increase in the number of taps will, thus, permit the generation of more rapidly changing functions. Potentiometers with *split tapped windings*, of which two typical examples are shown in Figs. 3(b) and 3(c), permit the representation of *step functions* as well as better approximations of functions having steep slopes for certain values of the argument. The arrangement of Fig. 3(c) is more flexible than that of Fig. 3(b) but uses twice as many adjustment potentiometers.

3. The output voltage must vary linearly between taps within a specified percentage, with the load connected. This requirement will be satisfied automatically by any of the circuits shown in Fig. 2 if the function generator in question is working into a load of very high impedance, such as a vacuum tube amplifier. If, however, a load of finite resistance R_e is connected between the output terminal of a function potentiometer and ground, the load will draw current from the potentiometer. The resultant voltage drop in the potentiometer winding and networks tends to make the absolute value of the output voltage smaller than that corresponding to linear interpolation. Figure 3(d) shows a graph of output voltage *vs.* shaft rotation for a case with relatively low load resistance and illustrates an extreme instance of the loading effect.

The proper design of the tapped potentiometers and adjustment networks involves the determination of the minimum load resistance in relation to the other resistance elements, which will still yield tolerably linear interpolation. For the analysis of this basic design problem, use is made of the fact that Thevenin's theorem[3] permits the representation of the tapped potentiometer and its associated networks by the *equivalent circuit* of Fig. 3(e).

Let E' be the open-circuit voltage measured between the potentiometer output terminal and ground if the load resistance R_l is removed. According to Thevenin's theorem, the potentiometer circuit is then equivalent to a voltage source of voltage E' connected in series with the resistance R_i' seen by the load if all real voltage sources are replaced by short circuits.

Consider now the variation of the internal resistance R_i' and the open-circuit voltage E' as the sliding contact is moved through any one segment of the tapped winding. Let x denote the fraction of the segment in question traversed by the wiper, with $x=0$ at that tap for which the value of R_i' is lower. It is possible, for each winding segment, to consider R_i' as the sum of a fixed term R_i and a term $r(x)$ variable with the shaft rotation measured by x. Thus,

$$R_i' = R_i + r(x), \quad \text{with } r(x) \geq 0, \quad r(0)=0, \quad 0 \leq x \leq 1. \quad (1)$$

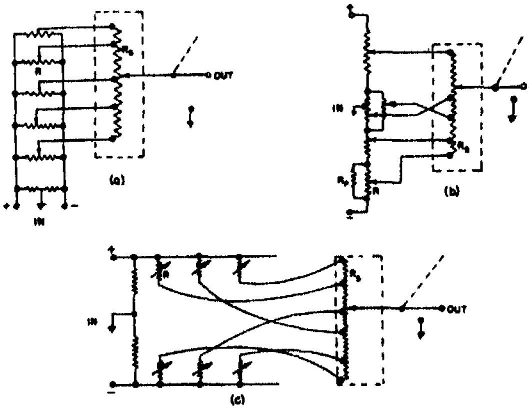

FIG. 2. Universal function generator circuit diagrams.

---

[3] W. R. Smythe, *Static and Dynamic Electricity* (McGraw-Hill Book Company, Inc., New York, 1939), p. 129.

If the tapped potentiometer is a linear one, it is, moreover, clear that the open-circuit voltage E' must be a linear function of x:

$$E'(x)=(1-x)E'(0)+xE'(1). \qquad (2)$$

With reference to Fig. 3(e), Ohm's law yields the output voltage E of the function potentiometer with the load connected, *viz.*,

$$E=(E'R_l)/(R_i'+R_l)=[E'(x)R_l]/[R_i+R_l+r(x)]. \qquad (3)$$

Since E' varies linearly with x, it is seen that, for reasonably linear interpolation, r will have to be made small compared to (R_i+R_l). This will now be discussed on a quantitative basis. Since, in all practical cases,

$$0\leq r(x)<(R_i+R_l),$$

it is possible to expand (3) into an alternating power series in terms of $r(x)$:

$$E=\frac{E'(x)R_l}{R_i+R_l}\left\{1-\frac{r(x)}{R_i+R_l}\pm\cdots\right\}$$
$$=\frac{E'(0)(1-x)+E'(1)x}{R_i+R_l}\left\{1-\frac{r(x)}{R_i+R_l}\pm\cdots\right\}R_l. \qquad (4)$$

It will be remembered that the tap voltages are adjusted with the load connected, so that the output voltage assumes the correct values for $x=0$ and $x=1$. The result of an ideal linear interpolation between these values is

$$E_{\text{lin}}=(1-x)E(0)+xE(1). \qquad (5)$$

Using (1), (2), and (4), this becomes

$$E_{\text{lin}}=\frac{R_l}{R_i+R_l}\left\{(1-x)E'(0)+xE'(1)-xE'(1)\times\left[\frac{r(1)}{R_l+R_i}\pm\cdots\right]\right\}$$
$$=\frac{R_l}{R_i+R_l}\left\{E'(x)-xE'(1)\left[\frac{r(1)}{R_l+R_i}\pm\cdots\right]\right\}. \qquad (6)$$

The error due to the load is given by the difference of (4) and (6), or

$$E-E_{\text{lin}}=\epsilon=\frac{R_l}{R_i+R_l}\left\{xE'(1)\left[\frac{r(1)}{R_i+R_l}\pm\cdots\right]-E'(x)\left[\frac{r(x)}{R_i+R_l}\pm\cdots\right]\right\} \qquad (7)$$

which is seen to vanish for $x=0$ and $x=1$ because of (5).

An attempt will now be made to estimate an upper bound for the error (7). The right side of (7) cannot decrease in absolute value if the full value R_s of one winding segment is substituted for both $r(x)$ and $r(1)$. Since $0<R_s<R_i+R_l$ in all practical cases, moreover, the absolute value of the right side will not be decreased by terminating the power series after the first term. The resulting inequality

$$|\epsilon|\leq\frac{R_l}{(R_i+R_l)^2}R_s[xE'(1)-E'(x)]$$

may be further simplified through the use of (2),

$$|\epsilon|\leq\frac{R_l}{(R_l+R_i)^2}R_s(1-x)E'(0)\leq\frac{R_lR_s}{(R_l+R_i)^2}E'(0). \qquad (8)$$

Equation (8) serves as an estimate of the error due to the load.

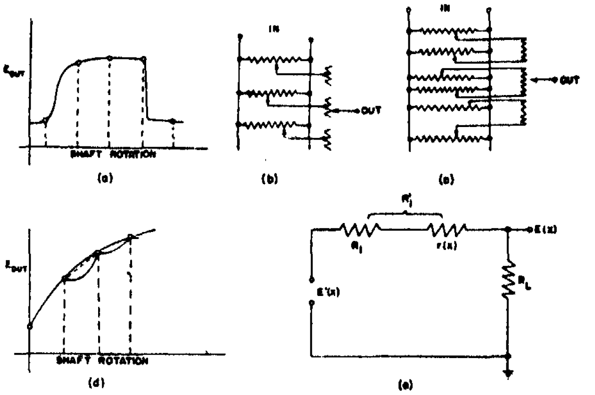

FIG. 3. Design considerations.

The error given by (7) or (8) may be compared to the full source voltage E_i or, more conservatively, to the tap voltage $E(0)=(R_l/R_l+R_i)E'(0)$. In the latter case the percentage error P is given by

$$P\leq\frac{100R_s}{R_l+R_i}(1-x)\leq\frac{100R_s}{R_l+R_i}. \qquad (9)$$

The use of (9) as a convenient design formula is illustrated by the following example. For all the arrangements shown in Fig. 2, the lowest possible value R_{min} of R_i is $R_i=0$, so that (9) yields

$$P\leq 100R_s/(R_i+R_l)=100R_s/R_l. \qquad (10)$$

It should be kept clearly in mind that (10) is *not* a necessary condition which applies to all special cases of function generating potentiometers; it is merely a rather general *sufficient* condition which will hold for many different circuits and a wide range of functions to be generated. If it should be desirable to find optimum design values for special cases, and in particular for the representation of one fixed function, Eq. (7) should be referred to for each winding segment of the potentiometer in question. In many cases such a procedure will lead to much higher values of the ratio R_s/R_l than those given by (10).

In practically all cases the loading errors, as given by (7), may be reduced by introducing resistors in series with either the load or the voltage source supplying the function potentiometer. This will increase R_l or R_i, respectively, at the expense of the output level. *A better scheme is to introduce series resistors between certain taps and the corresponding adjustment networks.* This procedure decreases only the maximum voltage available at the taps in question and may also help to increase the input impedance of the potentiometer and to prevent excessive currents in the winding segments.

4. *The function generator should present a specified impedance to the voltage source.* Since the formulas (7)–(10) for the loading error all involve resistance *ratios* referred to the given load resistance R_l, the input impedance is determined by the network arrangement chosen and by the load resistance R_l. The choice of networks has been discussed in Section I; it may, however, not be possible to obtain input impedances as high as required if the load resistance R_l is necessarily too low. In such cases it may be necessary to sacrifice the output level in order to isolate the function from either the source or the load by means of series resistors. Vacuum tube amplifiers will, of course, serve the same purpose without sacrificing output level.

Apart from these considerations, an intelligent choice of resistance elements for the tapped potentiometer and its associated networks will often involve a preference for types of components which are readily available commercially.

III. CONSTRUCTION OF TAPPED POTENTIOMETERS

At the present time several manufacturers of wire-wound potentiometers will tap their windings on special order, but for small production runs and large numbers of taps the cost of this operation may be quite high. If the demand for tapped potentiometers should increase, however, there is little reason why the cost per tap should exceed fifty cents on orders of 25 or more potentiometers. In any case, the operations involved in tapping potentiometers in the laboratory are not too difficult and will be described in the following.

Figures 4 and 5 illustrate two possible methods for tapping several types of wire-wound potentiometers. At this writing, only wire-wound potentiometers were considered to have the resolution necessary for adaptation as universal function generators.

Figure 4 shows an exploded view of a General Radio type of potentiometer which has been modified by tapping. This type of potentiometer has a cylindrical card or mandrel wound with resistance wire. At each desired tap location part of a single turn of wire has been lifted off the card. This wire was then separated from the rest of the winding by an insulating strip of plastic or cellulose tape, and scraped free of insulation. Contact to these free portions of the winding is then made by (preferably silver-plated) rivets or screw heads fastened to the outer Bakelite housing of the potentiometer in the proper locations. It can be seen from Fig. 4 that this thin outer potentiometer housing is attached to the inner shell by screws which also serve to hold the card in place. Since these screws alone may not effect sufficiently firm contact between the rivets and the winding, it is suggested that an insulated strap, also shown in Fig. 4, be fitted over the rivets and secured tightly by means of a turnbuckle.

Figure 5 shows an alternative method for tapping wire-wound potentiometers and is suited to potentiometers having a thick outer or inner Bakelite shell. The card and winding are first removed from the shell. Holes corresponding to the desired tap locations are drilled in the shell; it will be remembered that the location of the taps is not critical. The holes are then tapped with a fine thread. After the winding has been replaced in the shell, it may be contacted by silver-tipped screws screwed firmly into the tapped holes. Wires may be soldered to these screws, after which the screw heads are secured in position by a layer of sealing wax.

This last method of tapping is especially applicable to potentiometers of the helical card type (Helipots), some of which have shells with thick ribs admirably suited for drilling and tapping. The proper location of the holes for such a helical potentiometer is easily found by placing the shell in a lathe and cutting a very light thread of the proper pitch. This thread, which need only barely score the ribs in the shell, may be located so as to indicate accurately the location of the helical winding inside the shell. The function potentiom-

eter shown in Fig. 5 was constructed in this manner, and the locating scores may still be seen on those ribs not used for tapping.

Figure 6 illustrates one of several methods of locating the adjustment potentiometers and networks around, above, or beside a tapped potentiometer. The most accessible location of the adjustment shafts may have to be chosen separately for each application.

A more sophisticated arrangement is applicable wherever shortness of leads is not a paramount consideration. The tapped potentiometer is mounted in a box. The leads from the taps are brought out to a Jones connector. The adjustment networks are arranged in a separate metal box fitted with a multiple plug in such a manner that it can either be plugged into the potentiometer box directly or connected to it by means of a suitable cable. This arrangement permits the interchanging and filing of several function networks for each tapped potentiometer. This makes it possible to set up several frequently needed function networks once and for all and to interchange them at will. Since the tapped potentiometer proper constitutes a major part of the total cost of the function generator, this may result in considerable savings. This arrangement also permits more convenient location of the adjustment shafts (e.g., on the front panel of a computing machine) for easier adjustments and function changes.

IV. HISTORY AND ACKNOWLEDGMENTS

To the best of the writer's knowledge, tapped potentiometers, with only fixed resistors connected across the taps, were first used by the Arma Corporation of Brooklyn, New York, in connection with computing equipment. The universal function generating potentiometers were developed by the writer's group in the research laboratories of the Curtiss-Wright Corporation, Airplane Division, in Columbus, Ohio. Credit for the circuits shown in Figs. 2(a) and 2(b) is due Mr. D. Kahn of that organization. The split tapped winding was invented by Mr. R. Muirhead, formerly with the Curtiss-Wright Corporation. Several units of the type shown in Fig. 6 were built in the electrical laboratory of the Curtiss-Wright Corporation and were tapped as indicated in Fig. 4 under the direction of Mr. R. Lemon. This work was sponsored by the Applied Physics Laboratory, Johns Hopkins University, Silver Spring, Maryland, under a contract with the Curtiss-Wright Corporation. Figures 1, 2, and 6, as well as part of the accompanying text, were taken from Curtiss-Wright reports written by the present writer.

A number of potentiometers of the type illustrated in Fig. 5, were built in the laboratory of the Physical Research Unit, Boeing Airplane Company, Seattle, Washington, the writer being on loan to that organization under a temporary arrangement with the Curtiss-Wright Corporation. The plug-in network arrangement was conceived by Mr. G. Brown of the Boeing Airplane Company; the mechanical design is due Mr. W. Dillman. The writer wishes to thank Messrs. Brown, Dillman, Kates, and Cosby of the same organization for their able assistance in the construction of universal function generating potentiometers.

The writer also wishes to express his gratitude to Dr. E. H. Gamble of the Curtiss-Wright Corporation, Dr. R. Kershner of the Applied Physics Laboratory, and Mr. G. Stoner of the Boeing Airplane Company for their interest in, and encouragement of, this project; and to Mr. E. C. Wells of Boeing and Mr. R. Blaylock of Curtiss-Wright for their permission to publish this material.

Small Probing Geiger-Müller Counters

C. V. Robinson
Biophysical Laboratory, Harvard Medical School, Boston 15, Massachusetts

(Received September 2, 1949)

Experiments with argon-ethyl acetate mixture in small counters are described. Details of construction are given for two designs of brain probing counters of 3- and 2-mm diameters.

SEVERAL small probing counters have been built by the author and used at the Massachusetts General Hospital during the past year for the localization of brain tumors with the aid of radioactive phosphorous.[1] The first counters constructed were filled with ether-argon mixtures.[2] Subsequently ethyl acetate-argon was found to be a better mixture (see comparison below). For localization of brain tumors the neutro-surgeon requires a counter which has a probing tube of 3 mm diameter or less and a length of 7 cm or more.[1, 3] For precise localization it is desirable that the sensitive volume be small and located near the tip of the counter. Since, in general, a smaller sensitive volume gives a slower counting rate in a given region, a practical compromise must be reached between speed of counting and precision of localization. The 2-mm diameter probing counter described below is considered to be near the optimum for this application.

I. EXPERIMENTS WITH MIXTURE AND GEOMETRY

Experiments to ascertain suitable mixtures and geometry for small counters were carried out with an experimental multiple counter on the filling system. This apparatus consists of four counter frames enclosed in a metal envelope with five lead-through connections (Fig. 1). Each frame permits a cylinder and wire to be readily screwed into position and the four frames are connected independently to the plate. The plate is screwed to the envelope and the four counters may then be operated with a common gas mixture. Data on ethyl acetate-argon mixtures obtained with this apparatus are shown in Table I. The cathodes are of copper treated with CrO_3 solution activated with H_2SO_4 except for numbers 2 and 13 which are stainless steel No. 304 degreased with acetone. These cathode materials are found to be interchangeable when used with ethyl acetate-argon or ether-argon. The counter wires are shielded with Pyrex capillary except for a central length of 15 mm in order to give a sharply terminated sensitive volume. The threshold readings in numbers 3–12 were

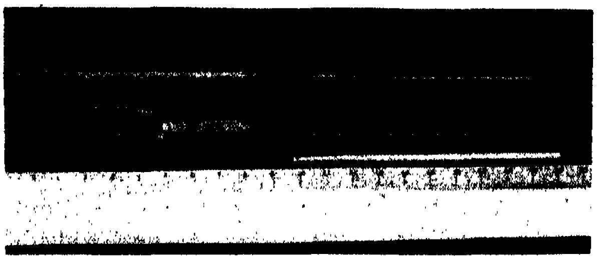

FIG. 2. Probing counters.

made with the same voltmeter so that their relative values are significant, although the absolute values are less accurate.

The effect of cathode diameter on plateau length, other things being equal, is illustrated by counters 1, 2 and 5. The necessity for using a sufficiently high argon pressure is illustrated by a comparison of the plateau slopes of counter 4 with 5, 6, or 7 and counter 9 with 10, 11, or 12. The effect of wire diameter on plateau length is seen by comparing counters 4 with 9, 5 with 10, etc.

It is of interest to compare ethyl acetate-argon with ether-argon,[2] previously tried for small counters. The optimum mixture of ether-argon in an experimental counter which had a geometry almost identical with that of counter 12 gave a plateau length of 80 volts as compared to 175. Even with a larger wire in the same diameter of cylinder, the ethyl acetate gives a longer plateau (counters 6 and 7).

In the author's experience, ether-argon counters are more likely to be permanently damaged by excessive voltage than ethyl acetate-argon counters. Although no systematic breakdown studies were made, a number of ether-argon counters were runied by breakdown, whereas of several ethyl acetate-argon counters which broke down, all recovered.

Although probing counters with both kinds of mixture have served for periods of six months or more, insufficient life test data are available for a comparison. Life tests on a small ether-argon counter without a gas reservoir gave 5×10^7 counts.[2] It has been shown that the life of ethyl acetate-argon counters is limited by depletion of the quenching vapor.[4] Hence a gas reservoir should serve to extend the life of counters with this filling. A reservoir has been incorporated in the designs shown in Figs. 2 and 3.

If helium is used as the noble gas rather than argon, larger wires may be used. Ether-helium mixtures show stable operation with experimental counters having 0.067-in. and 0.030-in. cathodes with 0.005-in. and 0.0025-in. wires respectively. The counting characteristic is short and steep but these counters, like the ethyl acetate-argon counters, were apparently not injured by excessive voltage. The same experimental counters were also operated with a quenching circuit, described elsewhere,[5] using helium plus an impurity,[6] thought to be mercury vapor. The 0.067-in. counter with four atmospheres pressure operated stably and passed a good Chi Square Test.[7,8] The counting characteristic extended from 540 volts to 600 volts. Over this voltage range the counting rate increased 25 percent. The 0.030-in. counter with 8 atmospheres behaved similarly with a threshold of 490 v. From these results with helium, it appears feasible to build small counters with a simple gas filling and hence with an indefinite life.* Since small self-quenching counters need to be used with a cathode follower or preamplifier, the necessary quenching circuit for helium counters does not represent much, if any, additional complication.

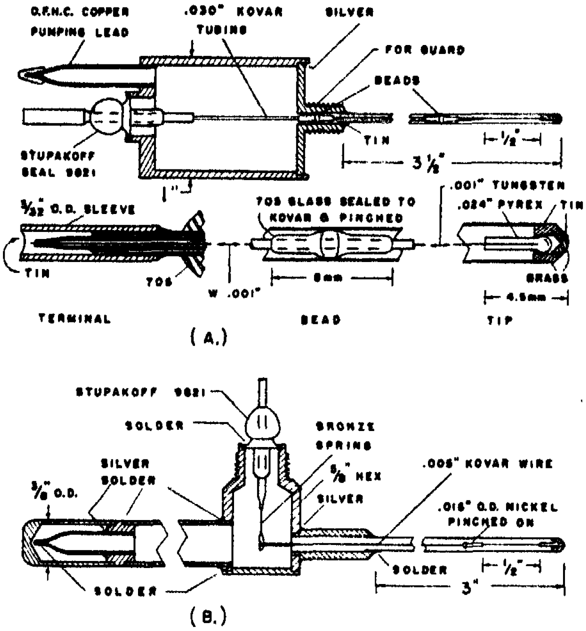

FIG. 3. Details of construction: (A) 2-mm diameter probing counter, (B) 3-mm diameter probing counter.

II. CONSTRUCTION OF PROBING COUNTERS

A pair of 3-mm probing counters including the one shown in the upper half of Fig. 2, have operated satisfactorily for several months. The probing tube is 0.121 in. O.D. with 0.004-in. wall stainless steel 3 in. long.† The sensitive volume coincides with a 12-mm length of 0.001-in. tungsten wire near the tip of the counter (see Fig. 3B). The filling is 25 mm of ethyl acetate and 2 atmospheres of argon. The thresholds are 1050 volts and the backgrounds 4 or 5 counts per minute, unshielded.

* Halogen mixtures have also been used for small counters with some success. M. L. Griem, private communication.

† Superior Tube Company, Norristown, Pennsylvania.

A pair of 2-mm probing counters including the one shown in the lower half of Fig. 2 have more recently been put into service. The tube is of stainless steel 0.081 in. O.D.×0.0025 in. wall, 3½ in. long. Since this tube is more flexible, the center conductor is supported with three glass beads, as shown in Fig. 3A. These counters are filled with 35 mm of ethyl acetate and 4 atmospheres of argon, which gives a threshold of 900 v. The plateaus were examined for a range of 60 volts and showed slopes of 7 percent and 12 percent/100 v. The backgrounds were 3 or 4 counts per minute unshielded.

These counters produce pulses considerably smaller than the average counter, because the exposed length of wire is short. To obtain as much life as possible a cathode follower, preamplifier or quench circuit is used, and the operating voltage kept near threshold.

III. ACKNOWLEDGMENTS

This work was supported in part by the Massachusetts General Hospital, the ONR, the United States AEC, and by the American Cancer Society. The author wishes to thank Dr. B. Selverstone of the Massachusetts General Hospital for his close collaboration in the applied aspects of this work, S. C. Brown of the Massachusetts Institute of Technology for his helpful suggestion, especially in regard to the use of helium, and A. K. Solomon for advice and encouragement.

Book Reviews

Atomic Energy Levels, Vol. I, $^{1}H-^{23}V$

By Charlotte E. Moore. Pp. 309+xliii, 23×28 cm. Circular of The National Bureau of Standards 467, 1949. For sale by Superintendent of Documents, U. S. Government Printing Office, Washington 25, D. C. Price $2.75.

In 1932 a compilation of atomic energy values by Bacher and Goudsmit was published in a volume entitled *Atomic Energy States*. This brought together with a uniform notation the results of all of the analyses of atomic spectra that had been made up to that date. This collection has been of very great assistance to all physicists and astronomers concerned with spectroscopic problems. Unfortunately for its present usefulness this compilation was made at about the middle of the great period of spectroscopic analysis in the nineteen twenties and thirties and as a result contains only about one-fifth to one-fourth of the material which is now available. Every user of spectroscopic techniques will therefore welcome a new compilation by Charlotte E. Moore, the first volume of which has just appeared with the title *Atomic Energy Levels*.

Departing from the alphabetical arrangement of the elements of the earlier collection, the present compilation lists the elements in order of atomic number. The volume which has just appeared tabulates the energies of the levels of the elements from hydrogen to vanadium. The form of the present tables follows closely that adopted by Bacher and Goudsmit. Each term is defined in three columns giving the generally accepted notation for the configuration, the designation of the level and the value of J. This is followed by columns listing the energy of the level and the multiplet separations in wave number units. In cases where the original author has used a notation differing appreciably from the generally accepted one, an additional column has been added with this notation. This, combined with an extensive bibliography of the literature for each ion, makes it easy to correlate the tabulated terms with the observed lines listed in the original literature. All energy values in the present volume are given with respect to the lowest level in the ion. The present tables include one new feature namely the series limit for each ion. With the aid of this the energy necessary to remove an electron from any given level to infinity can be rapidly calculated. This is of importance to anyone using isoelectronic sequences for the prediction of terms in ions that have not been analyzed.

In the cases for which detailed Zeeman patterns have been obtained, the observed g value is listed for each level. Theoretical Landé g values for all types of terms are given at the beginning of the volume. Additional tables in the introductory chapter list all terms that are predicted for all ions tabulated in the present volume.

Through the co-operation of various spectroscopists the author has been able to include a substantial amount of unpublished material. Thus, the term values of the hydrogen-like ions from H_{I} to D_{VIII} and including D, T, and $He^{3}{}_{II}$ are based on recent calculations by J. E. Mack. A substantial number of new observational energy values have been supplied prior to publication especially by the Swedish spectroscopists working with Edlen.

The importance of this compilation of atomic energy levels and of Miss Moore's earlier *A Multiplet Table of Astrophysical Interest* can hardly be overestimated. By bringing together on a uniform basis and with a uniform notation the data from the truly enormous literature of spectroscopy of the last few decades, Miss Moore has made it possible for the average astronomer or physicist to effectively apply these spectroscopic results to his researches where hitherto this could only be done by a few spectroscopic specialists. Astrophysical research in particular should be greatly expedited by these compilations.

I. S. Bowen
California Institute of Technology

Introduction to Radiochemistry

By Gerhart Friedlander and Joseph Kennedy. Pp. 412. John Wiley and Sons, Inc., New York, 1949. Price $5.00.

With the rapidly expanding use of radioactive materials by investigators in every branch of science, an increasing demand for instruction within these fields on the general subjects of Radioactivity and Nuclear Physics arises. Some question as to who should give this instruction is certain to appear.

There is a certain reasonableness in the principle of the "division of labor." Any physics department which insists on teaching its own students mathematics and/or chemistry should rightfully be made to justify such procedure. Similarly, the teaching of physics to chemistry students by the chemistry department or the teaching of physics to biologists by the biology department might leave something to be desired.

In an *Introduction to Radiochemistry*, the authors offer a text comprising thirteen chapters, ten of which deal with atomic physics, radioactivity, and nuclear physics. Only three of the chapters, 56 pages in all, deal with chemical phenomena, such as the identification, the concentration, and the isolation of radioactive species, the chemistry of low concentrations, and tracers in chemical applications. Surely the wealth of material dealing with the modern relationship between radioactivity and chemistry warrants a more exhaustive treatment. For example, complete texts can and have been written on the reactions of carbon alone.

Physics departments that would like to have their graduate students take a substantial course in "radiochemistry" could not but feel neglected if most of the time is spent on subject matter more adequately treated in their own department.

There can be no doubt that the eminence of the authors entitles them to discuss authoritatively the material presented in this text. The only reservation of the reviewer is to question the wisdom of such a superficial treatment. For example, wave mechanics is covered completely in one page, and Bose statistics, Fermi statistics, and the Pauli exclusion principle in one paragraph.

At the end of the text a table of isotopes, covering 92 pages, is included. While this table should prove to be useful, it is completely lacking in references to the original investigations. Users of a particular radioactive isotope will usually not be satisfied until they have reviewed the original literature and, to find this, they must consult some other table of isotopes.

The publishers have done an excellent job in making the text attractive in appearance and in legibility. At the end of each chapter is a set of problems of varying difficulty, whose solution should aid the student in understanding the text material. Some 53 figures consisting of line drawings and half-tones help elucidate the expositions.

For a brief, readable survey of modern physics and radiochemistry the text is highly recommended.

J. M. Cork
University of Michigan

An Introduction to Criminalistics

By Charles E. O'Hara and James W. Osterburg, Staff Members, Police Laboratory, New York City Police Department. Pp. 705+xxii, Figs. 314, 24.5×16 cm. The Macmillan Company, New York, 1949. Price $10.00.

The true nature and scope of the applications of the physical sciences to crime detection are something of a mystery to scientific workers generally. The applications are many and varied. The procedures draw heavily on chemistry, physics, and mathematics, with emphasis on microchemical and optical methods of exploration. The objective is accurately to define a physical fact and to determine its usefulness as legal evidence.

Information along these lines has been available for many years in scattered form, but here at last we have a book in which both the familiar and the new applications are assembled. Here are the descriptions of the procedures and the instruments, accurately detailed, that disclose instructively how the scientist in the laboratory, operating in the support of police tactics, goes about it in making his finds of the evidence of forces incongruously applied, the traces of the lethal bullet, the identity of a clot, the source of a fiber, the telltale fingerprint, the differing ink, the flaw in the metal, the slip of the pen, upon which, in the dramatic setting of our courts, turn the liberty of individuals or the rightful titles to property.

The book contains 48 chapters, 46 of which are highly useful. The 47th and 48th chapters are a plug for a centralized institute for the study and development of police laboratory procedures. The inclusion of such a debatable project mars an otherwise unbiased presentation of scientific method as applied to police problems. But the reader can skip these. Forty-six chapters deal with laboratory design and resources; physical measurements; tracks and impressions; photographic explorations; physical tests, mechanical and optical; semimicro- and microchemical testing and analysis, and finally special applications of recent advances in instrumentation in the field of light waves, more particularly the wave-lengths shorter than the visible wave-lengths. Useful references are appended to each chapter, of which about half are in print and are generally easily available.

The authors have titled their book *An Introduction to Criminalistics*. It is more than an "introduction." It comes nearer to being a manual for the indoctrination of a chemist or physicist in crime detection. The general reader should have substantial grounding in the basic sciences. The special reader will need a sound knowledge of the physics of light, since optical methods are stressed throughout the book. All of the topics and methods of procedure treated are within the ready adaptation of a graduate chemist familiar with microchemical analysis; or of a graduate physicist familiar with the spectrographic field. While not encyclopaedic, it covers well the segment of criminal traces chosen to be investigated. Some gaps in the available literature of crime detection are filled. The text is well written. It is instructively supplemented with good illustrations. What is omitted is available elsewhere and may be located from the references given. It has both table of contents and comprehensive subject index.

Obviously, here is something different from the ordinary conception of a textbook. The various modern optical, photographic, and chemical procedures that are requisite for the most satisfactory results in scientific crime detection are gathered here. The worker or student occupied with the search for unequivocal legal evidence scientifically obtained will find it an introduction into the world of ideas. It is excellent and well worth having.

Edward Oscar Heinrich
Berkeley, California

Laboratory and Workshop Notes

Compiled and Edited by Ruth Lang. Pp. 272, Figs. 195. Longmans, Green and Company, Inc., New York, 1949. Price $5.25.

This book is a compilation of selected notes which have appeared in the *Journal of Scientific Instruments* during the past twenty-five years. The selection suffers, as the Foreword states, from the paper restrictions in Great Britain, and because of this only approximately half of the selected notes were published. Readers in this country will also feel that it suffers even more from having been selected only from the *Journal of Scientific Instruments*. Also, since the selection period extends over the past twenty-five years, some of the notes raise nostalgic memories of the "string and sealing-wax" era of physics. Since all the notes from which this is a selection are not available to the reviewer, it is difficult to say whether this selection was the best that could have been made under the restricted conditions of publication. Some of the notes, such as No. 39, entitled, "3-in-1 Oil" (for delicate mechanisms), seems to indicate that at least in some cases it was not.

The work also suffers from being merely a selection without any continuity or critical comparison of methods. It must be pointed out in justification, however, that the author makes no pretense of its being anything more than a verbatim transcript of published material.

In the field of physics represented by these notes, the dissemination of knowledge still depends largely on the "father-to-son" method. There are only isolated efforts at compilations such as this one and *Procedures in Experimental Physics* by John Strong. The latter, although having been of immense value, suffers from representing the experience, if not of one man, at least of a very small school. The following is suggested as a workable method of overcoming these limitations. A publication should be started in the form of a handbook in which the chapters cover fields, such as, for example, vacuum techniques, to be written by one or more experts in the particular field, the chapters to be bound individually, and in turn to be brought together in a loose-leaf cover. This procedure is suggested to permit bringing up-to-date individual chapters where advances in the field make it necessary. These new chapters could then be bought to replace the old ones without the necessity of purchasing a whole new edition.

To return to *Laboratory and Workshop Notes*, it is felt that in spite of the previous discussion, this compilation will prove highly useful, and it is hoped that, as suggested in the Foreword, more volumes of this kind will be published.

L. A. Delsasso
Aberdeen Proving Ground, Maryland

Isotopic Tracers and Nuclear Radiations with Applications to Biology and Medicine

By William E. Siri. Pp. 653, Figs. 136. McGraw-Hill, Book Company, Inc., New York, 1949. Price $12.50.

The title of this very important addition to nuclear physics literature is misleading. It more properly fits the description of a handbook of nuclear physics. The articles on isotopic tracers, while interesting and well written, comprise only about 70 pages of the whole 600 odd. The remainder is divided between a bibliography of tracer work (about 90 pages) and the handbook of nuclear physics (about 500 pages). This short remark is made, not in any critical spirit, but because the title may not make clear to the general nuclear physicist that he has now a handbook available to him.

The first two-thirds of the book are given to a statement of the fundamental facts and relations of nuclear physics. Chapters on nuclei in general, gamma-rays, beta-particles, protons, deuterons, neutrons, etc., are plentifully loaded with equations and tables of all kinds. The ability to convey any kind of explanation in a book so full of material content is naturally limited and no great attempt has been made in this direction. Thus by the end of 200 words we have been told that nuclei are stable when the binding energy is a maximum or when the lowest proton and neutron levels are filled. Further, that if this is not so, K-capture or positron emission may result and so on. Such an approach is clearly that of a handbook and a biologist who is not too sure of such things as K-capture needs considerable supplementary reading before he can make good use of the material in the text.

Granted this approach, the choice of material is admirable, very carefully prepared, and is a book which should definitely be on hand wherever reference material in nuclear physics is needed. The compact statement of the facts of particle absorption is particularly good as is the chapter on Geiger-Müller counters. A very welcome chapter on the theory of tracer methods is also included.

There are several important deficiencies. There is no adequate account of the method of photographic detection, which with the new electron emulsions promises to be a powerful weapon in research. Also scintillation counters are not mentioned. From the biological point of view, there is no discussion of the mechanism of the action of radiation on the living organism, a field of work in which such rapid and interesting progress is being made. In a book which is primarily a handbook, one can also ask more of the index than is here.

In spite of these few criticisms, the reviewer has already made excellent use of the book in courses both in nuclear physics and biophysics and it is a great relief to have a single volume to which a student can be sent in place of the mass of scattered references hitherto available. No one whose work goes along with the tide of postwar physics will regret possessing the book.

E. C. Pollard
Yale University

Seismicity of the Earth

By B. Gutenberg and C. F. Richter. Pp. 273, Figs. 34, Tables 19, 8×11 in. Princeton University Press, 1949. Price $10.00.

This book occupies a unique place in the literature of seismology. It supplies the only uniform as well as systematic analysis now available of a great volume of instrumental observations of earthquakes accumulated since the turn of the century.

The authors, who developed the scale now universally used for assigning a magnitude to earthquakes on the basis of instrumental records, have selected their material scientifically with reference to the magnitudes, hence the energies, involved. This includes deep, intermediate, and shallow earthquakes. Thus, for the first time in the history of seismology, truly significant statistics have been distilled from the chaos that previously resulted from simple tabulations of varying samples of the estimated million earthquakes per year around the globe.

This book bears little resemblance to Special Paper No. 34, of the Geological Society of America, 1941, and a supplementary paper in 1945, under the same title by the same authors. It is completely revised, expanded, and reorganized, in addition to including for the first time statistical results for deep-focus shocks on the same basis as for shallow shocks.

Seismicity of the Earth evaluates the present relative seismicity of the globe, discusses the geography and the geological character of the areas of seismic activity, and correlates earthquake locations with alignments of active volcanoes, gravity anomalies, oceanic deeps, mountain structures, and the mechanism of crustal folding and block faulting. Tsunami, or seismic sea-waves, popularly known as tidal waves, are discussed and a list of 450 active volcanoes is included, with latitude, longitude, date, and type of latest reported activity. According to the authors, "All shocks prior to 1946 which have been located are included in regional tabulations. Of great shallow shocks, 98 have been identified between 1904 and 1947; 361 major shallow earthquakes of less magnitude have been identified for 1918–1946. These are given in separate chronological lists which are believed to be practically exhaustive. Over 2000 shallow shocks, and about 1000 deep-focus shocks, 266 with magnitude greater than seven were selected for study because of magnitude or geographical location."

The authors have calculated that the annual average of energy released by earthquakes between 1904 and 1945 was 12×10^{26} ergs, a value comparable to the annual flow of heat from the interior to the surface, which is 66×10^{26} ergs. In terms of annual values, the energy released by earthquakes varied from a high of 59.7×10^{26} ergs in 1906 to a low of 1.5×10^{26} ergs in 1930. No correlations with such phenomena as sunspots stand up over the interval for which data are available, although 1905–07 were years of high numbers.

Every library in the world that wishes so much as a single book on the subject of earthquake occurrence, distribution, and significance, should have *Seismicity of the Earth* on its shelves. It is a true classic in the field.

L. Don Leet
Harvard University Seismograph Station

Advances in Catalysis and Related Subjects, Vol. I

By W. G. Frankenburg, V. I. Komarewsky, and E. K. Rideal (Editors). Pp. 289+xiii, Illustrated. The Academic Press, Inc., New York, 1948. Price $7.80.

This is the first volume of a projected series, to be published annually. It is the intention of the editors that this series shall eventually "present a compilation of papers, written by competent specialists, which should enable anybody to obtain a fairly complete concept of the practical achievements of current and new methods and of the various theoretical approaches to the manifold problems."

It should be emphasized that the present volume is in no sense a compendium of catalytic information but more closely approximates a series of reviews dealing with specialized and limited fields and summarizing the current state of knowledge in those fields. A work of this kind is clearly not suitable as a text but will be highly appreciated by specialists, who have felt for many years the pressing need for systematization in this rapidly advancing and technologically important field. The contributors to the present volume are all men of outstanding ability in their specialities and the generally high quality of the book is a reflection of their competence. If these standards are maintained in future volumes the plan of the editors will be well fulfilled.

This volume contains eight sections; two deal with methods and techniques of quite broad interest over the whole field of heterogeneous catalysis, two more discuss fundamental theoretical questions, again of wide interest, and the remaining four deal with restricted classes of reactions. Heterogeneous catalysis receives the greatest attention "in view of its particular problematic aspects and its preponderant practical importance." The following specific topics are discussed:

"The Heterogeneity of Catalyst Surfaces for Chemisorption" by H. S. Taylor, Frich Chemical Laboratory, Princeton University, Princeton, New Jersey. (25 pp.) This section presents a brief review of the older literature dealing with this subject and much new data demonstrating the existence of centers of varied activity on a number of important catalysts.

"Alkylation of Isoparaffins" by U. N. Ipatieff and Louis Schmerling, Universal Oil Products Company, Riverside, Illinois. (36 pp.) Following a general introduction, the mechanism of catalytic alkylation, side reactions, and the behavior of particular catalysts are discussed.

"Surface Area Measurements. A New Tool for Studying Contact Catalysts" by P. H. Emmett, Mellon Institute, Pittsburgh, Pennsylvania. (25 pp.) A brief but comprehensive survey of the history, limitations and application of this essential method for the study of solid catalysts.

"The Geometrical Factor in Catalysis" by R. H. Griffith, The Gas Light and Coke Company, London. (23 pp.) A remarkably concise summary of the role of the geometrical arrangement of atoms in solid catalysts in effecting a variety of reactions. This is one of the aspects of catalysis which has been very incompletely developed, and at the same time it is one which promises to be most rewarding in the future.

"The Fischer-Tropsch and Related Processes for Synthesis of Hydrocarbons by Hydrogenation of Carbon Monoxide" by H. H. Storch, Synthetic Liquid Fuels Research and Development Branch, Bureau of Mines, Pittsburgh, Pennsylvania. (41 pp.) This is a detailed discussion of the past and present research on a problem of great practical importance. The need for such a compilation is sufficiently indicated by the large number of references (91) to published work.

"The Catalytic Activation of Hydrogen" by D. D. Eley, University of Bristol, Bristol, England. (42 pp.) The wide participation of hydrogen in catalytic reactions, as well as the controversial status of some of the interpretations of experimental results, makes this survey especially valuable. Chemisorption, dissociation and recombination, the parahydrogen conversion, exchange reactions, and a number of specific reactions are discussed. A brief recapitulation of present theories is given.

"Isomerization of Alkanes" by Herman Pines, Universal Oil Products Company, Riverside, Illinois. (54 pp.) A detailed account of the experimental results and mechanisms of isomerization of butanes, pentanes, and hexanes. Some data on higher hydrocarbons.

"The Application of X-Ray Diffraction to the Study of Solid Catalysts" by M. H. Jellinck, Linde Air Products Company, Tonowanda, New York and I. Fankuchen, Polytechnic Institute of Brooklyn, Brooklyn, New York. (32 pp.) The use of this powerful tool for catalyst studies is discussed as it applies to identification of components, determination of lattice constants, and estimation of crystallite and particle sizes. Examples of applications are given, and techniques are briefly outlined.

The book has good subject and author indexes.

K. A. Krieger
University of Pennsylvania

Introduction to Statistical Mechanics

By G. S. Rushbrooke. Pp. 334+xiii, Figs. 47. Oxford University Press, London, 1949. Price $5.50.

The aim of this book is to provide the student of physical chemistry with a working knowledge of the basic formalism of statistical mechanics. By using the device of proving certain theorems only for special cases and bridging gaps by lucid plausibility arguments, a surprisingly wide ground is covered with a modest mathematical equipment.

The first method used is essentially Boltzmann's, in which the number of complexions is maximized. The discussion of assemblies of localized and non-localized systems demonstrates the procedure. The first one leads to the Einstein model of a solid consisting of independent oscillators, the second to the theory of the perfect Boltzmann gas.

The counting of microstates is carried out from the point of view of quantum mechanics. This is considerably simpler than the approach from the classical phase space. The latter is introduced, however, as a limiting case of the quantum treatment.

On the other hand, the case of ideal quantum gases (Fermi-Dirac and Bose-Einstein statistics) is mentioned only cursorily.

The results obtained up to this point provide the opportunity for a wealth of applications: The specific heat of diatomic and polyatomic gases including a chapter on ortho- and parahydrogen, a discussion of Nernst's heat theorem, dielectric constant of polar and non-polar gases, mixtures of gases, the law of mass action and phase equilibria of one- and two-component systems.

The discussion of Nernst's theorem in the literature is frequently characterized by objectionable overstatements. In trying to avoid this mistake the author gives a very careful discussion of the question of zero-point entropy but finally rather understates the importance of Nernst's law. We read on p. 145: "Applied to a single substance it (Nernst's law) has no meaning. We exclude from consideration here changes in the environment of the assembly, due, for instance, to changing an external magnetic field." It seems somewhat misleading to state that a law has no meaning if one arbitrarily ignores the conditions under which it has one. Still in the same context it is hard to concur with the statement on p. 139: "In practice, measurement of the specific heat may be made, calorimetrically . . . down to, perhaps, 10°K, but thereafter measurements become impracticable." Actually, extensive calorimetric studies have been carried out in the liquid helium range and at magnetic temperatures down to a few thousands of a degree and the Debye extrapolation is hardly the only means of gaining information on the low temperature entropies.

In the above-mentioned discussion on phase equilibria, the relevant thermodynamic conditions of equilibrium are always derived from purely statistical considerations. This leads to a certain amount of redundency compared to a combined use of thermodynamic and statistical methods. Whether or not this is justified by a better insight into the phenomena is largely a matter of opinion.

The last part of the book deals with the explanation of the methods of canonical and grand canonical partition functions and their application to such difficult problems as the Ursell-Mayer theory of imperfect gases and the theory of regular, but non-perfect, solutions including order-disorder transformations. In the latter problem particularly Guggenheim's method is followed. In view of the elementary nature of the book, the ample application of the powerful grand canonical method must be considered most remarkable.

The reviewer feels that a short discussion of fluctuations would have been appropriate and would have helped to give a physical basis for the transition from the microcanonical to the canonical method.

The usefulness of the book is increased by problems and examples following the majority of chapters. Mathematical and thermodynamic formulas are derived in Appendices.

The book is a most welcome addition to the literature of statistical mechanics on an intermediate level.

L. Tisza
Massachusetts Institute of Technology

Engineering Optics—The Principles of Optical Methods in Engineering Measurement

By K. J. Habell and Parker Cox. Pp. 411+xiv, Figs. 182. Pitman Publishing Corporation, New York, 1948. Price $7.50.

The subject matter of this book is described more accurately by the second part of the title than by the first. In the United States particularly the term engineering optics has come to have a broader meaning than optical methods in engineering measurement.

The first chapter deals with the fundamental properties of optical systems, laws of image formation and the like, without consideration of lens defects. The second chapter gives a brief but fairly adequate treatment of the principal aberrations of lenses together with the influence of diffraction in limiting the performance of an optical system. This is followed by a short section on the eye and its performance which is brief, but of far better quality than usually encountered in a book of this sort. Chapters three through six deal with light sources and the optical instruments of particular interest in engineering measurement, including microscopes, telescopes, and optical projection systems. Chapters seven and eight deal with profile measuring systems and miscellaneous optical methods including interferometers. The last chapter of the book considers briefly certain construction features of optical parts and their mounts.

Within its scope the work is well planned and executed. Although many of the descriptions tend to omit important details (perhaps for the sake of brevity), they are in the main clear and accompanied by excellent diagrammatic illustrations. One could wish that certain sections had been expanded, particularly that on interferometry, but in the main the relative space devoted to the several portions of the subject appears a good compromise. The work is a contribution to the subject of optics, and should prove of particular value to one who wishes to apply some of the very powerful methods of optics to problems of engineering measurement.

Brian O'Brien
University of Rochester

Electric Resistance Strain Gauges

By W. B. Dobie and Peter G. Isaac. Pp. 114+xiv, Figs. 89. MacMillan Company, Ltd., London, 1949. Price $3.50.

This fine work by two British authors is in quintessence a handbook devoted in its entirety to the tools for experimental stress analysis. The text is rudimental but the student and engineer will never the less find it extremely useful, for in its hundred odd pages it touches upon stress analysis, strain gauge techniques, electronics, and a smattering of brittle lacquer coating science. The references gathered throughout the book are outstanding and do much in making this book a fine reference source.

The introduction credits Lord Kelvin with the metal wire strain-resistance relationship upon which the entire electrical resistance strain gauge theory is based.

Chapter One, "Guage Characteristics," derives the strain gauge sensitivity factor and the cross sensitivity factor. Considerable emphasis is placed on the technique and the "do's" and "don't's" one should rigorously follow in applying the strain gauge. An itemized table is included disclosing American and British gauges available on the market and the characteristics of each. Some space is given to gauge stability and the effects of high temperature on gauge sensitivity.

Chapter Two, "The Determination of Static Strains," interjects the common Wheatstone bridge and the deviation thereof. Bridge circuits of the series, slide wire, and shunt balancing are shown in detail. The Kelvin form of bridge is derived and although extremely sensitive the authors point out that it is expensive to set up. There is a dissertation on temperature compensation, however the authors refrained, until Chapter three under "Gauge Arrangements," from mentioning the full bridge, which on a bending beam is fully temperature-compensated besides having twice the sensitivity of a single gauge and dummy combination. Another scheme not mentioned in the text is mounting the temperature gauges at right angles to the measuring gauge on the specimen under observation, which automatically compensates for temperature and makes use of Poisson's ratio to give greater sensitivity.

In Chapter Three, "The Fundamentals of Stress Analysis," the authors attempt to give a rather comprehensive outline of elementary tensile, compressive and shear stress and strains. Full derivations are given for complex stresses, ellipse of stress, principal stresses, and Mohr's stress circle. The method for analytical determination of principal stresses and strains for use in stress analysis from experimental results is well executed. Such equations can be utilized in the determination of stress from equilateral and rectangular rosettes. A small section is devoted to gauge arrangements for determination of direct tension or compression, bending, shear and torque.

Chapter Four, "Elementary Electronics," an excellent chapter, touches on cathode-ray oscilloscopes, their fluorescent screen focusing arrangements, and timing circuits; galvanometer oscillographs, their limitations, and the construction of the galvanometer. A very unique discussion of amplifiers, oscillators, and rectifiers gives a rather complete picture of the operation of the electron tube and circuits.

Chapter Five, "Electronic Bridge Circuits," is a carefully written presentation offering highlights of the d.c. bridge and modulator, the carrier wave as it is applied to a.c. circuits, and the common Maxwell's impedance bridge, a modified Wheatstone bridge to determine individual capacitance or resistance. The chapter describes two strain gauge instruments made in the United States for Baldwin-Southwark by the Foxboro Company.

Chapter Six, "Problems in Measuring Dynamic Strain," is concerned with calibrating the apparatus electrically by inserting a known resistance change in the circuit, or by mechanical means such as deflecting a beam a predetermined amount. There is a discussion involving materials used in slip rings and brushes and the effect of their position in the bridge circuit.

Chapter Seven, "Applications of Strain Gauges," some of the uses mentioned; measuring residual stresses trapped inside materials during manufacturing processes such as heat treating, forging, etc. The complicated problem of measuring torque in a shaft is quite easily accomplished with the strain gauge. Measurement of the loads in ships upon launching has been successfully accomplished by the use of strain gauge accelerometers and portable weighting cells for aircraft use, pressure indicators, reinforced concrete measurements, flight test of aircraft, are but a few of the more obvious applications.

Chapter Eight, "Brittle Lacquer Method of Stress Estimation," is a brief resume of the application of brittle lacquer, its uses, limitations, and calibrations.

G. L. Rogers
McDonnell Aircraft Corporation

Constructive Uses of Atomic Energy

Edited By S. C. Rothmann. Pp. 258+ix, Figs. and halftones 48. Harper & Brothers, New York, 1949. Price $3.00.

Fourteen essays on the constructive uses of atomic energy are presented for the interested layman who still wonders whether atomic research is good for anything but to make bombs. These essays are for the most part reprints of papers written for various professional journals, and the array is impressive by reason of the diversity of fields represented: aeronautics, industry, chemical engineering, metallurgy, ceramics, soil research, biology, medicine, and pharmacy.

The series opens with a contribution by Arthur H. Compton on "Atomic Energy as a Human Asset," based upon a paper read in 1945 before the American Philosophical Society at a time when the future of the new atomic age was rosy. This great force was to make men demonstrate greater humanity (perforce). Now, after four years, the need is still there. Next, an elementary exposition of atomic structure is given by L. W. Chubb, and there follow twelve other essays on applications of tracer techniques and atomic radiations to various fields. These essays differ greatly in value and effectiveness. Some exhibit a high degree of analytical thought in which optimism is kept firmly in check by a critical review of the state of the art at the present time. Some authors admit frank skepticism, even pessimism, about the value of the new tools in their fields. Now and then, one can detect the presence of *bullonium* as a contaminant, but fortunately this defect does not dominate the book. On the whole, conjecture is kept under cautious control. That the by-products of the atomic pile have made available large supplies of inexpensive radioactive elements, that these can be used for investigations with tracer techniques, that there are dangers inherent in their use and that experimenters must exercise caution, that there are possibilities for power from atomic energy, and that there is promise of important advances in all fields—such conclusions are not surprising to any intelligent person in these days. However, this group of articles points out somewhat more specifically the limitations of these promises as of the present time.

Your reviewer found most interesting some of those chapters dealing with fields on the borderline of physics in which the details of experimental researches and findings opened to him new vistas and showed the manner in which tracer elements have been employed in such fields as medicine, metallurgy, and soil research. The chapter on "Atomic Energy for Aircraft," by Andrew Kalitinsky, was enlightening and provocative. Anyone who, within this lifetime, expects to have his private plane with plutonium-driven motor may be disappointed to read the analysis which the writer gives to this subject. The chapter by Blau and Carlin on "Industrial Applications of Radioactivity" was stimulating to the imagination with its numerous smart applications of radioactive materials to problems of control. The economics and feasibility of atomic power are discussed by H. Etherington.

At the end of the book there is an Appendix containing a brief chronological list of significant events in the development of atomic energy, a glossary of terms for the uninitiated, and a bibliography of 323 articles on atomic energy. A breakdown of this bibliography shows that the papers are selected from the publications of the Atomic Energy Commission (31), *Chemical and Engineering News* (12), *Nucleonics* (11), and the *Bulletin of Atomic Scientists* (9), with a scattering from 120 other publications, not including the *Physical Review* but including *Coronet*, *Colliers*, and *Popular Science*.

The book gives a good sampling of the fields of human endeavor that are now being touched by the possibilities of radioactive isotopes as a tool for research. It shows where progress has already been made, where lack of promise is apparent, and (as might be expected) how much work remains to be done before the promise of atomic energy as a constructive element in our civilization can be fully realized.

In the meantime, we still have the atomic bomb! What to do about?

Richard M. Sutton
Haverford College

Elektrische Messgeräte und Messeinrichtungen

By A. Palm. Pp. 284, Figs. 232. Verlag. Julius Springer, Berlin, 1948.

This book presents a very complete summary of electrical apparatus used in physical measurements. Since the book is of modest size the material is necessarily mostly descriptive. But adequate references to more detailed treatments are given throughout the text.

The book is divided into two parts of which the first is devoted to a description of electrical meters and the second to other electrical instruments and devices. The scope of the material presented is easily seen from the Table of Contents: Part I (Electrical Meters): Moving Coil Meters, Meters with Crossed Coils, Moving Magnet Meters, Moving Iron Meters, Watt Meters, Meters using Electromagnetic Induction, Hot Wire Meters, Electrostatic Meters, Vibration Type Meters, Relays, Recording Meters, Electricity Meters, Series and Shunt Resistances, Transformers, Summary of Characteristics of Electrical Meters. Part II (Electrical Instruments and Other Devices): Precision Resistors, Inductors and Capacitors, Bridges, Compensating Newtorks, Vacuum Tube Instruments, High Voltage Meters, Ohm Meters, Temperature Meters, Telemetering Systems, Miscellaneous Meters (Piezoelectric Pressure Indicator, Illumination Meter, Liquid Level Indicator, Gas Concentration Meter).

In the foreword to the book the author mentions that much of the recent foreign literature was not available to him. This probably explains why only one chapter is concerned with vacuum tube instruments, whereas nowadays vacuum tubes can be found in most electrical measuring instruments. Similarly much recent work done on telemetering systems is not mentioned in the text.

On the other hand especially the first part of the book is written with care and the book is worth while reading for anybody who would like to familiarize himself with the construction and operation of electrical meters and other instruments which were in use before the last war.

W. E. Meyerhof
Stanford University

Theory of Dielectrics

By H. Frölich. Pp. 179+vi, Figs. 47. The Clarendon Press, Oxford, 1949. Price $4.50.

The book is intended to give a systematic account of the theory of dielectric constant and of dielectric loss. The treatment, based on classical statistical mechanics, is rigorous and methodical. Controversies on the subject which have left it until recent years in the literature are analyzed and clarified in the light of modern investigations by Van Vleck, Onsager, Kirkwood, and the author himself.

The book begins with an exposition of the properties of the electrostatic field in dielectric media and of the thermodynamics of systems in external electric fields. The theory of the static dielectric constant is then treated in detail on the basis of certain general theorems developed by the author, from which the Onsager-Kirkwood theory of polar dielectrics is deduced as a special case. A critical discussion of the Clausius-Mossotti formula is presented from the macroscopic and the microscopic points of view. The limitations of the microscopic formula are discussed in the light of the work of Van Vleck and Kirkwood.

Anomalous dispersion and dielectric loss are treated from the standpoint of the Debye equations with a single relaxation time. Models for the Debye equations are discussed and generalizations are considered. In the final chapter the relationship between structure and dielectric properties is treated in detail, both for non-polar and polar substances. The dielectric behavior of dipolar substances in the gaseous state, in dilute solution, and in the liquid and solid state is reviewed. The book concludes with a discussion of ionic crystals.

The book can be recommended without reserve, not only to specialists in the field of dielectrics but also to all physicists, chemists, and applied scientists who wish to gain a clear and comprehensive grasp of this important field.

John G. Kirkwood
California Institute of Technology

Principles of Electricity and Electromagnetism

By Gaylord P. Harnwell. Second Edition. Pp. 670+xvi, Figs. 398, 16×23½ cm. McGraw-Hill Book Company, Inc., New York. Price $6.00.

Harnwell's book is an important book. Its roots lie right in the laboratory, its approach is modern, it is remarkably up-to-date in the choice of material, and it is written with vigor. It covers a great variety of topics in electricity and magnetism, all of them topics that every physics student today must somehow find the time to learn. This book should help to convince the budding experimentalist that certain equations, obstruse as they may seem at first sight, are not just frills but are essential for the understanding of electromagnetism. In the case of a theoretically inclined reader, this book should help to put across the idea that physics is made in the laboratory. I am sure that, both directly as a student's textbook and indirectly as an instructor's reference book, Harnwell's book has during the past ten years done a great deal toward making college courses in electricity and magnetism more interesting and more vital. With the appearance of the second edition, this important influence of Harnwell's book should become even more widespread.

The breadth of scope of Harnwell's book is shown by the chapter headings: Electrostatics (44 pages in the first edition, now 47 pages); Electrostatic Energy and Dielectrics (31 pages, now 34); Physical Characteristics of Dielectrics and Conductors (27 pages, now 29); Direct-Current Circuits (32 pages, now 34); Non-ohmic Circuit Elements and Alternating Currents (30 pages, now 36); Chemical, Thermal and Photoelectric Effects (33 pages, now 39); Thermionic Vacuum Tubes (38 pages, now 40); Electrical Conduction in Gases (35 pages); Electromagnetic Effects of Steady Currents (34 pages, now 37); Changing Electric Currents and Electromagnetic Reactions (34 pages, now 42); Magnetic Properties of Matter (41 pages, now 43); Electromagnetic Machinery (37 pages); Simple Circuits Containing Inductance, Capacitance and Resistance (35 pages); Coupled Circuits, Filters and Lines (37 pages); Vacuum Tube Circuits (38 pages, now 43); Radiation (46 pages, now 55); Mathematical Appendix (30 pages). The number of problems, most of which are of the more substantial sort, has risen from 381 in the first edition to 431 in the second. The text has been rewritten in a large number of places. The most important new topics added in the second edition are electron structure of crystals (including a brief description of the P-type and N-type semiconductors), magnetic induction accelerators, nuclear induction, very high frequency oscillators, and the propagation of electromagnetic waves in metallic enclosures.

The imposing list of chapter headings given above points up the fact that Harnwell's book is not only a comprehensive textbook, but also a valuable reference book for practicing physicists as well as for the growing group of electrical engineers whose work borders upon physics. This is especially so because, for a book written primarily as an orderly presentation of electromagnetism, this book lends itself unusually well to looking up individual bits of information. Also, one will find here thorough accounts of several important topics that are often slighted in books written primarily for physicists—one example is the excellent discussion of circuit theory. A most important feature of the author's style is that he somehow makes what he writes about especially interesting—as one turns the pages of this book, the various topics not only develop in a logical sequence, but also come to life.

Harnwell's book cuts across the lines of the usual undergraduate physics courses, such as the "E. & M." course, the electronics course, and the atomic physics course; its plan thus serves to emphasize the interdependence of the ideas involved in these branches of physics, and to tie them up with experimental techniques. This very fact would ordinarily make it difficult to fit Harnwell's book into the undergraduate program of a physics major; but I believe that, whether or not this book is used as a text in any of his courses, a student majoring in physics will do well to get a copy of "Harnwell" for his bookshelf—it should prove useful to him for many years to come.

My few criticisms of this book are minor and rather subjective. The equations are not punctuated; in my opinion this fact makes it harder to grasp the organization of the mathematical arguments and is therefore regrettable. The symbols grad and curl are printed **grad** and **curl**, in order to emphasize the fact that they stand for vector fields; to my mind this practice mars the appearance of the printed page to such an extent as to outweigh the small advantage that it may offer to a reader who is at all prepared to read a book as advanced as this book (strictly speaking, the symbol $\mathbf{A}$ for a vector is needed only because the symbol A is needed for another purpose). Volume density of charge is denoted by q_v and current density by $\mathbf{i}_v$; I think that, while in the case of q_v the subscript v suggests the correct units, it suggests incorrect units in the case of $\mathbf{i}_v$. (Some of the sentences in the book are too long; but since more than one sentence in this review has over 50 words, I am making this comment only parenthetically!)

By writing this book and by preparing ten years later this second edition, Professor Harnwell has done an important service to physics; he is to be congratulated heartily.

V. Rojansky
Union College

Our Sun

By Donald H. Menzel. Pp. 326+viii, Figs. 178. The Blakiston Company, Philadelphia, 1949. Price $4.50.

With the exception of the English translation of Abetti's book on the sun in 1937 there has been no new book on this subject for too long a time. The only place where one could look for new developments in the field of solar research was in the literature which though not too unpleasant is a time consuming task. Now a book of this type has appeared as the final number in the Harvard books on astronomy series. Delayed by the war the book has been enhanced by incorporating the war researches done by solar observatories under the sponsorship of the United States Navy. The author is Dr. Donald H. Menzel, Professor of Astrophysics at Harvard College, a recognized leader in the field of solar research.

It is rather curious that books on the sun are so rare. Of the 100,000 million stars in our galaxy there is only one whose surface can be studied in detail and that is the sun. In a sense the sun is the only cosmic laboratory where stellar theories can be formulated and tested for validity.

Since 1937 our knowledge of the sun has expanded through the introduction of powerful research tools like the spectroheliokinematograph, the coronagraph, and the skillful use of electronics in the fabrication of monochromatic filters and the use of electronics as operating and guiding aids. As a result there is found in the literature an enormous amount of detail about the sun which is difficult to trace. This book obviates the necessity of using many references in solar study.

In the planning of the book, Dr. Menzel seems to have pursued a definite pattern. He has glossed over some of the details of sunspots such as their distribution, use in the determination of the solar rotation, temperatures, law of polarity, proper motion, and other features in comparatively few pages. The above information is static and may be found in most textbooks on astronomy. He has reserved the book for the elements of new interest such as the newer theories for the formation of sunspots; the motion, classification and structure of prominences; and he has dealt in detail with the mystery of the solar corona a puzzling feature where the ionization of some of the atoms indicate a temperature in excess of a million degrees yet the photosphere has a temperature of but 6000 degrees. He has discussed the source of the sun's energy in terms of nuclear reaction. He has developed the interrelation of solar phenomena with short wave radio communication, to geophysics of the upper atmosphere and to meteorology. These subjects are fresh, dynamic, and in this reviewer's opinion the author is a dominant figure in this field and knows of no one better qualified to write about them.

Dr. Menzel has been very clever in his choice of analogies to strike home the essential features of a presentation. His comparison of atoms with radio transmitters and the development of this idea is striking in its impact as a device for interpretation. The effectiveness of a good writer lies in his ability to translate from the abstruse to the level of the general reader. Dr. Menzel has developed this skill to a high degree.

The addition of a table of eclipses for the 20th century is a welcome addition and at least for this reviewer it will relegate Oppolzer to the library.

There is one disturbing feature of the book and that is the rather high price. The Harvard series were originally published to sell for $2.50 and now for the same size book the cost has practically doubled. This increase in price simply means that it has been priced out of the range of some people who would want a copy. By careful examination of the book it seemed possible that the cost of the book could be cut by a decrease in the number of illustrations and a subsequent decrease in the number of pages. For instance, in *Our Sun* there are 19 photographs on the solar corona. Many of these could be eliminated without detracting in any way from the excellence of the book. As an example, in Dyson and Woolley's book *Eclipses of the Sun and Moon* there are four coronal illustrations. In this book there seems to be no justification for more than eight or nine. Further, the illustrations and tables tend to cover the larger part of a page or an entire page. It is this procedure which has helped make the cost of the book rise sharply. It is hoped that in the second edition these features will be closely examined to see whether a reduction in the cost of the book is a possibility.

Our Sun compares most favorably with the other books in the Harvard series. It is an invaluable source of up-to-the-minute solar information and it is highly recommended as an excellent addition to the library of both the astronomer and the general reader.

The Fels Planetarium of The Franklin Institute

Experimental Physics for Colleges

By Walter A. Schneider and Lloyd B. Ham. Pp. 411+xiv, Figs. 182. The Macmillan Company, New York, 1949. Price $3.80.

Experimental Physics for Colleges is a revision of a book first published in 1932. With the experiences gained and with opportunities provided for trying out many new experiments in the interim, the original text has undergone considerable change.

This book, while it is supposed to be used as a laboratory text with any general college physics text seems to be almost a general text in itself as well as a laboratory text. There are seven parts to the book including Units and Measurements, Mechanics, Sound, Heat, Electricity, Light, and Notes and Tables. Each part is divided into chapters making 33 in all and the chapters are divided into a total of 56 experiments plus four optional ones.

A chapter consists of experiments dealing with a common idea, includes a clear explanation of the general theory of the idea, and good directions for the specific experiments. Chapter XXI, Measurement of Resistance and Simple Circuits, for example has eight pages of theory and three experiments-measurement of the resistance of resistors in series and parallel by the ammeter-voltmeter method, Kirchhoff's laws, and measurement of resistance with a slide wire Wheatstone bridge.

The authors have written the book in such a simplified and explicit fashion that most students should be able to study the majority of the theory and experiments themselves, and be ready to go to work upon entering the laboratory. The experiments are designed for at least a two-hour experimental period. In the early chapters sample data are given and tabular forms suggested, but as the experiments progress the student is left more to his own ingenuity.

All the chapters include problems and questions for each experiment. The problems may be worked out by the students in preparing for laboratory but the questions are such that they must be answered after doing the particular experiment.

An idea the authors kept in mind was the use of inexpensive equipment as much as possible so that a laboratory without too large a budget could use the even front procedure. Good examples of this idea may be found in the experiments dealing with centrifugal force, impedance, and index of refraction. In the case of impedance instead of recommending a commercial piece of apparatus, the authors suggest using an inductor wound with No. 16 wire, a capacitor of about 10 microfarads, and a lamp of about 100 ohms. Then in the case of index of refraction, instead of requiring an expensive refractometer, the basic piece needed is a semicircular disk of glass.

Valuable suggestions are offered from time to time throughout the book such as the difference between totally and partially immersed thermometers, how to reason out certain equations rather than just memorizing them, and formulas for cleansing solutions.

The text concludes with notes on useful instruments and procedures, and the usual tables necessary for carrying out experiments in elementary college physics. The notes are especially good. Here can be found bits of information which can be of much help to the student. For example, one set of notes explains the differences between double beam trip scales, ordinary triple beam trip scales, and the better triple beam trip scales used for determination of specific gravity.

Experimental Physics for Colleges deserves careful consideration by anyone looking for a laboratory text for elementary physics. Part one may be a little disappointing but after that the book is interesting, clear, and challenging. A picture of a *fine balance* (analytical balance) might have been included in part one and the theory of the vernier could perhaps be improved.

ROBERT N. JONES
Philadelphia College of Pharmacy and Science

Industrial Rheology and Rheological Structures

BY HENRY GREEN. Pp. 311, Figs. 76. John Wiley and Sons, Inc., New York, 1949. Price $5.50.

This excellent rheological guide will be of decided interest and value to the experienced industrial rheologist and should also provide outstanding assistance and stimulation for the perplexed novitiate in the confused but important field of industrial rheology.

The book is divided into four parts entitled, respectively, "A Rheological System", "The System Applied to Laboratory Measurements", "The Particle—the Basis of Rheological Structure", and "Particle Groups Rheological Structures."

In the first seven chapters constituting Part 1, it is convincingly demonstrated that the position of the proponents of single point so-called "viscosity" determinations is absolutely indefensible, and that complete rheological diagrams must be established for non-Newtonian materials to provide the necessary information to define the system under examination. Anything less is not only useless but frequently is dangerously misleading. The author progressively leads the reader from Newton through Bingham, Buckingham and Reiner, and Rivlin, to his own contributions and those of his associates, based upon microscopic observations in combination with rotational viscometer determinations, particularly on thixotropic materials. The theoretical background, explanation of fundamentals, definition of various and sometimes confusing rheological concepts and nomenclature such as yield value, plastic viscosity, thixotropy, dilatancy, psuedoplasticity, and the like, and descriptions of previously suggested systems, are all extremely well presented.

In Part 2, Chapters 8 to 11, are given detailed information on the rotational and parallel plate viscometers, and instructions, with detailed examples on their use. Other types of viscometers frequently encountered in industrial laboratories are also briefly described.

In Part 3, Chapters 12 to 16, the value of the microscope in studying crowded particle systems is maintained and demonstrated. Definite rules are suggested in connection with detectability, size, shape, preparation of mounts, and finally precautions on the use of the electron microscope.

Part 4, Chapters 17 and 18, contains a tabular summary and discussion of discontinuous and connected structures, together with descriptions and comments on various classes of rheological materials.

Appendices, references, and author and subject indices complete this worth-while work. This book is recommended to all interested in industrial rheology from either the control or the research point of view.

Laboratory and Shop Notes

Units of Radioactivity

L. F. Curtiss, R. D. Evans, Warren Johnson,
and Glenn T. Seaborg
National Research Council, Washington 25, D. C.

November 10, 1949

In November, 1947, a joint committee of the Divisions of Chemistry and Chemical Technology and of Mathematical and Physical Sciences of the National Research Council was appointed to make recommendations regarding standards and units of radioactivity. This committee unanimously adopted the recommendations quoted below. The committee would like to point out that these recommendations effectively divorce the curie from the disintegration rate of radium by assigning to the former an arbitrary magnitude (3.7×10^{10} dis./sec.) approximately equal to the disintegration rate of radium. This arbitrary figure is therefore not influenced by any future revisions of the generally accepted disintegration rate of radium. This recommendation has been submitted to the Joint Commission on Standards, Units, and Constants of Radioactivity of the International Unions of Chemistry and Physics for the purpose of obtaining international agreement.

This changes, slightly, the meaning of the curie when applied to radium. For example 1 curie of radon is no longer, on the basis of these recommendations, the amount in equilibrium with 1 gram of radium, but is the amount undergoing 3.7×10^{10} disintegrations per second. Similarly, 1 mg and 1 mc of radium are no longer rigorously synonomous. This distinction has a number of precedents in physics; for example the international ampere, now abolished, was not quite equal to the absolute ampere and the angstrom unit is nearly, but not quite, equal to 1000 x units.

> "*curie.*—The curie should be defined as that quantity of any radioactive species (radioisotope) undergoing exactly 3.700×10^{10} disintegrations per second.
>
> "*rutherford.*—The rutherford should be defined as that quantity of any radioactive species (radioisotope) undergoing 10^6 disintegrations per second.
>
> "*r.h.m.*—For the quantitative comparison of radioactive sources emitting gamma-rays, for which disintegration rates cannot be determined, the *roentgen per hour at one meter* (r.h.m.) is recommended. This is not essentially a new unit since all units involved are well established, explicitly defined, and are in common usage."

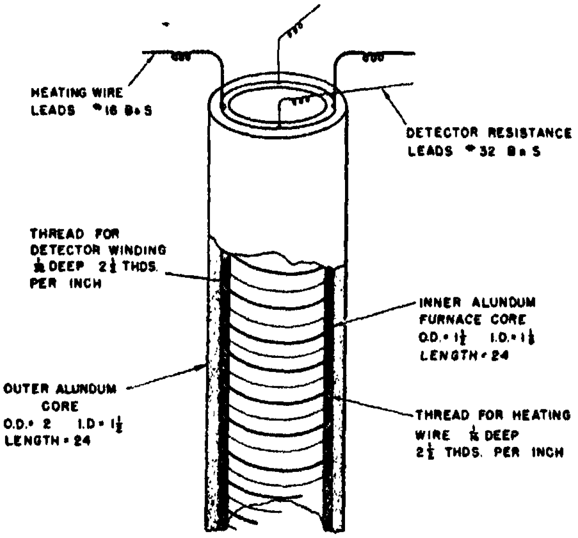
The recommendation of this latter unit is a practical step to insure that, by its use, gamma-ray measurements are so made with instruments and under such conditions that measurements on a given isotope (nuclear species) made in any laboratory will be directly comparable with similar measurements made in other laboratories. This will result, if the procedures used comply with the definition of the unit; that is, a source is 1 r.h.m. if it produces 1 roentgen per hour at a distance of 1 meter.

A Temperature-Controlled Resistance Furnace for High Temperature Measurements

W. G. Schneider and N. R. S. Hollies
National Research Council, Ottawa, Canada

August 1, 1949

Several temperature controllers for resistance furnaces have been described.[1-3] In these the temperature sensitive control element is either a thermocouple (or a resistance element) placed in the center of the furnace, or alternatively, the heating wire itself. The first of these methods is not sufficiently sensitive for larger furnaces due to the lag of the thermocouple (or resistance thermometer) in responding to small changes in heating current. The second method lacks stability, and hence also sensitivity, when operated from a power line with large voltage fluctuations. The present control system was developed for a furnace which was required to maintain a platinum gas pipet at a uniform temperature to within 0.05°C over a working temperature range from 600°C to 1200°C. The temperature control element is a small platinum resistance wire which is wound between turns and on the same core as the heavier heating wire. In this manner intimate thermal contact between the control element and the heating wire is achieved, resulting in a rapid response and a high degree of sensitivity to small changes in heating current. Stability in the control circuit is obtained by using a d.c. Wheatstone bridge fed from a 6-volt storage battery.



HEATING WIRE LEADS #16 B&S
DETECTOR RESISTANCE LEADS #32 B&S
THREAD FOR DETECTOR WINDING 1/32 DEEP 2½ THDS. PER INCH
INNER ALUNDUM FURNACE CORE O.D.=1½ I.D.=1⅛ LENGTH=24
OUTER ALUNDUM CORE O.D.=2 I.D.=1½ LENGTH=24
THREAD FOR HEATING WIRE 1/16 DEEP 2½ THDS. PER INCH

Fig. 1.

The assembly of the furnace core is illustrated in Fig. 1. It consists of two separate alundum* tubes which were specially selected free from warp and "kiln burn." The smaller tube with inside diameter 1⅛ in., wall thickness 3/16 in., and length 24 in., was ground down so that it fitted snugly inside the second and larger tube which had the same length and an inside diameter of 1½ in. and a ¼-in. wall thickness. To grind down the outer diameter of the smaller tube, the tube was fitted on a brass mandrel and waxed at both ends to prevent turning. Thus mounted the tube could be ground on a lathe using an ordinary grinding wheel and a stream of water flowing over the tube to catch the abrasive dust. After this operation four separate threads were cut on the inner tube, each with a pitch of 2½ threads per inch. Two of the threads, which were started 180° apart, were cut with an abrasive cut-off wheel† 1/16 in. in thickness, to a depth of 1/16 in. The remaining two threads were started at 90° and 270° and were cut with a wheel of 1/32 in. in thickness, to a depth of 1/32 in. The purpose of cutting the grooves in this manner was to allow for bifilar winding of both the heating wire and the resistance wire.

The heating wire consisted of 46 ft. of No. 16 B and S gauge platinum-10 percent rhodium wire, and the control resistance wire was a No. 32 pure platinum wire. The wires were wound on the tube while the latter was still held on a mandrel in the lathe, the heating wire being wound bifilarly in the 1/16-in. grooves, and the control wire in the 1/32-in. grooves. At room temperature the resistance of the heating wire measured 2.2 ohms and that of the control winding approximately 48 ohms. The wires were anchored at both ends by threading through small holes which were bored in the inner alundum tube with an ordinary high speed drill. After the wires were wound the tube was slid into the larger alundum tube.

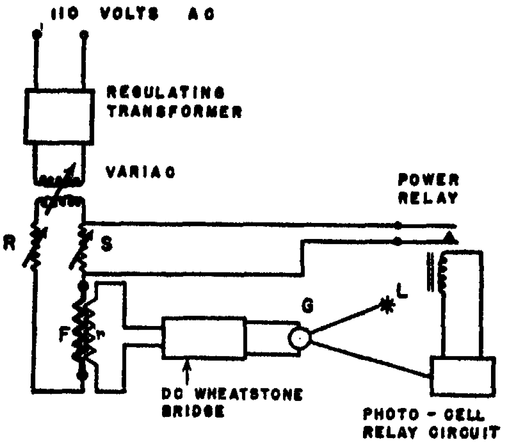


FIG. 2.

The latter served the double purpose of protecting the windings from impurities in the insulation material used around the core and of providing easy access to the furnace windings without disturbing the rest of the furnace assembly. Fitted cylindrical alundum bricks* were used on the ends of the furnace core and the whole assembly was surrounded with 4 in. of powdered aluminum oxide for insulation.

The heating and control circuit are shown schematically in Fig. 2. The furnace winding *F* is heated from a 110-volt a.c. line through a 3-kw Sola regulating trnsformer. A Variac and a variable one-ohm resistance *R* provide for adjusting the heating current of the furnace to a few degrees below the desired working temperature when the one-ohm variable shunt resistance *S* is in the circuit. The control resistance *r* completes a d.c. Wheatstone bridge circuit, the out-of-balance current of which is indicated by a sensitive mirror galvanometer *G*. The sensitivity is further increased by means of a 20-ft. optical lever on the galvanometer, which actuates a photo-cell relay circuit using an RCA No. 931A photo-multiplier tube. The relay circuit in turn operates a power relay which when closed shorts out the shunt resistance *S*. The latter, after the heating current has been properly adjusted and equilibrium reached, can be adjusted to a small fraction of an ohm to reduce the "on-off ripple" to a small value.

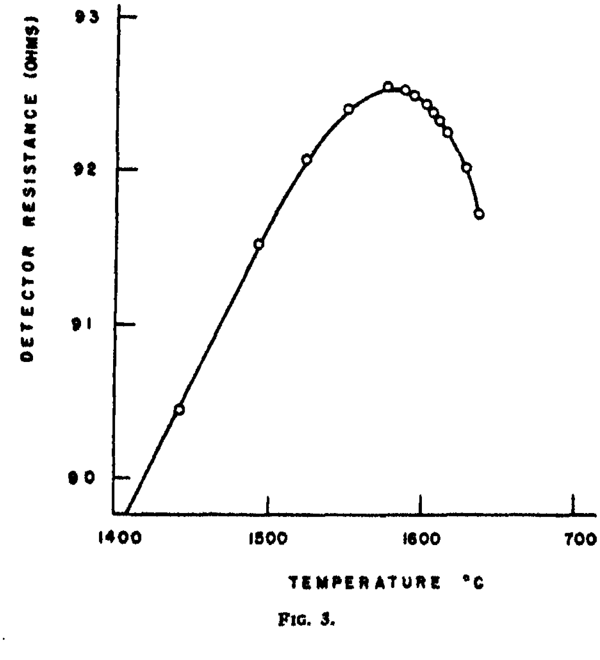

FIG. 3.

The temperature of the present furnace could be controlled at any temperature up to 1500°C. At temperatures above 1000°C the maximum ripple (as measured by a platinum, platinum-10 percent rhodium thermocouple in the center of the furnace) amounted to ±0.04°C and the average ±0.02°C. At lower temperatures the ripple was somewhat less. The resistance of the detector coil showed a slow but perceptible downward drift. For example, at 1000°C this amounted to approximately 0.2°C per hour, which was compensated for manually by adjusting the lowest resistance decade on the Wheatstone bridge. This drift is probably due to a slow recrystallization of the platinum wire. Above 1500°C an additional property of the platinum wire, shown in Fig. 3, was observed; the temperature coefficient of resistance of the detector winding (in this case a No. 28 platinum wire of "commercial" purity) became negligibly small around 1575°C and thereafter became negative. This behavior was also observed with a coil of No. 32 platinum wire procured from Johnson, Matthey, and Mallory Company and specified to be of "thermocouple purity." The coil was wound on a grooved alundum rod and supported in the center of the furnace. Accordingly the maximum temperature at which the control method described here could ordinarily be employed would appear to be approximately 1550°C. However there is a limited temperature range above 1600° in which the negative temperature coefficient of resistance could be utilized.

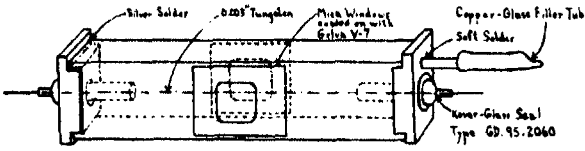
The Behavior of Rectangular and Square Section Transparent Beta-Counters

L. M. SILVER AND J. B. WARREN
Department of Physics, University of British Columbia, Vancouver, Canada

October 17, 1949

FOR some experiments it is necessary to use a Geiger counter through which beta-rays of moderately low energies may pass. Counters have been constructed as shown in Fig. 1, using rectangular section (1 in.×⅜ in.) and square section (⅞ in.×⅞ in.) brass tubing envelopes in the sides of which apertures up to 1 in.×⅜ in. have been milled and covered with mica windows. In this way with 2 mg/cm² windows the stopping power of the counter may be kept to 4 mg/cm² as compared to the 60 mg/sq. cm needed for a conventional cylindrical thin-walled glass counter with 30 mg/cm² wall thickness.



Silver Solder
0.005" Tungsten
Mica Windows sealed on with Glyptal V-7
Copper-Glass Filler Tube
Soft Solder
Kovar-Glass Seal Type GD.95.2060

FIG. 1.

The virtues, such as short dead time, of counters with rectangular envelopes as described by Curran and Reid,[1] have been substantiated. However, we have found that while square section envelopes give satisfactory Geiger operation over a range of 100 volts with plain mica windows ⅝ in.×⅝ in. and the usual argon/alcohol mixtures, it is necessary to make the inside surface of the mica conducting (with graphite or evaporated metal) when rectangular envelopes are used, since otherwise the central region of the counter behaves much as if the wire were beaded in the center.

Even when this precaution was taken with rectangular envelopes at the onset of the Geiger region over a range of 30 volts or so, two distinct size pulses were obtained, while if the counter was made with the windows placed asymmetrically, three pulse sizes were visible. In this last case it was possible to check that the two smaller sizes corresponded respectively to one or the other end of the counter discharging and the large size to those occasions when the discharge spread through the whole length of the counter.

Calculation showed that this failure of the discharge to spread at the start of the Geiger region and consequent lower efficiency in the window region can be explained by the reduction in the electrostatic field at the "critical" radius (taken as three times the wire radius) due to the small inevitable misalignment of the window with the inside surface of the envelope which, in this construction, amounted to less than $\frac{1}{32}$ in. Thus, for the maximum length plateau, it is preferable to use square section tubing. Rectangular envelope counters demonstrate clearly that it is important to avoid even small variations in the electrostatic field in the vicinity of the wire along its length.

We wish to thank the National Research Council of Canada for a grant and bursary held during the period in which this work was done.

A New Type Mass Spectrometer

Larkin Kerwin
Department of Physics, Laval University, Quebec, Canada

October 4, 1949

Of late a certain interest has been shown in improving the focusing properties of magnetic lenses. Bainbridge[1] has proposed the use of circular field boundaries to eliminate second-order aberrations, giving the radii which should be used, while Spighel[2] has also determined these radii. Hintenberger[3-5] has developed a more general theory which includes not only all circular fields, but also the "inflection" field developed in our own work.[6,7] In these latter papers is developed a theory which permits calculating the properties of lenses of any symmetric or assymetric shape, or conversely of designing a lens of any required order of focusing. The circular and inflection lenses are two of the several particular cases of this theory which appear to be of some practical value.

A mass spectrometer utilizing an inflection lens has recently been completed and tested in this laboratory. Although the mechanical appearance of the analyzing field is about the same as for conventional spectrometers, the use of the new focusing principle[5-7] has resulted in the achieving of third-order focusing. The appearance of the ion beam trajectory may be seen in Fig. 1. The shaded section represents the magnetic field of the available magnet, corrected for fringe effect.[8] The pole pieces constitute a magnetic sector of 90°, so that α is 45°. From Table I of reference 6, we see that a 90° magnetic sector may be used as a third-order inflection field if θ is made equal to about 30°. The geometric constants were calculated as follows.

From the given shape of the pole pieces, x was measured as 16.6 cm (corrected for fringe field effect). α was given as 45°. This angle must equal the slope of the ideal focusing boundary, which may be obtained by taking the derivative of Eq. (1).[6] Inserting the values of x and α given above and the relation between x, R, and a at the inflection point,[6] we find that $a = 51.8$ cm. Equation (7)[6] then permits us to calculate R, equal to 33.9 cm. Finally, from the relation $x = R \sin\theta$ we get $\theta = 29.3°$.

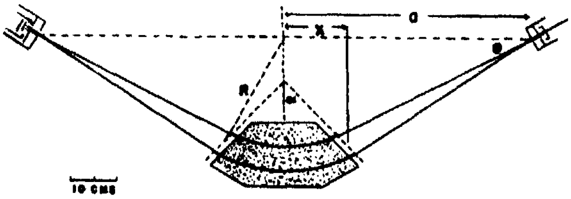

FIG. 1. Geometry of ion beam trajectory.

The magnet design resulted in a very compact instrument which is completely a.c. operated. The various circuits servicing the spectrometer are in the main similar to those described in the excellent paper by Thode, Graham, and Harkness.[9]

In operation, the spectrometer has a resolving power equal to that predicted by the third-order focusing theory, within the experimental error due to measurement of slit widths, etc. Second-order aberrations would thus appear to have been eliminated in practice. As pointed out previously, this advantage is used mainly to increase the beam intensity by increasing the beam divergence.

The magnet's field strength of 6000 gauss, ion beam trajectory radius of 33.9 cm and accelerating voltage of about 2000 volts permit the spectrometer to handle ions up to mass 800. The resolving power is set to the desired value by adjusting the slit widths.

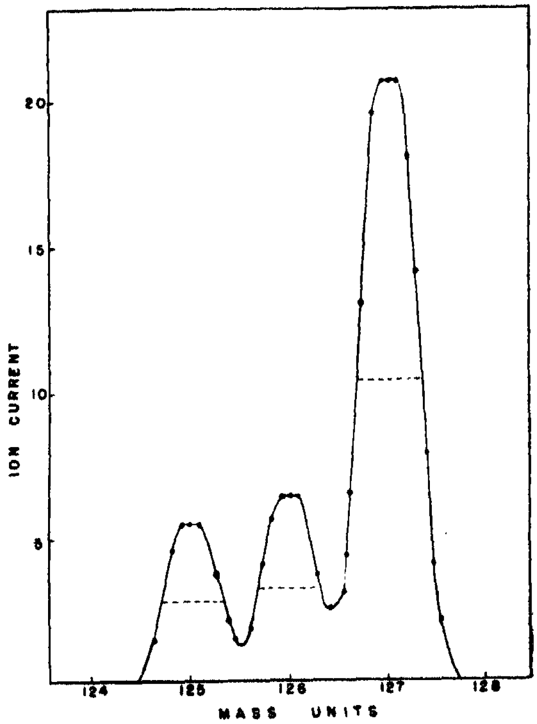

FIG. 2. Iodine peak in presence of naphthalene.

A typical spectrogram is shown in Fig. 2. For this run the slit widths were adjusted so as to give flat-topped peaks. (From the geometric constants of the spectrometer, Eq. (12)[6] enables us to calculate the dispersion per unit mass as equal to 1.8 mm at mass 126. The exit slit was made 1.4 mm wide, so as to be larger than the beam width. It can be shown that for a flat-topped peak, the width of the peak measured at half its height should equal the exit slit width. From the spectrogram, this width is measured to be about 1.3 mm. The beam width at the collecting slit was composed of the entrance slit image, the third-order aberration, and the velocity dispersion. The first is theoretically equal to the entrance slit width,[6] which was set at 0.3 mm. The second may be calculated from Eq. (9)[6] and for the beam spread of about 8° given here is equal to 0.2 mm. The velocity dispersion was set at 0.4 mm, permitting the use of wide electron ionizing beam to increase intensity. This gives a total image width of 0.9 mm. Since this is 0.5 mm smaller than the exit slit width, the flat top should be about 0.5 mm wide. From the spectrogram this is seen to be about 0.3

mm. Regardless of the shape of the ion peak due to intensity distribution, the width may be accurately calculated as being equal to twice the width at half-intensity (exit slit width) minus the top width. This method is often more accurate than direct measurement at the base, if the peak "tails" are difficult to measure. Theoretically this gives a total base width of 2.3 mm while the measured value is also 2.3 mm.

The resolving power for the inflection case may be calculated from the dispersion, aberration, and other image width components. It is given by:

$$RP=(2\times R)/(3\times W),$$

where R is the radius of curvature, and W the total apparent image width, including exit slit. In this case it should be about 96. Measurements on the spectrogram give a resolving power of 98, which thus verifies the prediction. These measurements are taken at half the peak heights. The usual practice of measuring peaks at the base, or of extending the peak sides to the base does not appear to be exact; due to the lack of knowledge concerning the exact intensity distribution in the ion beam, and consequent uncertainty regarding the shape of the curved tails on the peaks. These are often too small to be measureable, and it is this effect which causes some peaks to appear wider than others, although in the same mass vicinity they are the same size, could the exact extent of these tails be measured. Measurements at the apparent peak base, neglecting these tails, will give a higher resolving power than is theoretically obtained.

It is interesting to compare this type of spectrometer with one of the normal type. The same pole pieces used in the usual fashion would give a radius of curvature of only about 20 cm instead of about 34, and the magnet would have to be much heavier to supply the higher field necessary to bend the ion beams in this trajectory. The resolving power and intensity would have been correspondingly lower. A 90° sector normal instrument of the same resolving power and intensity would require a magnet of six times the weight.

It is to be noted that there is still room for improvement. In a recent paper[10] Geoffrion has shown how the optimum relationship between source height and width may be calculated for a 180° spectrometer. This technique may be extended to other instruments, such as this one.

The writer acknowledges with pleasure the encouragement of Professor Enrico Persico and Professor Paul Koenig during the construction of the spectrometer, as well as many fruitful discussions with his associate, Professor Claude Geoffrion. Skillful assistance was also generously given by Mr. Edward Leger of the Chemistry Department, and Mr. Robert Roy, Department Technician.

An Improved Method of Directing Liquid Flow in a Closed System*

L. G. Stang, Jr. and G. J. Selvin
Brookhaven National Laboratory, Upton, New York

October 27, 1949

A REMOTELY operated closed system for chemical processing requires, if it is to be flexible, a device for directing the flow of liquid into any one of several lines. A manifold from which lead several lines each containing a stopcock or valve is not con-

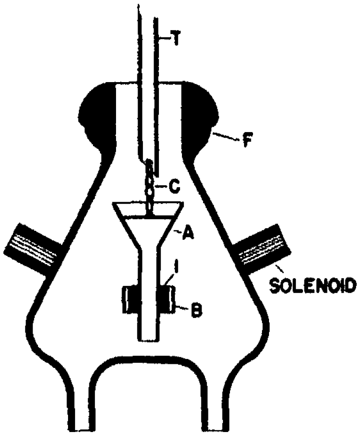

Fig. 1.

sidered appropriate for use with radioactive solutions for a variety of reasons: (1) Such a system invariably has some hold-up in it, and, as a rule, in handling radioactivity both total volumes and held-up volumes should be kept at a minimum. (2) Valves are usually made of metal and are, therefore, subject to corrosion and are sources of contamination. (3) Stopcocks, including even the so-called "No-Lube," require some grease which tends to adsorb activity from a solution. (4) Both stopcocks and valves require more maintenance than may be conveniently given them when they are part of an apparatus operated remotely from behind a concrete wall.

During the war, one of us (L. G. S.), in collaboration with D. Richardson and R. Ballard at Clinton Laboratories, Oak Ridge, Tennessee, solved this problem satisfactorily by constructing the all-glass "Magnetic Cow" shown in Fig. 1. This consists of a stationary flask, F, sealed into the system. Entering the top of the flask is a liquid-inlet tube, T, on the end of which is suspended a glass funnel, A, by means of a glass chain, C. Surrounding the stem of A is a soft iron cylinder, I, completely enclosed by a glass sheath over which is placed a plastic bumper, B. Around the periphery of the bottom of F are sealed any number of liquid-outlet tubes and against the outside of the flask in positions corresponding to the outlet tubes are placed solenoids, one for each outlet tube. By actuating the proper solenoid the funnel is inclined so as to divert liquid into any outlet. This device was quite successful and, with a little care in the design, could be made so as to give 100 percent diversion with no apparent splashing into other lines.

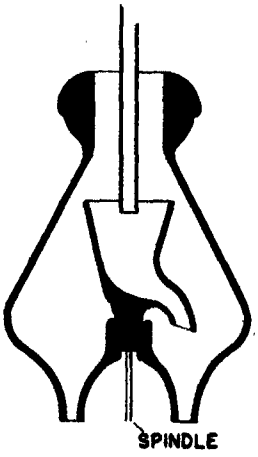

Fig. 2.

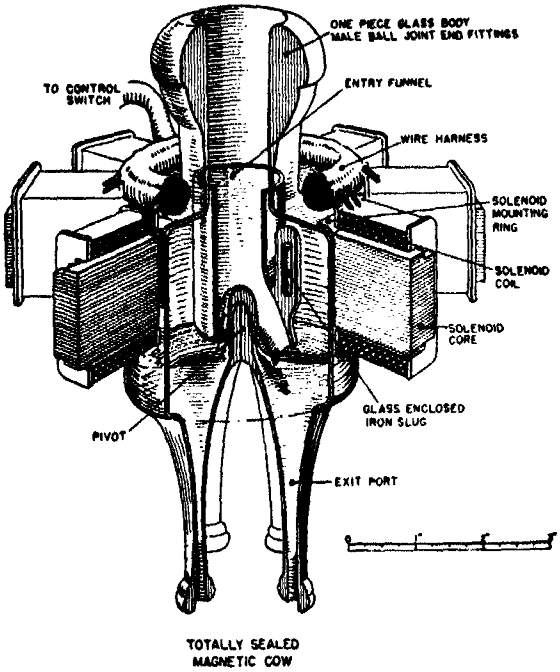

FIG. 3.

A previous model tried, the "Mechanical Cow," is shown in Fig. 2. In this case the funnel stem is offset and rotates about the center of the flask. Rotation is effected by a suitable mechanical connection to the spindle attached to the funnel extending through the joint in the center. This device was not successful since when the remainder of the system was evacuated, the joint in the center of the flask tended to leak even when held by a spring clamp, and when the system was put under pressure the joint stuck. Passage of a thermally warm solution through the funnel softened the grease used to lubricate the joint and aggravated both of these faults.

The authors have combined the above two principles into a third device, shown in Fig. 3. In this device the funnel rotates about a pivot as in Fig. 2. As in Fig. 1 solenoids are placed around the outside of the flask—one for every outlet. If these solenoids are too far apart for smooth operation auxiliary solenoids may be placed in between them. For a device using X solenoids an X-point rotary control switch is connected to the solenoids so that rotating the switch through a given angle rotates the funnel through an equal angle.

This device has numerous obvious advantages over the one shown in Fig. 2, and two important advantages over that shown in Fig. 1: (1) This device avoids the swinging of the funnel which occurred in the case shown in Fig. 1, and the consequent possibility of breakage each time the funnel hit the flask. (2) In the new device current is supplied to the solenoid only when changing position of the funnel. This avoids the necessity of having to dissipate heat from the solenoid and makes the device foolproof in case of power failure. Of course in case of power failure the funnel could not be rotated until power is restored but power failure itself would not cause a change in funnel position as in the case shown in Fig. 1.

Tests made at Brookhaven National Laboratory on a four-outlet glass cow sized as shown in Fig. 3 have proved the new device successful. It is obvious that this same device could be made of plastic instead of glass.

We are indebted to Mr. Paul Roman for the actual construction of the model.

Measurement and Amplification of Minute Displacements by Frequency Modulation

P. A. Bricout and M. Boisvert
Faculté des Sciences, Laval University, Quebec, P. Q., Canada

May 14, 1949

USE of f-m for detection of small changes of capacity is well known but the plain wiring of our apparatus seems noteworthy. All functions are performed using only two tubes: an oscillator and a discriminator, to which can be added an amplifier stage when the sensitivity of the recorder is insufficient. The displacement to be measured is secured to the moving plate of a condenser, which is part of an oscillating circuit and produces changes of frequency. As the *relative* one variation of capacity is always very small, say less than one or two percent, relative frequency shifts are of the same order of magnitude.

Use of a high-frequency is therefore necessary to obtain an *absolute* frequency change that can be easily detected. We have chosen a central frequency equal to about 10 mc so that a relative variation equal to one percent of this value will give a frequency shift of 100 kc, corresponding to the normal range of the discriminators used in f-m receivers.

Principle of apparatus.—The core of the apparatus is a variable condenser consisting of a pressure box (Fig. 1) closed by a thin diaphragm, D, and containing an adjustable insulated plate, B. The plates of the condenser are the envelope with the diaphragm and the inner disk. Capacity is adjusted by changing the distance from the diaphragm to the insulated plate which is firmly pressed by a spring, R, against the tips of three micrometric screws, V. For normal operation, a typical value of the capacitance is approximately 24 mmf. Any flexing of the diaphragm by reduced or increased pressure in the box will produce a capacitance variation, which is detected by a frequency shift of an oscillator connected to the plates of the pressure box. For a given flection, the variation of capacitance is the largest when inner plate and diaphragm are the nearest, hence an easy adjustment of the sensitivity.

Frequency modulation and amplitude modulation.—A basic point in the design of the apparatus is the possible interference between a-m and f-m. It is difficult in practice to obtain a perfect steadiness in the output of the oscillator and a change in amplitude may affect the discriminator in the same way as a change in frequency. As the displacements to be measured control only the changes of frequency, it is very important to make the discriminator insensitive to a-m. Use of pentodes as limiters in connection with resonant circuit discriminators is a conventional solution but it introduces one or two more tubes on the chassis.

A new discriminator described by W. Bradley in *Electronics* (November, 1946) is practically insensitive to a-m if the input e.m.f. exceeds a critical value (about 0.6 volt). It uses only one tube, the new Philco Pentagrid f-m 1000. We thought that this discriminator was fit to meet our requirements and we designed the apparatus to admit it.

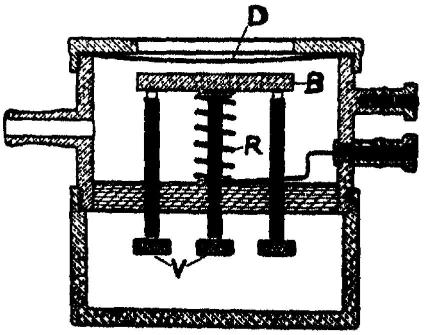

FIG. 1. A cross section of the pressure box.

---

* The device described herein was developed at Brookhaven National Laboratory under the auspices of the AEC.

Description of apparatus.—The pressure box is the capacitor, K, for a Hartley oscillator using tube 6J5 working class A (Fig. 2). A variable condenser is used to adjust the frequency of the oscillator within the range of the discriminator. The oscillator is coupled to the discriminator by a r-f stepdown transformer which applies the frequency to be measured between the cathode and the third grid of tube f-m 1000.

The discriminator can be considered as a T.P.T.G. oscillator with a plate circuit highly dampened by a shunt resistance and tuned to the main frequency. The grid tuned circuit, which is inductively coupled to the plate circuit, feeds the first grid of the heptode. This grid has a large negative bias. The triode part of the tube, made of the first two grids, works as a class C oscillator with a highly pulsating plate current. When the frequency to be measured is applied to the heptode mixing grid, the two frequencies tend toward synchronism. This may occur because the resonant frequency of the f-m 1000 oscillator is not critical due to the high damping of its plate circuit. The change in frequency varies the impedance of the plate and associated circuits, producing a variation of the direct component of the plate current.

By a suitable adjustment of the discriminator circuits, this component can be made proportional to frequency deviation within a range of 75 kc. It is also possible to give a slight curvature upwards or downwards to the response curve of the discriminator. Plate current flows through a 44,000 ohm resistor so that the output of the discriminator is a d.c.; e.m.f. proportional to the frequency deviation, i.e., to the displacement to be measured. The r-f component of the plate current (at 9.1 mc) is not registered by the measuring instrument. When this latter has a poor sensitivity, as in the case of electromagnetic oscillographs, it is necessary to use a d.c. amplifier stage. A 6L6 triode delivering 100 to 150 mA has proved satisfactory.

Adjusting.—It can be seen that one of the great merits of the equipment is its many adjustments which render it suitable for measurements of many kinds. (a) Sensitivity adjustment: The relative variation of capacitance of the pressure box for a given displacement of the diaphragm is greater when the internal part is close to the membrane. A very simple adjustment of the sensitivity is obtained by use of the micrometric screws. (b) Adjustment of the scale position: The discriminator is adjusted in a final position for a given main frequency. The variable condensor, C, of the oscillating circuit is adjusted to change the frequency of this circuit. If a series of tests is taken within a certain range of diaphragm movement and it is required to carry out further tests in another range, it is only necessary to adjust C to bring back the oscillator frequency within the working range of the discriminator. (c) Linear adjustment of scale: Though the diaphragm displacement may not be proportional to a physical dimension to be measured, an output proportional to the physical dimension may, however, be obtained to some extent by correcting the response curve.

Characteristics of apparatus.—The apparatus is of high fidelity and is stable if the tubes are in operation for approximately ten minutes before measurements are taken. The apparatus should be supplied with constant voltage having no alternating current components. Many measurements taken in the laboratory have shown that the output current was not showing sudden changes larger than 1/150 its normal value. If a sensitive oscillograph were used eliminating the need of an amplifying stage, the stability would be enhanced. In its present form, the relative error is less than one percent.

Applications.—The apparatus, due to its flexibility, has many applications. We will mention here a few of the uses it has had.

1. Manograph: An over pressure and an under pressure at the interior of the pressure box produced a displacement of the diaphragm which is measured. Using a steel diaphragm whose diameter and thickness are respectively two inches and 10 mils, the maximum amplitude of the apparatus (110 milliamperes at the output stage of the amplifier) was obtained for a difference in pressure not exceeding 20 millimeters of mercury. With the oscillograph paper traveling at the speed of 50 centimeters per second, variations in pressure were measured for durations of approximately 1/2000 of a second.

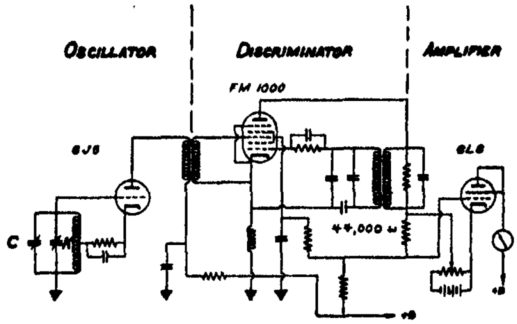

FIG. 2. Wiring schematic of the apparatus.

The following uses, as a graphic manometer, were made: (a) detection of muzzle shock wave in fire arm; (b) study of vibrations of a sound pipe; (c) study of a sudden entrance of gas in pipe; (d) in collaboration with Professor C. Ouellet, measurement of pressure created by a mixture of ether vapor and oxygen at low pressure (cold flame).

2. Vibrometer: In inserting the pressure box between the flange of a beam and a fixed support, it was possible to register the vibrations generating in the beam by an impact. It was possible to study the propagation of sound waves along the beam and their reflection at the end.

3. Seismograph: The vertical and horizontal movements of the mass of a seismograph can be registered by means of three pressure boxes mounted at right angles. The sensitivity of the apparatus allows the mass to be reduced in size.

Scintillation-Type Ion Detector*

PAUL I. RICHARDS AND E. E. HAYS
Brookhaven National Laboratory, Upton, New York

September 19, 1949

THE time-of-flight mass spectrometer[1] being constructed at this laboratory requires a sensitive detector to indicate the *time* of arrival of low energy ions and capable of working in a magnetic field of about 500 gauss. It was felt that one possibility worth investigating was the following: When the ions reach the detector, they are accelerated to relatively high energy and projected upon a luminescent material. The resulting photons are then piped along a quartz rod out of the vacuum system and away from the magnetic field, where they in turn may be detected by a conventional photo-multiplier tube and amplifier.

While the physical processes are rather redundant, the method has the advantage of simplicity, utilizing only commercially available or easily constructed elements; also, relatively little space and material are required within the vacuum system. Since a single energetic ion can produce many photons, there is even a possibility of a gain in signal-to-noise ratio over a simple electron multiplier. Against these advantages must be weighed the need for optical shielding and the finite emission time of the phosphor; our application requires a recovery time of less than one microsecond.

The ions from the mass spectrograph entered the detector through a grid and were accelerated around a corner as shown in order to facilitate optical shielding (Fig. 1). The 30 kv accelerating voltage was obtained from a television-type r-f high voltage supply with a voltage-doubler rectifier arrangement. Both the 1P21 and 5819 photo-tubes were used; the latter appeared to be only slightly more sensitive than the former in our arrangement. Cementing the

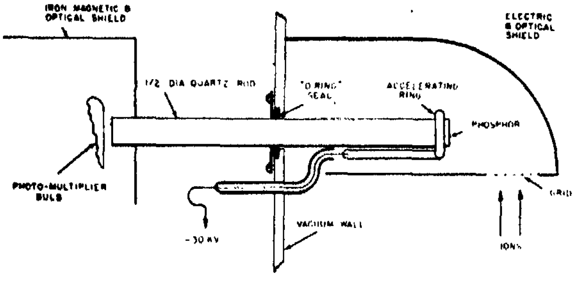

FIG. 1. Scintillation ion detector.

quartz rod to the bulb of the photo-tube with Canada balsam produced no appreciable improvement. The sensitivity of the detector was found to increase with increasing accelerating voltage up to at least 30 kv. Detection of the larger pulses (10^3 to 10^4 ions in about ½ microsecond) starts near 1 kv followed by a rise at first more than linear (up to about 10 kv) and thereafter tapering off to a more linear relation. These large ion currents could, of course, easily be detected by other means, such as an electrometer tube; our application, however, requires extremely rapid response. The only other possibility seems to be an electron multiplier designed to work in the magnetic field.[2]

Three phosphors were studied: silver-activated zinc sulfide, thallium-activated sodium iodide, and anthracene. The sensitivities of these three materials to positive ions appeared to be equal within a factor of about two, rough measurements indicating that, in our arrangement, each ion releases about one photo-electron from the cathode of the multiplier tube. Although a 30 kv ion probably produces 1000 or more photons, the efficiency of the multiplier cathode is only one percent, and the optical system is probably about ten percent efficient.

The synchroscope pictures shown in Fig. 2 were obtained with the preliminary model of the mass spectrograph described in reference 1. The ion source was pulsed during ½ microsecond at an arbitrary repetition rate. The magnetic field was about 600 gauss, so that the time of flight for one revolution was slightly more than one microsecond per mass unit. The sweep shown is 100 microseconds long, starting at the instant the source is pulsed. The peaks, from left to right, as seen in Fig. 2c, are K^{39}, K^{41}, K^{39} twice around, K^{41} twice around, Rb^{85} and Rb^{87}.

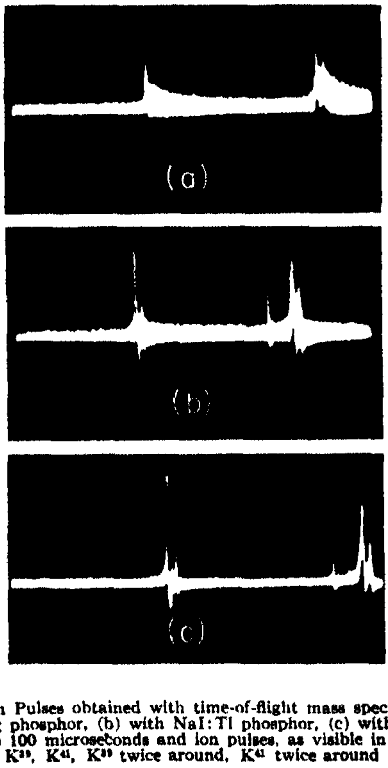

FIG. 2. Ion Pulses obtained with time-of-flight mass spectrograph: (a) with ZnS:Ag phosphor, (b) with NaI:Tl phosphor, (c) with anthracene. The sweep is 100 microseconds and ion pulses, as visible in (c) are from left to right K^{39}, K^{41}, K^{39} twice around, K^{41} twice around (weak), Hb^{85} and Hb^{87}.

Of the three materials investigated, ZnS:Ag is the most conveniently used. It is unaffected either by humidity or vacuum, and the powder will adhere to the end of the quartz rod after the latter has merely been rubbed in the hand. Because the material must be extremely pure, it cannot conveniently be made in the laboratory, but it is commercially available either in the form of a powder or a screen (Patterson-Type D x-ray intensifier screen). The principal disadvantage from our point of view is the long decay time of about 25 microseconds (Fig. 2(a)), which tends to mask small ion bunches following closely on larger ones. For measurement of d.c. ion current, however, ZnS:Ag is probably the most convenient of the three.

NaI:Tl[3] has a much shorter recovery time (Fig. 2(b)) than ZnS:Ag and, like the latter, will withstand the vacuum indefinitely. It is, moreover, extremely simple to prepare and ordinary reagent-grade chemicals are of sufficient purity. We have found the following method most convenient: NaI and TlCl are dissolved in distilled water roughly in the proportion 100 to one-or-more by volume. As the water is boiled off, the solubilities of the salts control the proportion of thallium "impurity" in the final powder, and an excellent phosphor is produced.[4] (TlI may be substituted for TlCl with almost as good results.) A convenient way of placing the phosphor on the quartz rod consists of heating the latter well above 100°C and painting the solution on it. The great disadvantage of NaI:Tl for ion detection, however, is its extreme deliquescence, which requires that it be placed in the vacuum system while still hot and renewed each time the system is opened. Also, it will be seen from Fig. 2(b) that there is evidence of a long-period component which might cover weak ion bunches.

Anthracene, of the three materials investigated, probably has the best combination of properties for our particular application. The recovery time is very short, and there is little evidence of a long-period component (Fig. 2(c)). The crystals were attached to the end of the quartz rod by imbedding them in a thin layer of Dow-Corning silicone stopcock grease. Although the material evaporates in a vacuum, the process is quite slow; in one case, 0.028 g of a 0.044-g crystal evaporated during 60 hours at 5×10^{-6} mm Hg, and its presence did not appear to affect the limiting pressure. Anthracene is not deliquescent and, for this application, need not be in the form of a single crystal. The commercial product, however, must be purified further before it will perform properly.

---

[4] Depending on the chemicals used, however, the efficiency may be as much as a factor of ten below that of a commercial "pure" crystal.

Method of Supplying Low Pressure Gases on a Vacuum System*

RAYMOND H. MCFEE
Photoswitch, Inc., Cambridge, Massachusetts

August 22, 1949

FREQUENTLY it is desired in connection with the treatment of work on a vacuum system to supply a gas to the manifold at a controlled low pressure. In a process which involves absorption of or reaction with the gas, a supply of the gas is required which is

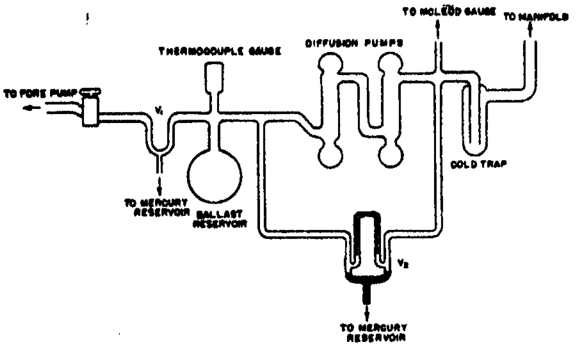

FIG. 1. Typical vacuum system with a double-range feed-back line with mercury valve control.

greater than that afforded by merely filling and closing off the system at the desired pressure. A reservoir of the gas could be connected to the system through a calibrated leak, while pumping on the system, but this is wasteful of gas, which may be of importance where a limited supply of expensive, high purity gases is available.

The method to be described has been in use for many months for the supply of a controlled, low pressure atmosphere to the vacuum system manifold for the purpose of processing photoconductive cells. A diagram of the system is shown in Fig. 1. It is essentially a standard, all-glass mercury diffusion pumping system with the addition of a feed-back line connected between the fore-vacuum manifold and the high vacuum end. A mercury valve is used to cut the feed-back line off, so that normal evacuation may take place. When the line is open the gas in the fore-manifold is pumped back through the feed-back line by the diffusion pumps, establishing a pressure differential between the fore-manifold and high vacuum manifold which is determined by the pumping speed of the diffusion pumps and the impedance of the feed-back line. Such a differential pressure scheme has been used by Monk[1] for the purpose of low pressure measurement by intermediate pressure gauges.

A double section feed-back tube is used, one section of which contains a length of capillary tubing, offering high pumping impedance. This allows two ranges of calibration of the pressure differential. The calibration curves for dry air in a typical system are shown in Fig. 2.

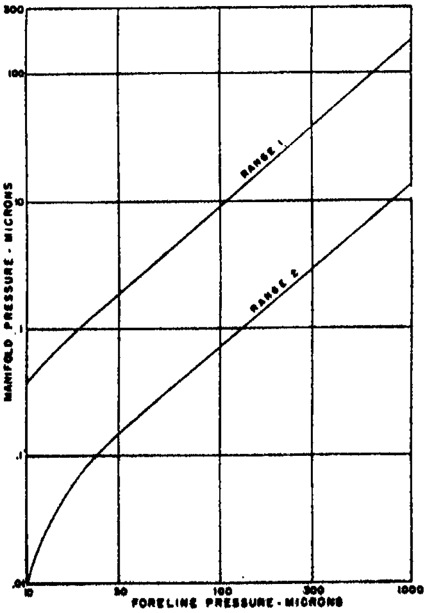

FIG. 2. Calibration curves for dry air for two feed-back line impedances.

The system in Fig. 1 is used as follows: The high vacuum end is pumped out thoroughly with the forepump and diffusion pumps. The forepump is then cut off and the pure gas introduced into the fore-vacuum manifold, its pressure determined by means of a thermocouple gauge. The mercury cut-off valve, V_2, in the feed-back line is opened, allowing the gas to circulate. After the pressure adjustment has been completed, the fore line cut-off, V_1, is closed, isolating the system from all stopcocks. The pressure in the manifold may be changed rapidly from one pressure to another, or to the high vacuum level simply by manipulating the valve V_2.

The advantages of both the closed, static system, and the leak flow system are present because a fixed, small quantity of gas is used with the flowing of the gas at constant pressure produced by the pumps. By the use of variable impedance feed-back lines, a system could be constructed which would allow rapid changing from one manifold pressure to several others without adjustment of the total quantity of gas in the system. The advantages of such an arrangement are obvious when applied to a set-up used for a large number of routine procedures.

A Convenient Gas Sample Tube Holder and Break-Off Applicable to Mass Spectrometers

FREDERICK HIGHHOUSE AND JULIUS WHITE
National Institutes of Health, National Cancer Institute, Bethesda, Maryland

November 1, 1949

IN conducting biological experiments using stable isotopes, many samples are collected for analysis. It has become necessary at times to store these samples for a considerable period before actual analysis in the mass spectrometer. In this laboratory these samples are conveniently collected and stored in sealed glass ampules. To transfer the gas from the ampule to the mass spectrometer, it became necessary to devise a gas sample tube holder and break-off which could be used directly on the spectrometer.

Figure 1 is a full scale illustration of the tube holder. Except for the rubber gasket *C*, the standard taper joint *F* (which leads into the spectrometer), and the windows at *G* the entire unit is constructed of stainless steel. By means of the screws *H* the entire tube holder is rigidly supported to a fixed bracket in the rear. Joint *F* is made air tight with sealing wax. Tube *A* which contains the sample to be analyzed is made of 10-mm tubing about

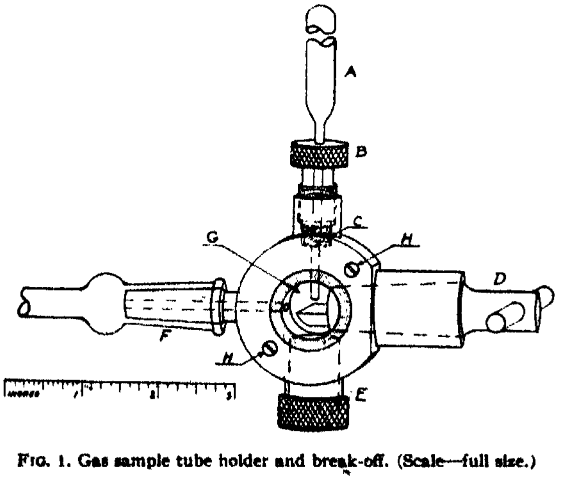

FIG. 1. Gas sample tube holder and break-off. (Scale—full size.)

6 inches long and joined to 3-mm tubing about 6 inches long. Before inserting the tube *A* into *B* a fine scratch is made near the 3-mm end (to facilitate breaking and prevent shattering). After tube *A* is inserted into *B* it is gently forced through the rubber gasket *C* into the well *G* and above the flat surface of the stopcock *D*. The knurled screw *B* is then tightened firmly (to prevent leakage of sample). After the assembly has been completely evacuated by the manifold pump of the spectrometer and the standard background reached, the stopcock of *D* is turned. As the flat edge of the stopcock in the well *G* turns it comes into contact with the 3-mm tube and breaks it releasing the gas into the spectrometer. This operation can be seen through the windows sealed in on both sides of the well *G*. The glass tip which has broken off drops down into *E*. After 20–30 samples, *E* can be unscrewed and the small glass tips which have accumulated drop out. After the sample has been analyzed, *B* is loosened, tube *A* removed and another sample tube inserted.

The advantages of this system are simplicity, ease of maintenance and removal of glass tips and old sample tubes, the relatively small internal volume and loss of little time in evacuation of the system between samples.

A Simple Contamination-Free Electron Gun[*]

H. E. FARNSWORTH
Brown University, Providence, Rhode Island

November 8, 1949

IN the usual type of electron gun, with the cathode mounted on the axis, evaporated material from the hot cathode produces observable contamination of a solid target in the course of several hours. This may be eliminated by mounting the cathode off the axis and deflecting the electron beam by magnetic or electrostatic fields. However, there are many applications in which the presence of a magnetic field is objectionable. Although the electrostatic method does not separate negative ions of different masses, and hence does not prevent them from following the path of the electrons, this method is adequate if one uses a cathode made of electropositive metal which does not evaporate in the form of negative ions. A thorough outgassing of the cathode before applying the deflecting voltage eliminates the possibility of contamination by negative gas ions.

A gun of the electrostatic type which uses only one deflecting electrode and produces an electron beam of high current density over a wide range of energies is illustrated in Fig. 1. This gun is similar to that previously described by the writer[1] except for the deflecting electrode G_2 and the off-axis cathode arrangement. Electrons emitted by *F* are accelerated and pass through G_1, are deflected by a suitable voltage on G_2, and pass along the axis of A_1 and A_2. G_2 is mounted so that its center of curvature lies on the circle passing through the center of *F* and the aperture in A_1, the circle being centered at the lower edge of G_1. None of the dimensions or adjustments appears critical, although no detailed study of this has been made.

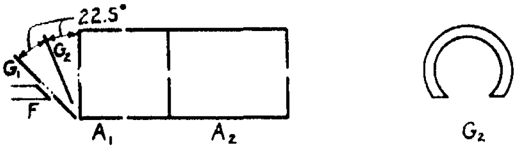

FIG. 1.

To simplify conditions, G_1 and A_1 are connected together. With an accelerating potential difference of 70 volts between *F* and G_1, the required potential on G_2 with respect to *F* is between −100 and −200 volts. The net energy of the electron beam is varied by altering the potential of A_2 with respect to A_1. Satisfactory results have been obtained for beam energies in the range 0 to 8000 ev with no indication that the upper limit has been reached. For the higher energies a slight readjustment of the potential of G_2 is required due to interpenetration of the fields. A guard ring *R*, surrounding A_2 and connected to G_2, prevents electrons from passing outside the electrode A_2.

To date the gun has been used with tantalum and tungsten cathodes, heated by conduction. A gun with a tungsten cathode has been used in a low speed electron diffraction tube which is sensitive to small amounts of contamination. No observable contamination occurred in a period of several hours. Because this gun possesses some velocity selection, the homogeneity of the electron beam is somewhat better than that of the conventional gun.

Financial aid has been received from the ONR and the Research Corporation of New York.

[*] The contamination referred to is from the cathode only. It is assumed that contamination from other sources is not present. This gun has been tested in all-glass systems which were outgassed by baking or torching and in which the residual gas pressure was less than 10^{-7} mm Hg. A cold trap surrounded by dry ice and acetone mixture was placed between the experimental tube and oil diffusion pumps in each case to eliminate oil vapors, and no grease or wax joints were present on the high vacuum side of the pumps.

Bent Crystal X-Ray Monochromators

B. E. WARREN
Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts

November 17, 1949

PLASTCALLY bent rocksalt and elastically bent quartz are used a great deal in x-ray diffraction work as focusing monochromators. To eliminate half-wave-length components, a bent 111 face of fluorite is often desirable. However, fluorite like many other crystals which might be used as monochromators is difficult to bend without breaking.

A crystal slab breaks on bending because the convex face is put into tension, and brittle substances are weak in tension. One way of avoiding this trouble is to grind the slab so thin that the tension developed is not excessive. This may involve grinding so thin that the slab will break in grinding and handling. A simpler method is to grind as thin as convenient, and then minimize the tension by superimposing a compression.

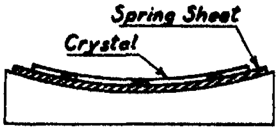

FIG. 1. Crystal mount.

A simple method for doing this is illustrated in Fig. 1. The thin slab of crystal is ground down to some convenient thickness, say 0.012–0.020 inch. It is then cemented to a flat strip of spring sheet metal such as steel or phosphor bronze. Duco cement has been satisfactory for this purpose. The spring sheet is then bent by screws along the side of the crystal slab and forced to fit a block having the desired curvature. Under these conditions, the concave side of the metal sheet is in compression and this diminishes the tension which would otherwise develop in the convex face of the crystal. By this method it is a simple matter to bend 111 slabs of fluorite, or to get good uniform bends in any of the other crystals commonly used.

A Motor for Use in Vacuum Systems

C. P. Butler and F. E. Carpenter
Naval Research Laboratory, Washington, D. C.

November 28, 1949

IN problems where evaporation techniques are used there is often a need for a motor which can be operated inside the vacuum chamber. Here the problem was that of turning a sectored disk in making an evaporated step wedge.

The most important requisite of any motor operated in a high vacuum system is that there shall be no outgassing from the coils, the armature or the bearings even at temperatures up to 100°C. This requirement precludes the use of any motor where insulated wire is exposed to the vacuum system. This requirement has been met by the use of a solid armature motor, whose field coils are hermetically sealed in a brass can.

A Model 61,115 volt a.c. 50/60 cycle 1550 r.p.m. 1/25 h.p. motor made by ILG Electric Ventilating Company, Chicago, Illinois was modified to operate in vacuum. The armature was removed and a brass can made to enclose the field coils. The inner sleeve of the can was of 1¾-inch O.D. brass tubing, and was press-fitted to the inside of the armature. The outer sleeve was of 3½-inch O.D. tubing. Two annular rings were cut to enclose the ends and soft soldered to the two sleeves, thus sealing the coils at atmospheric pressure. Two Kovar glass sealed lead-ins were fitted and soldered to one of the end plates, to which were connected the two wires from the coils. The separate units are shown in Fig. 1.

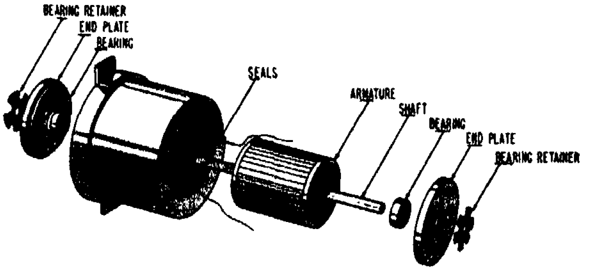

FIG. 1.

The armature of the Model 61 motor is made of laminated iron held together with a soft metal, and it can be easily turned on a lathe from its diameter of 1¾ inch to one of 1$\frac{11}{16}$ inch which gives ample clearance between the armature and the inside brass sleeve. Two end plates were cut to bolt onto the annular rings to support ball bearings for the motor. After completion, the ball bearings were removed from their mounts and the remaining assembly first immersed for 30 seconds in a "bright dip" solution, made with 2 parts sulfuric acid and 1 part nitric acid, and then thoroughly washed in water. The ball bearings were cleaned in acetone. The motor was reassembled and oiled with "Octoil."

In operation the motor was mounted in the bell jar and bare copper wires from the base plate terminals were clipped to the motor leads. A variac was used to control its speed.

The insertion of a brass sleeve between the field and the armature reduces the efficiency of the motor as well as increasing the heat developed when running at full speed. However, the temperature rise at full speed in vacuum was only 35°C during 2 hours operation.

This motor is currently being used to turn a sectored disk in making step wedges. It has been in operation for 4 weeks and no leaks have developed. After long usage, aluminum, chromium, nickel and other metals which have been used in evaporation form a deposit on all metal parts. This can be easily removed by repeating the "bright dip" operation.

New Instruments

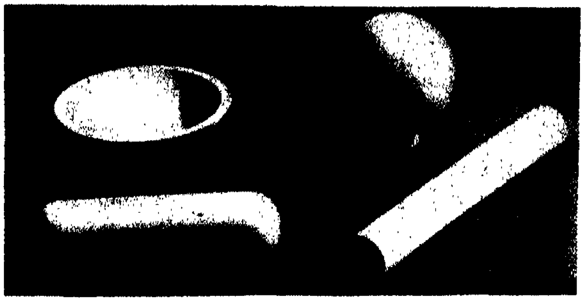
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Ultrasonic Equipment

The Brush Development Company has announced production of ultrasonic units of laboratory and industrial capacity to be sold under the trade name Hypersonic.

Included in this line of ultrasonic equipment are a variety of titanium ceramic transducers of special shapes for controlling the concentration of the sonic energy.



The ceramic transducers have the marked advantage over piezoelectric crystals previously used in that the electrical driving voltage does not have to be applied in a fixed direction relative to crystal axes; nor is the mechanical motion produced subject to this limitation. In ceramic elements, the direction of the mechanical direction is determined by a polarizing electric field applied during manufacture, and its direction may be made to vary at will from one point of the transducer to another. For example, in a tubular transducer element, the polarizing direction may be at all points directed toward the central axis of the tube, thus obtaining on the axis a high concentration of sound energy.

Write for detailed information on various models of Hypersonic equipment.—BRUSH DEVELOPMENT COMPANY, *Cleveland, Ohio.*

Oscillograph

Two new instruments, DuMont Types 304 and 304-H cathode-ray oscillographs, were announced recently as replacements for the famous Type 208-B cathode-ray oscillograph. The new units contain all the features of Type 208-B, plus others new to the low-priced field. Except for the somewhat higher accelerating potential of Type 304-H, Types 304 and 304-H are identical.

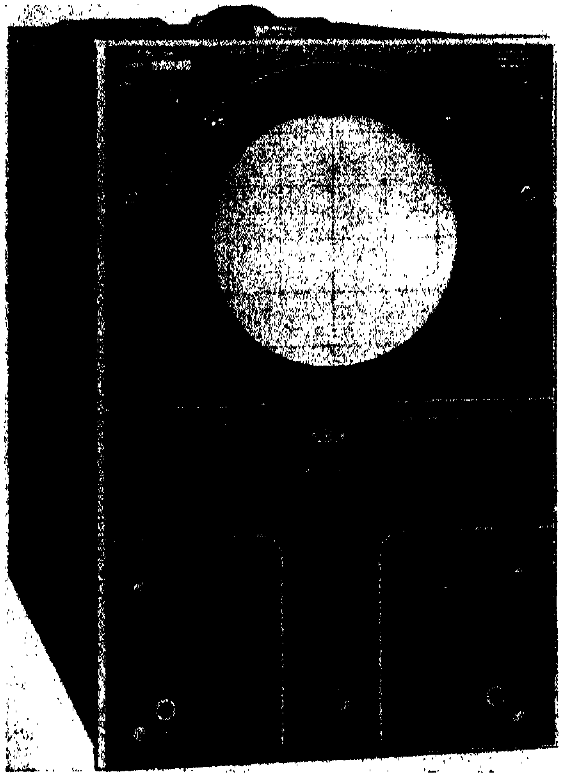
Stable, high gain a.c. and d.c. amplifiers are provided for both X and Y axes. Circuit design permits instantaneous recovery from signal overload, even at high gain.

Recurrent and driven sweeps are variable from two to 30,000 cycles per second. Through an arrangement of switches, extremely slow sweeps, of ten seconds or more, are available by the connection of external capacitors between the X-input terminals on the front panel.

Vertical deflections on these instruments may be expanded to four times full-screen diameter; horizontal deflections, to five times full-screen diameter. Positioning controls have sufficient range that any portion of a fully expanded pattern may be centered on the screen, with no on-screen distortion present.

Stabilized synchronization of the pattern is maintained in Types 304 and 304-H by a sync-limiting circuit, so the sweep length and synchronization are unaffected by variations in signal voltage level.

In Type 304, the cathode-ray tube is operated at an over-all accelerating potential of 1780 volts. In Type 304-H, an additional intensifier power supply increases this potential to 3000 volts. The higher accelerating potential of Type 304-H facilitates the use of long-persistence screens so that fullest possible advantage may be taken of the slow recurrent sweeps, the high speed driven sweeps, and the d.c. amplifiers of the instrument. Writing rates as high as 2.8 inches per microsecond may be photographed from the screen of Type 304-H using DuMont Type 314-A oscillograph-record camera with an $f/1.5$ lens.



In every dimension Types 304 and 304-H are smaller than Type 208-B, making them even more portable than was their predecessor.—INSTRUMENT DIVISION, ALLEN B. DUMONT LABORATORIES, INC., *1000 Main Avenue, Clifton, New Jersey.*

Ultrasonic Generator

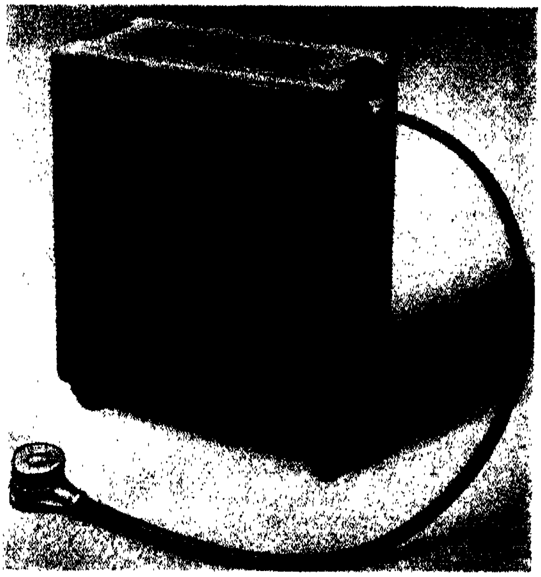
The Type E.7562 Mullard ultrasonic generator is designed as a laboratory tool for research.

The r-f output is generated directly by a silica triode capable of producing one kilowatt of r-f power. Four plug-in coil assemblies, which are rapidly interchangeable—are provided for operation around nominal frequencies of 250 kc, 500 kc, 1 mc, and 2 mc.

The output tube is matched to the crystal impedance by tapping the anode down the coil in the output circuit. Fine tuning of the output circuit and adjustment of grid coupling are effected by means of variometers.

The quartz crystal is contained in a metal case. It is connected to the generator by means of a coaxial cable. The crystal has silver electrodes fired on both sides to which the driving voltages are applied.

To give the maximum ultrasonic output in the forward direction, the generating crystal is air-backed. The limitations on the temperature at which the transducer can work are set by the polythene of the cable and the rubber sealing rings. If silastic rubber is used and the back of the holder is adequately cooled, the crystal can safely be immersed in liquids at temperatures up to at least 150°C.—MULLARD ELECTRONIC PRODUCTS, LTD., ABOYNE WORKS, *Aboyne Road, Tooting, S.W. 17, England.*

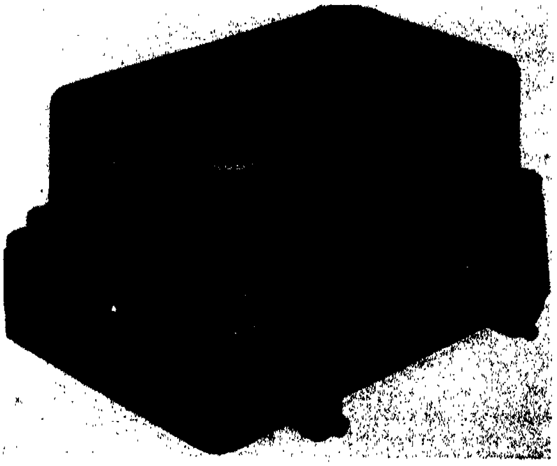


Universal Monochromator

The first true universal monochromator, which covers the ultraviolet, visible, and infra-red regions of the spectrum (0.18 to 40μ) when suitable prisms or gratings are used, is now in production at the Glenbrook, Connecticut, plant of The Perkin-Elmer Corporation.

Designated as the Model 83 monochromator, it consists essentially of the company's present Model 12 infra-red spectrometer optics from entrance slit to exit slit, with the wave-length and slit controls under a standard cover but on a new base assembly. The optics are totally reflecting so that the instrument can be focused with visible light for use in ultraviolet or infra-red as well.

The result is a new type monochromator, 14 in. long, 14 in. wide, and 9 in. high, completely enclosed with an entrance window before the entrance slit and a space 13×4 in. behind the exit slit for mounting detectors. There is also an exit hole in the cover behind the exit slit.



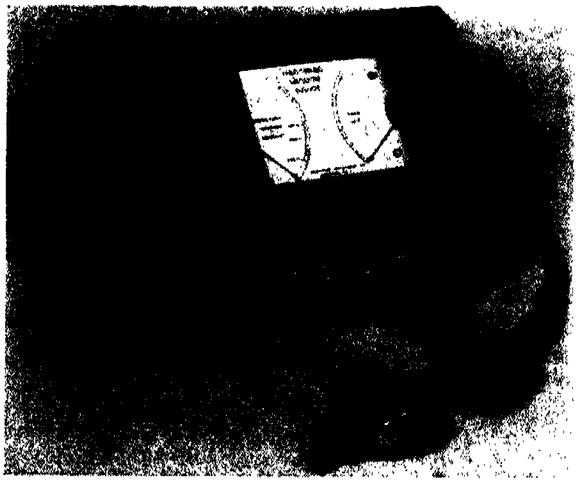
The collimator is an 18° off-axis parabola of 270-mm focal length, and the effective aperture of the Littrow mount is $f/4.5$. The prisms available are fused quartz, crystal quartz, glass, LiF, CaF_2, NaCl, KBr, or KRS-5. Where it is desired, a 14° parabola can be supplied to reflect directly to the Littrow mirror. Fifteen thousand and 7200 lines per inch replica gratings are available to mount in place of the Littrow mirror to furnish a Littrow grating monochromator. The slits are bilateral with entrance slit curvature of 5.59 in., and are adjustable to 0.5μ. The Littrow mirror has a coarse setting adjustment and can be moved through an angle of 9° with a fine micrometer marked with 2000 divisions.

Available for use with the new monochromator are many of the standard Model 12 infra-red spectrometer accessories, such as cell mounts, special covers, and a mirror assembly which permits the beam from the exit slit to be deflected at right angles or allowed to pass out the special cover.

Price of the monochromator without prisms, prism table, or entrance windows, is $1340.00.—The Perkin-Elmer Corporation, *Glenbrook, Connecticut.*

Vacuum Gauge

A new Hastings vacuum gauge is now available for measurements in the range 1 to 1000μ, which embodies a noble-metal thermopile and a dependable bridge circuit similar to those used in the Hastings precision air meter. The gauge consists of an accurate electrical indicator and a small rugged pick-up which screws into a ¼-in. tapped hole in the vacuum system. Fast response, interchangeability of pick-ups without recalibration, freedom from outgassing and corrosion, and freedom from damage by exposure to atmospheric pressure are outstanding features of this new gauge. Simplicity in installation and operation, rugged dependability, and laboratory accuracy are features of the instrument. Calibration is not affected by connecting cable length, thus allowing remote indication and recording. The unit operates at 115 volts a.c.

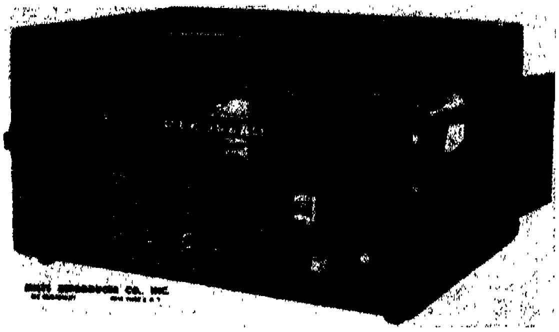


The physical and operating characteristics of the gauge make it adaptable to all vacuum processes in the micron range, such as vacuum tube manufacture, vacuum distillation, automatic exhaust machines, refrigeration service, vacuum dehydration, and laboratory and production processes involving high vacuum systems.

The prices of the control box and indicator and the pick-up are $90.00 and $10.00, respectively (f.o.b. Hampton, Virginia).—Hastings Instrument Company, Inc., *Box 1275, Hampton, Virginia.*

Film Tape Sound Recorder

The Recordall is a long-time permanent recording device in which sound records up to 3½ hr. can be made on each face of an endless plastic band of safety film known as Sonaband. The Sonaband is automatically self-aligning and can be removed or replaced within two seconds. By turning a vernier knob, any point in the recording can be located within a few seconds. Sonaband may be marked with pencil or ball-point pen and may be filed, stored, or mailed.



Other features of the recorder are automatic voice activation, automatic stop when within a few seconds after the cessation of sound, automatic volume control, automatic equalization of incoming and outgoing voices when recording telephone conversations, and instantaneous and permanent play-back at any desired speed. Foot controls facilitate the transcribing from a combination recorder-transcriber or from a separate transcriber.

The Recordall recorder-reproducer weighs only 15 lb.—Miles Reproducer Company, Inc., *812–814 Broadway, New York 3, New York.*

Improved RCA-1P21 Multiplier Photo-Tube

RCA tube engineers have been able to reduce the "equivalent noise input" of the Type 1P21 multiplier photo-tube to 5×10^{-13} lumen—a value showing six times improvement over that of 1P21's previously available. In addition, the improved 1P21 features a combination of extremely high photosensitivity, very high secondary-emission amplification, and very small d.c. dark current.

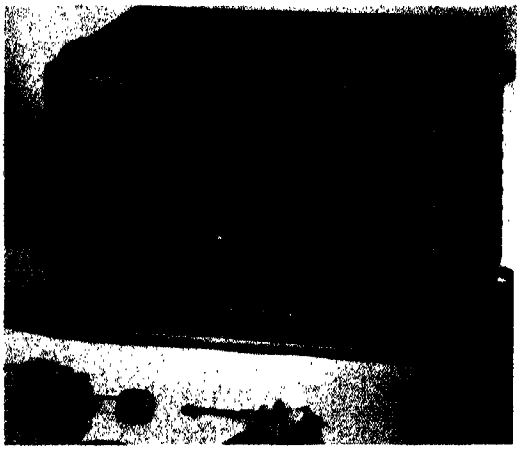
Because of its superior features, the improved 1P21 is recommended for applications involving extremely low light levels. Such applications include the use of the 1P21 in specialized scientific equipment of a laboratory nature represented by (1) photoelectric spectrometers, (2) astronomical telescopes, (3) scintillation counters utilizing "light piping," and (4) other types of equipment employing a collimated light beam.—Tube Department, Radio Corporation of America, *Harrison, New Jersey.*

Super-Brilliant Light Source

Light intensities of 90,000 candles per square centimeter are reached at maximum brilliance with the new Huggins Ames Type-A mercury arc lamp. Shown in the illustration are the lampholder with lamp extracted and, in the background, the fully controllable a.c. power supply. Light output is 65 lu/w; power input 2 kw (1.2 amp. at 1750 v).

Arc dimensions are 2.85 cm (1.125 in.) by 1 mm (0.039 in.). Cooling is accomplished with ordinary tap water, 2½ gal./min. being required; alternatively, a closed-circuit distilled-water system can be used. Average life at rated maximum brilliance is 5 hr., appreciably more at reduced voltages.

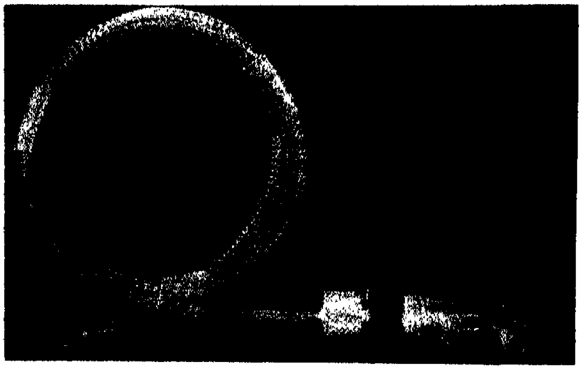
In the standard model, 100 percent intensity is reached at 4358A, with an 80 percent peak at 5461A, and a 73 percent peak at 4047A,



with a maximum radiation of 0.08 w/sterad./A. Intermediate areas average approximately 35 percent. Quartz accessories can be supplied for operation in the ultraviolet region. Direct-current, flash, and stroboscopic power supplies are under development for special applications.

These units are being used for light sources in interferometers, schlieren optical systems, shadowgraphs, monochronometers, and in high speed photography. As high powered ultraviolet sources, they are being used in the production of chemical, biochemical, and ionization changes in substances under study or processing. Numerous applications exist throughout the chemical-, physical-, aeronautical-, and biological-research fields.—HUGGINS LABORATORIES, *712 Hamilton Avenue, Menlo Park, California.*

Temperature Pick-Up The Trans-Sonics Type 17-2 temperature pick-up is designed for the measurement of transient and steady-state gas temperatures for the range of 0 to 315°C. The sensing element is a platinum grid, the resistance of which varies between 5.5 and 11.5 ohms. The total circuit resistance (including the constantan leads for low temperature coefficient) is 8 ohms at 0°C.



The thermal time constant of the instrument is less than 0.5 sec. in an air velocity of 5 ft./sec. When used with a Type 16-5 resistance bridge, the output varies between 0 and 5 mv/v applied over the temperature range. A 7/16-20 thread is provided for insertion of the pick-up into ram pressure tubes.

In conjunction with its balancing bridge, the Type 17-2 temperature pick-up is suitable for use with standard recording oscillographs and telemetering equipment.—TRANS-SONICS, INC., *Bedford Airport, Bedford, Massachusetts.*

Manufacturers' Literature

Electro-Chemograph—4-page illustrated brochure entitled, *An Advanced Electro-Chemograph Type E,* describes an equipment providing unusual stability, precision, and operating convenience for a wide variety of polarographic analyses in research, and industrial-process control laboratories.—LEEDS & NORTHRUP COMPANY, *4934 Stenton Avenue, Philadelphia 44, Pennsylvania.*

Stress Analysis—14-page booklet explains the services rendered by the Armour Research Foundation in the field of stress analysis.—ARMOUR RESEARCH FOUNDATION OF ILLINOIS INSTITUTE OF TECHNOLOGY, *Technology Center, Chicago 16, Illinois.*

Industrial Thermometer Data—Bulletin "E" gives complete data on liquid-in-glass industrial thermometers in an easy-to-use tabular and sectionalized form.—PRECISION THERMOMETER AND INSTRUMENT COMPANY, *1583 Brandywine Street, Philadelphia 30, Pennsylvania.*

Instrumentation—32-page house organ, Vol. 4, No. 2, contains articles of interest on measurement, control, and recording of industrial processes.—MINNEAPOLIS-HONEYWELL REGULATOR COMPANY, BROWN INSTRUMENTS DIVISION, *Philadelphia 44, Pennsylvania.*

Special Products Digest—4-page illustrated house organ, Vol. VII, No. 5, contains articles on various G.E. equipments, including winding-insulation tester, yarn tension tester, portable harmonic generator demonstrating wave shapes, leak detector, electron diffraction instrument, and ball-bearing grease tester.—GENERAL ELECTRIC COMPANY, *1 River Road, Schenectady 5, New York.*

Wattmeters—*Electrical Measurements,* 8-page house organ, is devoted to various types of low power factor wattmeters and reference standard wattmeters, and general testing single phase wattmeters, giving ranges, prices, and other pertinent information.—SENSITIVE RESEARCH INSTRUMENT CORPORATION, *9-11 Elm Avenue, Mount Vernon, New York.*

The Experimenter—8-page General Radio bulletin, Vol. XXIV, No. 6, features a description of a simple standard-signal generator for f-m broadcast use, amplitude modulator for v.h.f. standard-signal generators and a transformer for 300-ohm balanced output from standard-signal generators.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

CEC Recordings—10-page house organ, Vol. 3, No. 4, features the new Consolidated Titrilog, an instrument for recording traces of quantities of sulfur compounds, also contains descriptions of a new high capacity oscillograph record magazine, a leak detector adaptable as a continuous monitor, a special recording oscillograph for non-standard frequency operation, a new galvanometer, new antifog developer for recording paper, and an analog-type electrical computer, and other items of general interest.—CONSOLIDATED ENGINEERING CORPORATION, *620 North Lake Avenue, Pasadena 4, California.*

Mica Capacitors—1949-50 catalog, 9 pages, lists El-Menco capacitors, with prices.—ARCO ELECTRONICS, INC., *135 Liberty Street, New York, New York.*

High Frequency Voltage Measurement—National Bureau of Standards Circular 481 (illustrated) presents an up-to-date account of fundamental principles and techniques used for voltage measurements primarily for frequencies in the upper audio and radiofrequency ranges and including part of the u.h.f. range. Subject matter limited to principles and methods that have met with some degree of success for both high and moderate precision, emphasizing those developed and applied for primary standard work in this frequency range at the National Bureau of Standards. This paper is intended to give professional workers and graduate students a more comprehensive picture of the methods employed with regard to this subject than is presently available in textbooks and handbooks. Price 20 cents.—SUPERINTENDENT OF DOCUMENTS, U. S. GOVERNMENT PRINTING OFFICE, *Washington 25, D. C.*

Machine Computation—New 12-page, illustrated brochure entitled, *Engineered Machine Computation* describes available engineering-computing service and specialized equipment, of automatic graph readers, electronic graph recorders and novel vibration frequency pick-up.—TELECOMPUTING CORPORATION, *2901 Hollywood Way, Burbank, California.*

Instrument News—Vol. 1, No. 1, 8-page house organ, is devoted to the use of various electro-optical instruments in industry and research; tricks of technique, resumes of new research in optical analysis.—THE PERKIN-ELMER CORPORATION, *Glenbrook, Connecticut.*

Pulverizers—New 6-page bulletin entitled *For Better Testing and Small Scale Reduction* describes applications of laboratory crushers, grinders, and shredders for the reduction of coal, by-products, chemicals, clays, and many other products in testing laboratories.—AMERICAN PULVERIZER COMPANY, *1249 Macklind Avenue, St. Louis 10, Missouri.*

RCA Tubes—Technical bulletins on available new RCA tubes: 6CB6 sharp-cut-off pentode (miniature type); 202K5 converter transformer; 202K6, -7, -8, -9, and -10 picture-IF transformers; 202K11 cathode-circuit trap; 206K1 sound-IF transformer; 207K1 sound-discriminator transformer; and 5675 "pencil-type" triode, a triode of the miniature medium-mu-type for use at frequencies up to 3000 mc, with a power output of 475 mw at 1700 mc.—RADIO CORPORATION OF AMERICA, RCA VICTOR DIVISION, *Harrison, New Jersey.*

Megohmmeter—Bulletin No. 1029 describes the Model 29, a British-made 20 million megohmmeter for measurement of electrical resistance over the range 300,000 to 20,000,000 megohms. Said to exceed in range anything presently available on the American market.—HERMAN H. STICHT COMPANY, INC., *27 Park Place, New York, New York.*

Microphotometer—Bulletin describes the Romicron C. G. Grand microphotometer, especially designed for use with the microscope. Can be used as a microphotometer in general, for densitometry, or for determination of exposure time in photomicrography.—PAUL ROSENTHAL, *505 Fifth Avenue, New York 17, New York.*

Frequency Meters—New catalog describes a complete line of hermetically sealed, direct reading, precision frequency meters for use over the band from 500 to 40,000 mc/sec.—POLYTECHNIC RESEARCH AND DEVELOPMENT COMPANY, INC., *202 Tillary Street, Brooklyn 1, New York.*

Instrument Notes—No. 11, September–October, 1949, 8 pages, summarizes an article on "Electromagnetic determination of wire stress" and describes the Model TC-1 temperature test chamber, a compact temperature-controlled chamber for the rapid performance of ambient temperature variation tests from −65° to +275°F.—STATHAM LABORATORIES, *9328 Santa Monica Boulevard, Beverly Hills, California.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Centrifugal Bronze Castings

X-ray quality centrifugally cast bronze bushings are guaranteed to be completely free from porosity, blow holes, sand inclusions, pits, and to have excellent surface finish. These bushings are available in diameters from 2 in. to 18 in. and in lengths up to 12 in. Minimum production quantity is 100 units, and no pattern or mold charge is made.—INDUCTION PROCESSING COMPANY, *3319 West Fifth Street, Tulsa 6, Oklahoma.*

Precision Casting Alloy

Cerrocast, a non-eutectic alloy of bismuth and tin, has negligible shrinkage, extensive melting range, and reasonable hardness. Some of its physical properties are: Melting range, 281–338°F; Yield temperature, 302°F; weight, 0.296 lb./cu.in.; shrinkage, 0.0001 in./in.; Brinell hardness, 22.

This alloy is stated to be especially suitable for use in precision casting by the Lost Wax process. Because of its long melting range it will accurately reproduce the shape, dimensions, and fine surface details of the master pattern. It also works satisfactorily in spray guns and for low temperature soldering of pretinned metal parts. Further information may be obtained from the manufacturer.—CERRO DE PASCO COPPER CORPORATION, *40 Wall Street, New York 5, New York.*

Rust Preventive

Nox-Rust vapor wrapper, a chemical impregnant in wrapping paper, releases a vapor which inhibits the formation of rust on metal parts. The manufacturer has now developed a process for incorporating this chemical in chip-board and corrugated cartons. This development is designed for packaging of metal parts, tools, and appliances, and is stated to eliminate the need for temporary rust-preventive coatings. Full information concerning the paper and cartons can be obtained from the manufacturer.—NOX-RUST CHEMICAL CORPORATION, *2431 South Halsted Street, Chicago 8, Illinois.*

Fluoride Lens Coating

Transkote is a fluoride coating deposited on special glass surfaces, such as those of lenses and prisms, to improve light transmission and reduce reflection. A common fault of conventional fluoride coating is that the film is relatively soft and wears off under normal handling. An improved coating technique, operated under conditions of very high vacuum, is stated to result in a film which is less easily damaged. The process produces a film of the same thickness and with the same optical properties as are found in the conventional film. Information concerning the application of Transkote to specific surfaces may be obtained from the manufacturer.—PANCRO MIRROR, INC., *2958 Los Feliz Boulevard, Los Angeles 26, California.*

Casting Resin

Melpak IV is a casting resin designed specifically for encapsulating subminiature electronic circuits, wherever size, weight, temperature, moisture, or rough handling is a problem. Its dielectric constant is 4.76 at 8.4 mc and its power factor 6.4 percent at 34 mc. Operating temperature range of potted units is from −65°C (ambient) to +170°C (hot spot). Its curing time is 48 to 72 hr. and its shrinkage 6–8 percent. Further information is available from the manufacturer.—MELPAR, INC., *452 Swann Avenue, Alexandria, Virginia.*

New Organosilicons

Three new silanes (vinyltrichlorosilane, diethyldichlorosilane and phenyltrichlorosilane) have become available as "building blocks" which react easily with other organosilicons, alkyd resins, intermediates, and some unsaturated organics to produce liquid or solid polymers (used in hydraulic fluids, mold-release resins, electrical insulation, paint vehicles, and rubber-like materials). The new silanes, soluble in most organic solvents are colorless, fuming liquids. The great variety of useful polymers possible with them is due largely to the very reactive Si-Cl groups, which are readily converted to Si-O, Si-N, Si-S, and other groups. All chlorine atoms in the compounds are replaceable. Hydrolysis and condensation

reactions (with suitable catalysts) yield polymers whose composition and properties can be completely controlled. It is of special interest that the vinyl group is available for reaction either before or after polymerization. These materials are now in pilot production. Information and prices can be obtained from the manufacturer.—NEW PRODUCTS DIVISION, LINDE AIR PRODUCTS COMPANY, *30 East 42 Street, New York 17, New York.*

Fluorocarbons

In many particulars the fluorocarbons resemble the hydrocarbons of organic chemistry, with the important difference that the bond between fluorine and carbon is very much stronger than the corresponding one between hydrogen and carbon. For example, fluorocarbons are non-flammable. They can, however, be used in the formulation of various types of synthetics (lubricants, fibers, rubber-like materials, etc.) of extreme durability. During the early stages of the development of fluorocarbons high manufacturing costs prohibited most applications, but the development of a new electric-cell process now promises an effective solution to the economic problem. Feasibility of large-scale production by the electrical process is currently being demonstrated in pilot plant operation.—PENNSYLVANIA STATE COLLEGE, *State College, Pennsylvania.*

"Teflon" Coatings

Teflon, tetrafluoroethylene resin, is characterized by extreme resistance to corrosion and ability to withstand high temperatures. These properties have also made it difficult to fabricate into usable forms, except in relatively simple shapes with limited usefulness. It has recently been found that, when made up as a suspensoid (35 to 65 percent resin) it could be used as a spray finish, dipping enamel, compounded for extruding insulation on wire, for coating glass fabrics and tapes, and for fabricating unsupported film.

The spray-coating, after being dried at temperatures below 200°F, is brought to a temperature of 750°F, where the resin fuses to a continuous film. This finish will adhere to many metals, such as steel, stainless steel, aluminum, copper, brass, and to sandblasted glass, porcelain, and brick. Where damage occurs in use, the finish may be patched by cleaning down to the metal, applying more spray finish, and fusing with a blowtorch or gas flame. Such repairs can be made in 15–20 min. Spray finishes have chemical and heat resistance and moderately high resistance to wear or erosion. Indicated uses are coatings for chemical pipes and fittings, for agitators and rupture disks in chemical process vessels, for laboratory benches and hoods, and for insulation of equipment in electrolytic processes.

The fusing of Teflon wire enamels is comparable to that of spray finishes, although application is by dipping. **It has been demonstrated that a motor or transformer insulated with Teflon may be operated continuously at 400–500°F. Extrusion compounds have been developed for heavier insulation than is possible with enamel. Coatings from 5 to 20 mil thickness have been applied with a ram extruder, the resin being fused (after evaporation of the suspension liquid) at 700°F. The heavier coatings have exceptional dielectric** properties at high frequencies, and applications in radar and television installations are anticipated. They are also expected to be used for aircraft ignition, thermocouple leads, and in electrical equipment.

Coated glass fabric and unsupported films will complement the wire enamels and extruded coatings in electrical equipment, as slot liners, layer insulation, and possibly as a substitute for sheet mica. In the chemical industry, the fabrics may be used in protective clothing, gaskets, conveyor belts, and flexible ducts for hot, corrosive gases.

In effect, the coated fabrics are simply sheets of Teflon resin reinforced with glass cloth, and these may be laminated into strong, solid material of almost any desired thickness by bonding under heat and pressure.

The new forms of Teflon—spray finishes, enamels, and the raw suspensoid—are available in experimental quantities, and the film and tapes are being manufactured for testing purposes.—E. I. DUPONT DE NEMOURS AND COMPANY, ***Wilmington 98, Delaware.***

Rare Gases

The chemical inertness of the rare gases has led to commercial applications for all of them. The use of neon in electric signs, of helium as a lifting gas, and of argon for Heliarc welding and for filling incandescent lamps, indicates their wide fields of usefulness. Xenon and krypton occur in such small percentages in the atmosphere that their separation and purification has presented complicated problems. These difficulties have been overcome and spectroscopically pure gases are now available in quantity at reasonable prices. Krypton has been introduced as a gas filler for fluorescent lamps, and in some miniature lamps. Because of its low thermal conductivity, it permits the use of higher temperatures in tungsten-filament lamps. Xenon has been used in place of mercury vapor in certain types of thyratrons, since it does not condense at low temperatures. There are rare gas applications in the refining, alloying, and welding of metals. Argon may be used in the refining of calcium, lithium, titanium, chrome alloys, and other metals capable of combining with nitrogen. Another important application of the rare gases is in the filling of Geiger-Müller counter tubes.

Neon, helium, argon, krypton, and xenon are now available in 1-liter lead-glass bulbs containing approximately 1.1 liters of gas of high spectroscopic purity at normal pressure and temperature. —FISHER SCIENTIFIC COMPANY, *717 Forbes Street, Pittsburgh 19, Pennsylvania.*

A Precision Faraday Effect Apparatus[1]

Samuel Steingiser,[2] George J. Rosenblit, Robert Custer, and Chas. E. Waring
Department of Chemistry, University of Connecticut, Storrs, Connecticut

(Received March 28, 1949)

As a result of the improvements made in the Faraday Effect Apparatus as described, our results indicate an attainable precision of ±0.02 percent for visual measurements. Comparing this value with those reported by other investigators, indicates that a definite increase in precision has been achieved. As soon as our method for making measurements photoelectrically is fully developed, it is expected that the precision will be still higher. This will be especially true in the shorter wave-lengths where the eye is insensitive, and also where eye fatigue in general would be eliminated.

THE Magneto-Optic rotation, more commonly called the Faraday effect, is exhibited by all substances. This effect is becoming an increasingly powerful tool for research and analysis. In many cases, it is capable of producing results and giving information about various properties of these substances that are not readily obtainable by other means. In others, it serves as a useful confirmation of, or perhaps to question, conclusions arrived at by other methods. However, since the great amount of work done in the nineteenth century by Perkin and others, its use in the last forty years has been markedly restricted due to lack of sufficiently refined apparatus and also to lack of knowledge of structural effects.

In order to explore more completely the research possibilities of this tool, we have attempted to refine the experimental technique to such a degree so as to produce results of the highest precision possible. It is felt that, in preparation for publication of the results of our researches, a complete description of the apparatus should be given here, showing in what way advantage has been taken of modern equipment to re-establish the usefulness of the Faraday effect in chemical research.

When a plane polarized monochromatic beam of light is passed through a transparent isotropic liquid or solid, placed in a magnetic field and parallel to the lines of force of the field, the plane of vibration of the light beam is turned through a definite angle.

The rotation is proportional to the length of the light path in the medium and its direction is determined by the direction of the magnetic field only. If R is the total angle of rotation in minutes, l the length of the substance in centimeters through which the light beam passes, H the magnetic field strength in gauss, θ the angle between the direction of the magnetic field and the path of light, and V the proportionality constant known as the Verdet constant, then

$$R = V \cdot l \cdot H \cdot \cos\theta.$$

This Verdet constant varies with the nature of the substance through which the light is passing. In addition, it varies with the wave-length of the incident light and the temperature of the material. A more useful term actually employed is the molecular Verdet constant, which is the Verdet constant multiplied by the molecular weight and divided by the density.

It is thus apparent that a reliable determination of the Verdet constant involves the measurement of the angle of rotation of the polarized light, the wave-length of the light, the magnetic field strength and the temperature, to rather a high precision. In addition, subsequent calculations require the measurement of the refractive index and the density.

APPARATUS

Briefly, the major items of apparatus and their interrelationships are as follows. A large solenoid magnet,

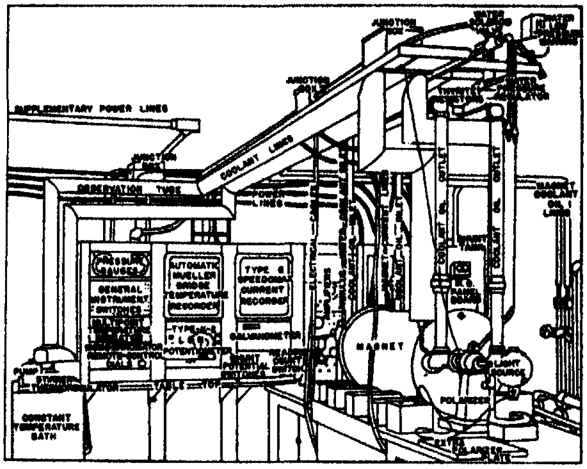

Fig. 1 (b).

surrounding the sample to be investigated, produces the rotation of the plane polarized light as determined by the polarimetric system. The dispersion of the light is produced by a monochromator placed in the light path. The current actuating the magnet is measured and recorded on a Speedomax recorder by means of a calibrated shunt-potential system. An indication is also made on this current record when the balance point of the light intensity of the two halves of the field in the split-field Lippich polarimeter is reached. This may be done visually or by a specially designed photoelectric comparator system. Thus, when for a specified value of the rotation angle, a balance of light intensities is reached, we have a record of rotation *versus* current, or in other words, rotation *versus* magnetic field strength. These are obtained at the exact same moment, the time lag being well within the precision of the measurements. This process can be repeated for any predetermined number of times, e.g., nine or thirty-six, etc., to produce a deviation measure of approx. ±0.01 percent.

Figures 1, 2, 3, and 4 are photographs of the completed apparatus. Outline legends are given with each photograph to identify the various portions of the apparatus. The apparatus as a whole may be subdivided for a more detailed description into three

sections: The electrical system (Fig. 5), coolant systems (Fig. 6), and the optical-null system (Fig. 7).

ELECTRICAL SYSTEM

The solenoid magnet is of the type described by Campbell and Houston,[3] as used by them for measurements of the Zeeman effect. It is 36 in. long, 18 in. in diameter, and is wound with No. 4 B and S gauge square copper wire, fiberglas insulated. Total weight of the magnet is approximately 1250 pounds. A d.c. motor generator set provides up to 200 amperes at 300 volts for maximum current through the magnet. At this value of current, the field generated is about 7200 gauss over each centimeter of length or close to half a million gauss cm over the entire length of the magnet. Thyrite resistors are inserted across the magnet lines as protective devices to prevent burnout of the coil due to high voltage arcing upon opening the circuit. The voltage and current through the magnet are controlled by means of 'fine' and 'coarse' adjustable field rheostats operating on the d.c. generator. The 'fine' rheostat is controlled by a geared motor device which drives for a definite period in one direction and then in the other direction causing the current to oscillate slowly about any preset value. The polarity of the direct current is

changed by means of a set of polarity switches operating through the field coils of the generator. The current is measured by means of a shunt-potential system using two large precision Leeds and Northrup shunts. For currents up to 100 amperes, the 0.01-ohm shunt, and for currents between 100 and 200 amperes, a special 0.005-ohm shunt is used. These are calibrated to ±0.04 percent and by placing them both in a thermostated oil bath to prevent any temperature rise, a precision of ±0.01 percent is attainable in their values. This is the limit of precision we are attempting to set for the overall instrument. Upon passage of current, these shunts will generate a voltage, which is bucked by a slightly lower voltage from a Type K-2 Leeds and Northrup potentiometer. This potentiometer is also precise to ±0.01 percent operating from a double set of large-capacity long-life Willard batteries, kept at a uniform temperature, and a standard cell newly standardized in absolute voltage units. The slightly excess potential which has not been bucked out by the potentiometer is then placed on a Leeds and Northrup Type G Speedomax 'current' recorder. This is a 10-millivolt unit, which in conjunction with the shunts used, will place 1 or 2 amperes across full scale. The speed of travel of the recording pen is $\frac{3}{4}$ seconds across the chart. There are 100 ruled divisions on the chart allowing all measurements of the current to be made to ±0.01 percent, with further estimates being made to ±0.001 percent. The chart speed of the Speedomax has been stepped up to 360 inches per hour or $\frac{1}{10}$ in. per second, producing a very precise continuous determination of the current. An auxiliary pen, mounted on the side of the chart, indicates by a pip, the optical-null point of the polarimeter. This null is obtained either visually or photoelectrically. This then gives us, for any angle set on the polarimeter, a definite value of the current and thus, since the current is directly proportional to the field strength, we have the value of rotation *versus* magnetic field strength. The number of pips or readings is automatically counted on a relay stepping switch which can be preset for any number of readings: 1, 4, 9, 16, 25 or 36, at which time a solenoid plunger relay, mounted with the large magnet power switch, is activated. This power switch is thus thrown off, the magnet is deactivated and a set of readings is completed.

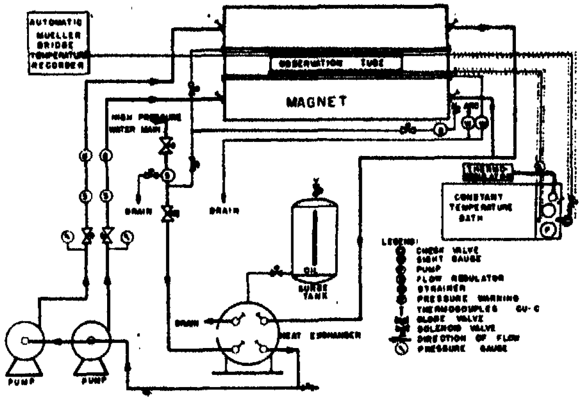

FIG. 6. Coolant systems.

COOLANT SYSTEM

Approximately 65,000 watts are generated each second of the run and this heat must be removed rapidly and uniformly to prevent overheating of the magnet and to allow closer control over the current being supplied to it.

The coolant system has three major divisions whose functions are the cooling of the magnet proper, cooling of the internal core into which the observation tube is set, and the maintenance of a constant temperature around the observation tube itself.

The magnet proper is cooled by pumping Westinghouse Wemco C transformer oil longitudinally through spaces so arranged that the upper and lower face of each winding is in contact with the transformer oil. Two centrifugal pumps, connected in parallel, pump the oil through the magnet at the rate of 100 g.p.m. and then through a heat exchanger after which it is recycled. The heat is transferred in the exchanger to the cold water supplied from a high pressure building main. The

flow of water through the exchanger is about 5000 gallons per hour. An oil expansion and surge tank is provided at the heat exchanger. With this coolant system, the magnet runs at room temperature with currents up to 150 amperes. At 200 amperes, a 10°C rise is produced in the magnet with a 1°C maximum differential from one end of the magnet to the other.

The internal core is cooled by passing an ⅛-in. annulus of cold water through it, regulated by a constant pressure valve. A Fischer-Porter Ratosight alarm flowmeter is used to indicate proper water flow and to sound an alarm at any water failure.

The temperatures of the inlets and outlets of the heat exchanger and inlets and outlets of the magnet and of the annulus core coolant are measured by means of miniature pipe-type copper-constantan thermocouples connected through a multipoint switch to a 0–200°C Wheelco pyrometer reading to ±1°C.

The third division of the coolant system is for the control of the observation tube. A condenser-type brass jacket is built around a quartz observation tube with inlet and outlet tube coming out of one side of the magnet core. The brass jacket is covered with an ⅛-in. asbestos coating for further heat insulation. A large Aminco refrigerated constant temperature bath, controlled to at least ±0.03°C, pumps a water-prestone solution via heavily cork-insulated lines through the observation tube jacket. A flowmeter alarm indicates the flow through the system and sounds an alarm if the values differ from the preset ones. A platinum resistance thermometer is inserted in a well in the brass jacket of the observation tube and is connected to an automatic Mueller Bridge temperature recorder[4] reading to ±0.01°C. An auxiliary pen, which produces a series of pips each time a reading is made, is also mounted on this temperature recorder. Thus, we know the mean temperature of the cell to ±0.01°C as each reading is made.

Another coolant line is available for use with the Hanovia hydrogen arc used as a light source. This line is also protected by a water regulating valve and a flowmeter alarm unit.

OPTICAL-NULL SYSTEM

Various light sources are used including the sodium and mercury arcs for the line bands, a Cenco tungsten lamp, a Hanovia hydrogen arc and a Western Union concentrated arc for the continuous range from the ultraviolet to the near infra-red.

The polarimetric unit, made especially for this Laboratory by the Gaertner Scientific Company, allows the

[4] See D. R. Stull, Rev. Sci. Inst. 16, 318 (1945).

measurements of the angle of rotation to be made to a precision of 0.001°. The analyzer and polarizer sections are so constructed as to permit their removal for the insertion of the observation cell into the magnet and for the subsequent return to their original optical alignment. The polarizer is a Lippich half-shadow type, made with Glan-Thompson prisms. The analyzer scale has an optical vernier consisting of a filar microscope and micrometer.

The observation tube in the magnet core is about 22 in. long and was made by the American Instrument Company to our specifications. The entire body and end plates are of fused quartz made within the usual specifications of absorption cells. A ground stoppered opening is provided at one end of the tube for emptying and filling. The entire cell is of one piece construction with no cement in any portion.

The light beam which has passed through the polarizer and the sample in the magnetic field and the analyzer, is now passed through a monochromator and then to the observer's eye or to an automatic photoelectric scanning device. Two monochromators, both built by Gaertner, are used interchangeably. One is a precision quartz long range unit from 1850–20,000A and the other a precision visual monochromator from 3900–8200A. Measurements are being made of the Faraday effect with a band width of 20A units. The range of the monochromators is greater at present than that of the polarimeter, which has optics only for the visual wave-lengths. Plans are being drawn up for ultraviolet and infra-red polarimetric units so as to extend studies to these spectral ranges.

The photo-multiplier device for indicating matched intensities or the "null" of the polarimeter is so arranged as to fire a thyratron tube which then activates the two relay pens, one located on the current Speedomax and the other on the Mueller Bridge temperature recorder. The circuits involved in this photo-multiplier scanning device will be published at a later date.

TYPICAL DATA

In Table I are given the measured data for a typical solution run in this apparatus. It is a binary mixture of acetone and chloroform. The letters *D* and *U* in the run number signifies the polarity of the current through the magnet. The correct combination of runs is that having a *D* and a *U* for the same conditions of temperature and wave-length, producing the average rotation. The angle read is the angle set on the polarimeter scale for that run. The current is the mean of 18 individual settings of equal intensity of the polarimetric field as described earlier. The current deviation gives the actual average deviation of the mean, A.D. The wave-length is that set on the monochromator for that run. The average temperature is the mean temperature during the entire run as shown on the Mueller Bridge temperature recorder. The temperature range is one-half the spread of the temperatures furthest apart during a run. In Table II are given the calculations for the data shown in Table I. Two runs are combined, one for each polarity at the same temperature and wave-length. $\overline{\text{Temp.}}$ is the mean temperature of the two runs, $\overline{\text{Rot}}_{\text{Tot}}$ is the average rotation of the sample including that for the tube windows, etc., $\bar{I}_{\text{Tot}}$ is the average current for the two runs, and $\bar{R}/\bar{I}=k_T$ is the ratio of these two factors. k_Q is the same ratio for the quartz tube windows as determined earlier. k_T-k_Q is the value of the ratio for the sample only. Δt is the difference in temperature between the two measured k's at the two temperatures used, Δk_s is the difference in the k's for the same temperatures, $\Delta k_s/\Delta t$ is the value of this difference per degree C, $t-t^*$ is the difference in the experimental temperature and the whole number temperature t^*, and Δk_s^* is the difference to be added or subtracted to k_T-k_Q to give the final value of the ratio k_s^* at the uniform temperature intervals of 20.00° or 25.00°C. It is this value of k_s^* which, when multiplied by the apparatus constant, K, of 0.028030, will give the Verdet constant of the material under investigation.

Velocity-Acceleration Response from a Seismic Pick-Up via Controlled Damping

ROBERT J. JEFFRIES*
Department of Engineering Research, North Carolina State College, Raleigh, North Carolina

(Received June 30, 1949)

The basic theory of the seismic pick-up is developed and interpreted to show that it is theoretically possible to make a simple seismic system directly amplitude-sensitive to velocity as well as acceleration and/or displacement. This is accomplished by appropriate control of the damping.

INTRODUCTION

SPRING-SUPPORTED seismic masses are used to detect and measure various dynamic characteristics of vibratory motions. Figure 1 illustrates the basic form and application of such a pick-up having "viscous" damping. The relative motion, $s=y-x$, between the seismic mass and the case to which it is connected through a supporting spring system, is usually utilized as being proportional to the quantity to be measured. This relative motion may be detected by mechanical or electrical means. The case (shown partially in cross-section) is securely fastened to the member whose vibratory motion is to be studied.

Numerous pick-ups of this type are available commercially. They are frequently used for both root-mean-square and instantaneous measurements of the displacement and acceleration of vibrating members. In such applications they are known respectively as vibrometers and accelerometers. The theory permitting these applications is well known and will not be repeated here.[1]

An output signal approximately proportional in amplitude to the velocity of the vibrating member is frequently derived from the relative motion, s, in commercial equipments, by generating a voltage in a coil of wire moving with the motion, s, through a magnetic field, the voltage thus induced being proportional to ds/dt, and hence approximately proportional to dx/dt.

It is the purpose of this paper to show that a basically different technique for obtaining a velocity-sensitive response is theoretically possible. The method proposed makes it possible to design for a relative motion. s, which is directly proportional to *either* velocity or acceleration of the vibrating member over a given frequency range, by appropriate control of the damping.

PICK-UP CHARACTERISTICS REQUIRED FOR VELOCITY AND ACCELERATION-SENSITIVE RESPONSE

Given a steady-state displacement function represented by

$$x=A\sin\omega t \tag{1}$$

there is associated both a velocity and an acceleration, represented respectively, by the following expressions:

$$\text{velocity}=dx/dt=\omega A\cos\omega t=\omega A\sin(\omega t+90°), \tag{2}$$

$$\text{acceleration}=d^2x/dt^2=-\omega^2 A\sin\omega t =\omega^2 A\sin(\omega t+180°). \tag{3}$$

Figure 2 illustrates, in wave form, the phase relations of these quantities. Figure 3 illustrates, in terms of amplitude and phase, the characteristics required of a pick-up for exact velocity and acceleration-response.

PERFORMANCE CHARACTERISTICS OF A SEISMIC ELEMENT AS A FUNCTION OF FREQUENCY

The amplitude- and phase-response-*versus*-frequency characteristics of a simple seismic system of the type illustrated in Fig. 1 are shown in Fig. 4 with damping as a parameter. The abscissae for these curves are the various ratios of the frequency of the impressed displacement function of the pick-up case to the natural mechanically-resonant frequency, ω_n, of the seismic system. The damping is expressed as the ratio of the actual damping present to the critical value.[2]

A qualitative inspection of the amplitude-response characteristics reveals that for relatively small values of the damping ratio ($0.5<\delta<1.0$) and for frequencies between zero and the natural resonant frequency of the mechanical system, the peak variation in relative motion, s, with frequency of the displacement function, approximates a square law relation. This approximates, then, the required amplitude characteristic for ac-

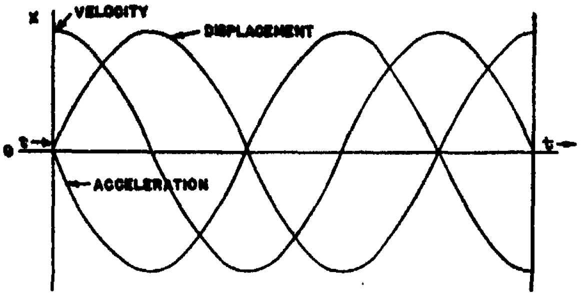

FIG. 2. Phase relations of the dynamic characteristics of a simple harmonic displacement.

celeration-response. However, reference to the phase-response characteristics for values of ω/ω_n between zero and one reveals no value of δ in this range for which the characteristic even approximates the desired 180° phase shift, corresponding in this plot to an indicated constant phase angle of zero degrees.[8] A value of δ between 0.5 and 1.0 will, however, yield an approximately linearly increasing phase angle, and it is a well-known fact that any system possessing a phase characteristic such that the output phase angle is directly proportional to the

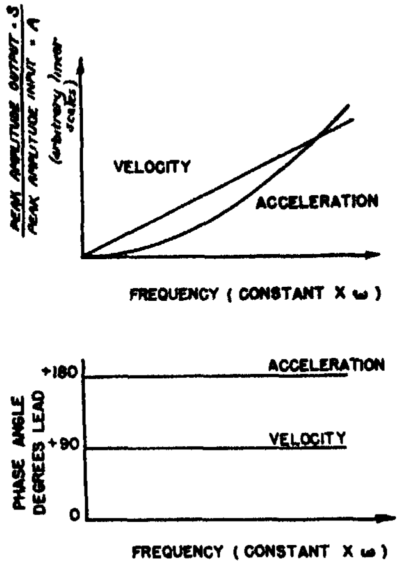

FIG. 3. Amplitude and phase-response characteristics of an ideal velocity and acceleration-sensitive pick-up.

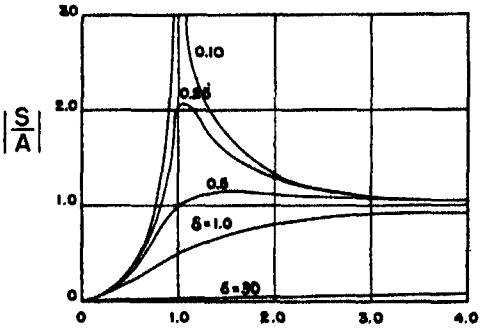
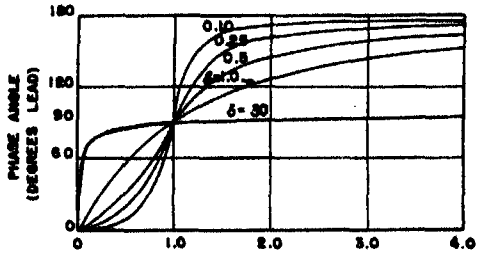
input frequency will transmit a function without distortion but with phase delay. A selection of $\delta \simeq 0.7$ for acceleration response is, therefore, a necessary compromise which yields a reasonably good square-law amplitude-response characteristic over a wide frequency range, and a phase-response characteristic which will delay, but not distort the output wave form.

From qualitative observation of both the amplitude and phase-response characteristics, it is apparent that for large degrees of damping ($\delta \gg 1$) the amplitude-response characteristic approximates the linearly increasing function required for velocity response, and the phase-response characteristic closely approximates the required 90° phase shift, lead, over a substantial frequency range between $\omega/\omega_n = 0$ and $\omega/\omega_n = 1$. These observations lead to the conclusion that the same seismic system may be made either acceleration or velocity-responsive by proper selection of the damping. Because the amplitude of the output decreases with increased damping, it is desirable to use the minimum amount of damping consistent with the accuracy desired.

Desirable values of δ for both velocity- and acceleration-response may be readily selected by reference to a plot of the actual and required amplitude-response characteristics on log-log paper. If the required amplitude-response *versus* frequency characteristics are plotted on log-log paper, they appear as straight lines, the velocity characteristic having a slope of one and the acceleration characteristic a slope of two. By superposing the actual characteristics one may easily select the degree of damping which will yield either velocity- or acceleration-response, over any desired frequency range, to the accuracy desired. Figure 5 shows such a super-



RELATIVE AMPLITUDE RESPONSE
(a)



RELATIVE PHASE RESPONSE
(b)

FIG. 4. Amplitude and phase-response characteristics of a seismic pick-up.

---

[8] The correspondence of a constant phase characteristic angle of 0° in Fig. 4(b) to the ideal constant phase characteristic angle of 180°, lead, for true acceleration response is a result of the sign of the solution of the differential equation arising from the assumption of an impressed *displacement* function.

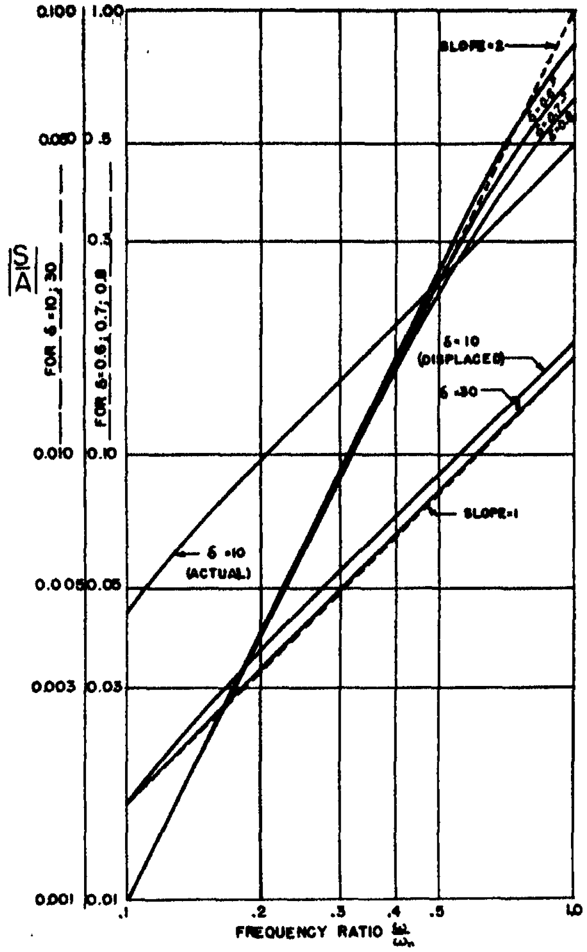


FIG. 5. Amplitude-response characteristics of a seismic pick-up with various degrees of damping.

position. It is readily apparent that a damping factor of 0.7 will give a near-perfect acceleration-response while a damping factor of 30 will yield a near-perfect velocity-response. The reduction in sensitivity (of the order of 10:1) occasioned by the greater damping required for the velocity-sensitive characteristic is not excessive.

It is suggested that the two values of damping required might conveniently be achieved by electrical "drag-type" damping, in which the strength of the magnetic field through which a conducting sheet moves (with motion s) might be controlled by a two-position switch, the switch positions corresponding respectively to velocity and acceleration-response.

CONCLUSIONS

It is theoretically possible to make the output of a seismic pick-up directly proportional to either velocity or acceleration of an impressed displacement function by appropriate control of the damping. A value of damping factor, $\delta = 0.7$, represents a compromise between the available amplitude and phase-response characteristics, and will yield a near-perfect acceleration-responsive pickup. A value of the damping factor, $\delta = 30.0$, yields a near-perfect velocity-responsive pick-up in which both the amplitude and phase-response characteristics closely approximate those required for perfect velocity-response. The control required on the damping to effect either velocity or acceleration-response might conveniently be achieved by electrical damping.

ACKNOWLEDGMENT

The author wishes to express his appreciation to Dr. G. B. Hoadley of this Institution's Department of Electrical Engineering for his careful reading of the manuscript and his valuable suggestions, and Mr. E. H. Tompkins of the Department of Engineering Research for his assistance with the illustrations.

Variation of Grain Density with Temperature of Exposure in Nuclear Emulsions[*]

ELSIE M. DOLLMANN
Brookhaven National Laboratory, Upton, New York

(Received August 1, 1949)

Ilford C-2 unloaded and C-2 boron loaded plates, subjected to temperature changes varying from −66°C to +66°C, were bombarded with 10-Mev neutrons. The recoil protons showed that the temperature change had caused an increase in grain density which varied as much as ⅓ from −66°C to +25°C. Although the C-2 boron loaded plates showed a greater initial grain density than the unloaded plates, the ⅓ increase was preserved.

WHEN scattering and grain density measurements of a number of prongs from stars found in nuclear emulsions exposed to cosmic radiation were compared, an inconsistency was found to exist. In order to examine the possibility that the inconsistency was due to the fluctuation in temperature during the balloon flights, a preliminary survey of temperature-controlled neutron-irradiated plates was made. The results indicated that temperature change had caused a reduced grain density which varied as much as ⅓ between −66°C and +25°C. A temperature correction caused the inconsistency to disappear.[1]

Two groups of experiments were performed in which Ilford C-2 unloaded and C-2 boron loaded plates were subjected to various temperature changes before being exposed to a beam of 10-Mev neutrons from the cyclotron at Columbia University.

Wide mouth glass test tubes, each holding Ilford plates wrapped in black paper, a thermometer, and a mixture of rice and silica gel, were immersed in Dewar flasks containing various cooling and heating mixtures having temperature ranges from −77°C to +66°C. The rice and silica gel was used to maintain a constant relative humidity of 67 percent throughout the experiment. In the first trial each tube contained two Ilford C-2 unloaded 50μ plates, three old Ilford C-2 boron loaded 50μ plates, and three new Ilford C-2 boron loaded 50μ plates. For the second run two Ilford C-2 unloaded 100μ plates and two new Ilford C-2 boron loaded 100μ plates were placed into each tube. The plates remained in the Dewar flask for four hours during which time a temperature equilibrium was reached.

The thermally insulated Dewar flasks were then opened in the cyclotron room; the plate containers were removed and exposed to a beam of 10-Mev neutrons. The temperature before and after each exposure in each case is given in Table I. The variation in temperature in the second group is small due to greater care in handling the plate containers during exposure and better insulation. After exposure the plates were allowed to return to room temperature before being developed according to the standard method recommended by Ilford.

A microscope having a 90× oil immersion objective with a 12.5× compensating eyepiece was used for grain counting. The observers counted the number of grains in 150-eyepiece scale divisions starting 100 divisions from the end of the track. Each division is equivalent to 1.13 microns. Only those recoil proton tracks more than 300μ long and ending in the emulsion were considered. The results are given in Figs. 1 and 2.

Each point on the curves represents the average grain count of many (from 15 to 20) recoil proton tracks. Figure 1 shows two curves. Curve 1 represents the values obtained from Ilford C-2 unloaded 100μ plates. The grain density of the recoil proton tracks shows about a ⅓ increase from −66°C to +25°C, after

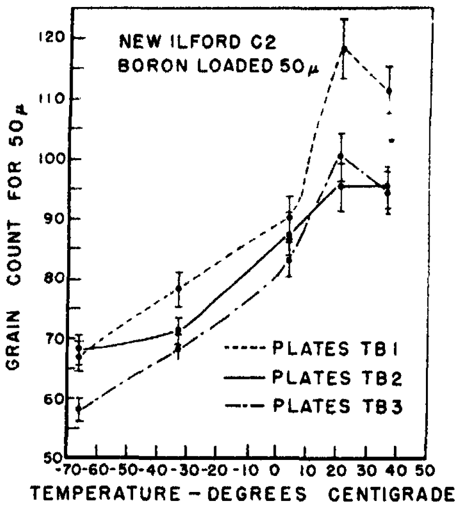

FIG. 2. Temperature *versus* grain density for new Ilford C-2 boron loaded 50μ plates.

which temperature there is a decrease that is primarily due to a photo-chemical change occurring in the emulsion as the temperature is increased. Beyond +40°C a simple interpretation can no longer be given to the curve. A second group of points which fall close to Curve 1 is from Ilford C-2 boron loaded 50μ plates. These plates, however, had been lying around the laboratory for almost a year before exposure. It is likely that they did not possess their full sensitivity at the time of exposure. These plates have been designated as "old". It is well known that, for the same development, tracks in boron loaded plates are on the average much heavier than those in unloaded plates. This is seen in Curve 2 where a fresh batch of Ilford C-2 boron loaded plates was used. Although the intrinsic grain density is heavier, the increase of $\frac{1}{3}$ in grain count for −66°C to +21°C is still preserved. Due to the irregular concentration of boron in the plates the grain density shows a variation as seen in Fig. 2. The three curves show the average value plotted for three sets of plates. Here only fifty microns were counted, starting, as before, 100 divisions from the heavy end of the track.

Similar interpretations were obtained by Cosyns, Dilworth, and Occhialini[2] in their experiments on reducing background tracks by storing the plates at low temperatures. Kodak NT2A plates were exposed to gamma-rays from a radium source between the temperatures of −87°C to +20°C.

Due to decrease in grain density of tracks at low temperatures and the possibility of mistaking low temperature protons for mesons, thereby increasing the apparent meson yield, it is advisable to include temperature recorders or controls in all flights where these nuclear emulsions are used.

I am indebted to Dr. M. Blau for arranging the exposures at the Columbia University cyclotron, and to Dr. C. W. van der Merwe of New York University and Mr. Joseph E. Smith of Brookhaven National Laboratory for helping with the grain counting and to Dr. E. O. Salant for suggesting this problem.

The Design and Construction of a Stark-Modulation Microwave Spectrograph

A. Harry Sharbaugh
General Electric Research Laboratory, Schenectady, New York

(Received August 10, 1949)

A detailed description of a Stark-modulation (see reference 1) microwave spectrograph which has been designed and constructed in this laboratory is given. Circuit diagrams and values of the components are given for all the custom-built equipment. The frequency range is from 17 to 28 kmc/*s*. Peak Stark-modulation voltages up to 1500 volts sine wave and 800 volts square wave are used. The sensitivity is better than 1×10^{-8} cm^{-1}. The absorption lines are about 300 kc wide at half-power and the practical limit of resolution is between ½ and 1 mc. Frequencies may be measured to better than ±0.08 mc.

A. INTRODUCTION

In postwar years the field of spectroscopy in the microwave frequency region has grown with tremendous rapidity. This growth has been stimulated chiefly by the great advances in microwave techniques during the last war and the fact that the method provides the molecular structure investigator with a new source of valuable information. Microwave spectroscopy permits precise evaluation of absorption frequencies (to about one part per million) and resolving powers thousands of times better than the best infra-red spectrometers; thus contributing to a more complete knowledge of the spatial arrangement of atoms in the molecule as well as a study of nuclear spins and quadrupole moments. As evidenced by the wide use of optical spectrometers in industry, the future of the microwave instrument as an analytical tool promises to be a great one.

One of the most successful approaches used for detecting weakly absorbing lines in this high radiofrequency region is that devised by Hughes and Wilson[1] and is usually referred to as the Stark-modulation method. This paper will be concerned with the design and construction details of a microwave spectrograph using this principle.

Briefly, the Stark-modulation scheme makes use of the change in the absorption frequency of a gas molecule when the molecular energy levels are perturbed by an external electric field, i.e., the so-called Stark effect. Referring to Fig. 1, microwave energy from a source is passed through the gas-to-be-studied which is confined in a wave guide cell by transparent mica windows at each end. If the source is tuned to an absorption frequency then a diminished amount of power will be received at the crystal detector. However, the absorption frequency of the gas is being alternately switched between two frequencies corresponding to the peaks and troughs of an externally applied 100 kc square or sine wave electric field based on zero voltage. This field is applied between an insulated electrode strip running down the center of the wave guide and the wave guide itself. Hence the signal reaching the crystal detector is amplitude-modulated or, as we may say, Stark-modulated, at a 100-kc rate and may be amplified and presented on the vertical plates of an oscilloscope. In order to examine a finite region of the spectrum at one time, a frequency axis is provided on the oscilloscope by frequency-modulating the source with a lower frequency saw-tooth voltage and applying this same voltage to the horizontal plates of the oscilloscope (refer to Fig. 1). Figure 1a shows a complete block diagram of the system and the components will be discussed individually in the ensuing sections.

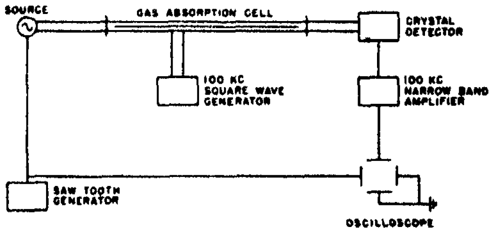

FIG. 1. Simplified block diagram of a Stark-modulation spectroscope.

The main advantages of this system over straight detection and amplification at audiofrequencies without any Stark-modulation are: (1) By detecting and amplifying at a frequency of 100 kc, one avoids the lower frequency region where there is high crystal and source noise. At higher frequencies the impedance of the wave guide cell becomes so low that it is difficult to obtain a good high amplitude square wave modulation voltage. Also, if one uses modulation frequencies higher than about 100 kc, the true absorption line shape becomes distorted (see reference 6). Consideration of these factors thus lead to the adoption of an optimum Stark-modulation frequency somewhere in the neighborhood of 100 kc; (2) Commercial receivers having a very narrow and variable band width may be used as the 100-kc amplifier; (3) Spurious responses caused by standing waves and other frequency sensitive devices in the wave guide system are eliminated. It is evident that, with this scheme, that a 100-kc response is obtained only when one tunes the source through an absorption line; (4) The Stark patterns of the absorption lines are omnipresent and are often useful in identifying the transition and for measuring dipole moments. The disadvantages are that absolute intensity meas-

urements are difficult to make (though relative measurements may be made with reasonable accuracy) and, under some conditions, the observed lines are sufficiently broad as to limit the ultimate resolution.

It is the purpose of this article to give a rather minute account of an instrument built in the General Electric Research Laboratory in the hope that it may facilitate construction by other interested workers in the field. Wherever special circuits have been designed, these will be reproduced together with circuit constants in order to be of greatest usefulness.

B. SPECIFICATIONS OF THE SPECTROMETER

The frequency range which may be covered with selected tubes is from 16.6 to 28.0 kmc/*s*. This range will be referred to as the "*K*" band throughout this paper. The Stark-modulation voltage may be varied continuously from 0 to 1500 volts sine wave; or from 0 to 800 volts square wave. The factor for converting these voltages to e.s.u./cm is 0.00691. The maximum sensitivity is estimated to be better than 1×10^{-8} cm^{-1}. This figure is based on the fact that the weaker $N^{15}H_3$ lines, present in about 0.4 percent concentration in ordinary ammonia, have been readily observed with a one-foot absorption cell. The absorption lines are about 300 kc/*s* wide at half-power points and the practical ultimate limit of resolution is between $\frac{1}{2}$ and 1 mc/*s*. Frequencies may be measured to an accuracy of ±0.08 mc/*s* over this range. Measurements have been made from room temperature down to −78°C.

C. DESCRIPTION AND DISCUSSION OF COMPONENTS

1. Wave Guide Components and Sources

Sources: The most commonly used power source has been the "*K*"-band radar 2K33 tube (also referred to as 2K33A and QK33). Although the normal frequency coverage is 22.0–25.0 kmc/*s*, these tubes have been used from 16.6 to 28.0 kmc/*s*. By selecting tubes, this range has been usually covered with three tubes. Operation at the extreme ranges has been improved by a 10 percent decrease or increase of the diameter of the external cavity peculiar to this tube. The external cavity appears to be sufficiently closely-coupled to the inner frequency-determining cavity so as to "pull" its frequency slightly. Other operating hints that have been noticed are that low beam currents and voltages favor the generation of low frequencies and *vice versa* at high frequencies. The high frequency limit may be sometimes extended by increasing the heater voltage 10 or 20 percent and operating the tube with beam currents as high as 15 ma. It is realized that such operation represents considerable abuse of the manufacturer's ratings but was considered justifiable in the limited use here. For reference, the base connections are given in Table I and, in Table II, the nominal ratings of this and other microwave tubes which are now being manufactured by the Raytheon Manufacturing Company, Waltham, Massachusetts.

Another type tube which is also used on this spectrometer is the G.E. Z-668.* Unfortunately, this tube was not produced commercially and only a few laboratory samples are available. Since it was designed originally for use in the "*K*" radar band, it covers essentially the same range as the 2K33. In sweeping over wide ranges of frequency, it is easier to keep the Z-668 in a state of oscillation, since there is no external cavity to keep in adjustment as with the 2K33.[2]

Directional couplers: These are essentially of two types; *viz.*, narrow and wide band. The latter is to be preferred, although the demands are not very stringent as used here and both types have been used successfully. A Type TPK-16HU was purchased as surplus

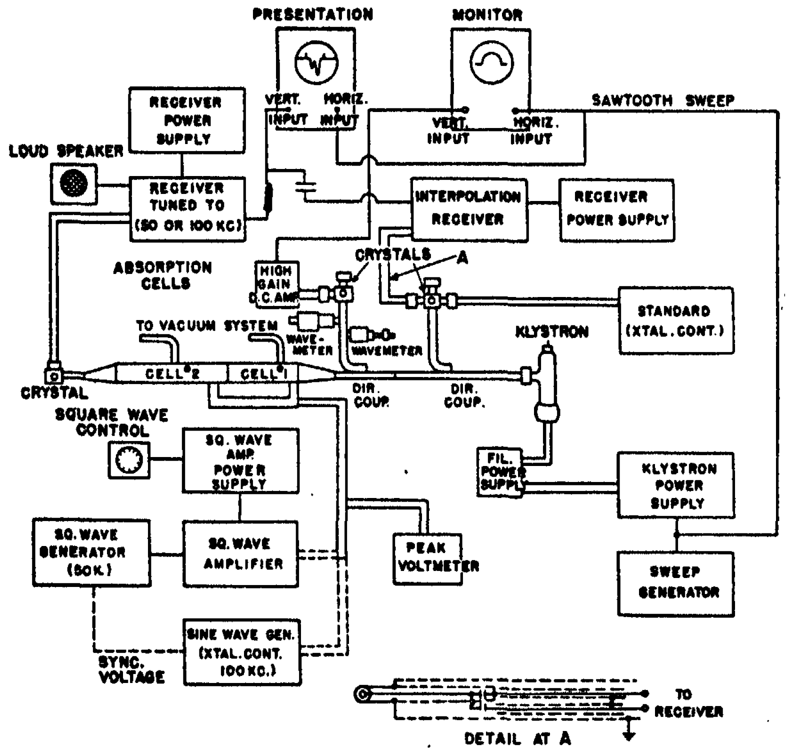

FIG. 1a. Complete block diagram of the microwave spectroscope electronic gear.

from the Humble Oil Company at a very reasonable price. Other couplers were designed according to the procedure outlined by W. W. Mumford[3] with good results.

Wave meters: A Type TFK-2 absorption wave meter[4] utilizing the TE_{111} mode, is used in the range 21–28 kmc/*s*. This wave meter is self-calibrating and, with care, one can measure frequencies to an accuracy of ±7 mc. Such accuracy may be obtained only by narrowing the swept frequency range and measuring the two half-wave responses without changing the wave-meter coupling.

Below 21 kmc the TFK-2 wave-meter response becomes quite broad and is not satisfactory. For this range, a wave meter using the TE_{011} mode was designed using the coupling scheme suggested by Bleaney *et al.*[5] The critical dimensions are indicated in Fig. 2 where all the shaded parts are to be made of high conductivity copper. A wave meter constructed according to this design has been satisfactorily used in the range 16.6–22.0 kmc/*s*.

Crystals and crystal mounts: 1N26 silicon crystals have been used almost exclusively as detectors for the 1-cm energy. There is a wide variation in their performance and great improvement in sensitivity and noise figure can be obtained by using selected crystals. Comparable detector performance could be obtained by using biased germanium crystals but, in general, the silicon crystals, without bias batteries, were more convenient. One precaution, which may be appropriately mentioned here, is always to remove the crystals from the wave guide equipment and shield them before using a sparking coil on the vacuum equipment. Failure to do this will result in burned-out crystals.

The crystal mounts which are used are of the "cross-bar" type shown in Fig. 3. These mounts are designed so as to terminate the wave guide in a matched load

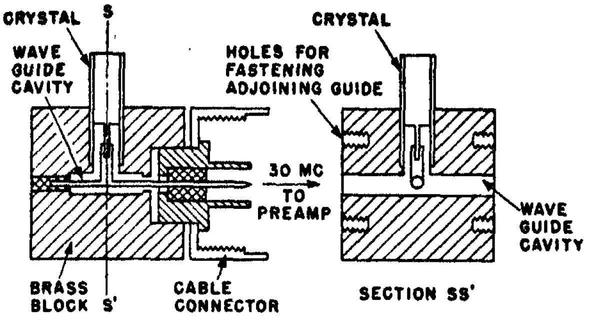

FIG. 3. Construction of the crystal mounts.

when an average crystal unit is inserted. The mounts are tuned to give optimum performance at 24.0 kmc/*s* but are very broadband and work well over the entire tuning range. If it is desirable to obtain a more perfect match at the extremes of the tuning range, a tuning screw and adjustable short circuit can be added to the circuit.

Transformer sections: The transformer sections which are used to join smoothly the $\frac{1}{4}$ in.×$\frac{1}{2}$ in. wave guide to the $\frac{1}{2}$ in.×1 in. size were fabricated in the machine shop. The four sides of the taper were first soft-soldered together and a jig used to align a short length of standard guide to each end. These final joints were made with a lower melting solder so as not to disturb those already soldered. The taper was made three inches long to insure a minimum of reflected energy. From the point of view of reflections, a somewhat smoother taper could be obtained by an electroforming process.

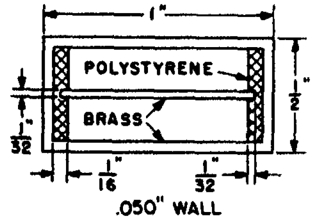

FIG. 4. Cross section of the wave-guide absorption cell.

Wave-guide absorption cell: The absorption cell was constructed of two 16 ft. lengths of $\frac{1}{2}$ in.×1 in. brass wave guide. The lengths are arranged side-by-side on a 2 in.×6 in. board and are made as independent units so that either one or both may be used at a time. The connecting "*U*" is bent out of similar guide and has an inside radius of $1\frac{1}{4}$ in. The two cells are thus sufficiently close to permit enclosure by a wooden box (made of 1 in. boards) to house dry ice refrigerant. The box terminates 6 in. away from the wave-guide windows in order to avoid cracking the beeswax. When it is desirable to chill the gas, the insulation is sufficiently good to allow a single daily filling with crushed dry ice.

The dimensions of the cross section of the cell are shown in Fig. 4. The polystyrene strips were stacked and milled as 6-in. lengths. The center electrode was made by rolling up oversized $\frac{1}{32}$-in. brass strip and cutting to the desired width on a lathe. The strip was unrolled and fed into one end of the wave guide along with the polystyrene strips. It was found convenient to pass a wire down the guide and pull the electrode through rather than push it. The tolerances on the polystyrene strips and brass electrode must be held as closely as possible so as to insure uniform spacing of the electrode since this is the limiting factor in the precision with which the applied Stark field is known. Also, a cell with a slightly off-center septum will cause a doubling of the Stark pattern and thus make their interpretation very difficult. Care should be exercised

to obtain pure polystyrene since a plastic which is loaded with a volatile plasticizer may cause much difficulty in obtaining a good vacuum.

When measuring dipole moments, it is desirable to know the Stark electric field as accurately as possible. One possible source of error is the fringing caused by the presence of the dielectric which supports the Stark electrode inside the wave guide. To determine the magnitude of this effect, a flux plot was made in an electrolytic tank.** The difference in dielectric constants was simulated by a difference in tank depth; the dielectric ratio being directly proportional to the conductance. A line of small insulated wires served to define the interface boundary. Figure 4a shows the equipotential flux plot so obtained and demonstrates the exact amount of fringing. Advantage was taken of the symmetry and so only one-quarter of the wave guide cross section was actually plotted. To find out the field distribution, the flux plot was divided into 170 squares and the field strength estimated for each square. The square of the field strength was then plotted against number of squares having the same field; the envelope of which gave a rather smooth distribution curve. The peak of this envelope coincided with the field computed neglecting inhomogeneity and was sufficiently sharp as to demonstrate the inconsequential nature of the fringing at the dielectric boundary. In actual practice, this distribution would have a $\sin^2(\pi x/l)$ weighting factor (l is guide width), which would even further decrease the importance of the fringed regions.

The $\frac{1}{2}$ in.×1 in. wave-guide size was selected in preference to $\frac{1}{4}$ in.×$\frac{1}{2}$ in. size for several reasons: 1. it is easier to fabricate into a cell; 2. percentwise, closer tolerances could be maintained and hence the Stark-field is known more accurately; 3. the chances of saturation and consequent broadening and weakening of the lines is diminished because of the greater cross-sectional area; 4. the attenuation is smaller. A disadvantage is that higher modulation voltages are required to obtain equivalent field strengths. No serious trouble was experienced with the expected higher order modes although their presence was demonstrated by the detection of electric field components at right angles to that in the normal TE_{10} mode. The capacity per foot is about the same with either $\frac{1}{2}$ in.×1 in. or $\frac{1}{4}$ in.×$\frac{1}{2}$ in. wave guide; *viz.*, 60 µµfd./ft. The attenuation is about 1 db/foot which is very high compared to a similar guide without an inner electrode. A brass wave guide having the dimensions $\frac{1}{2}$ in.×1 in. and operated at 24 kmc. in the TE_{10} mode should have about 0.07 db/ft. attenuation. One may readily compute that in the geometry used here, only about 1 percent of the power flowing down the wave guide goes through the di-

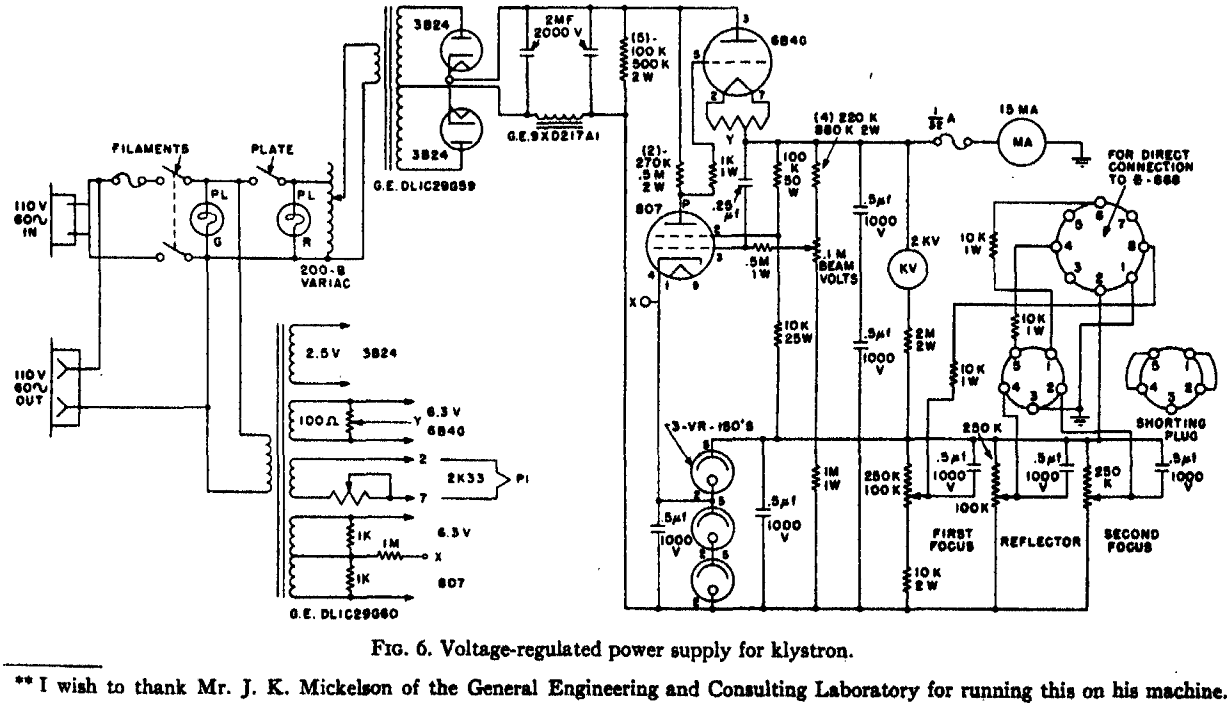

FIG. 6. Voltage-regulated power supply for klystron.

** I wish to thank Mr. J. K. Mickelson of the General Engineering and Consulting Laboratory for running this on his machine.

electric, so this cannot contribute heavily to the losses even if it were a poor dielectric. Because of the division of the absorption cell by the Stark electrode, we actually have energy transmission down two wave guides having the electrode as a common wall. The attenuation by a guide of these dimensions is about twice that previously computed on the basis of the outer geometry. The remainder of the high attenuation is likely due to window reflections and conversion of power to the several other modes of propagation which may be supported by a guide of these dimensions and which are not detected at the crystal mount. The voltage standing wave ratio is of the order of 2 to 1.

The electrical connection to the insulated strip was made with a Fernico wire-glass seal, the Fernico eyelet being soft-soldered to the wave guide. It is well to provide ample clearance of the connecting wire (or, better yet, insulate it) from the outside wave guide so as to avoid short circuiting caused by relative movement when the guide is being chilled. A Type N connector was mounted externally for convenient connection and thorough shielding.

Other variations in construction would be to use a thicker electrode (tapered at the ends to avoid reflections) and hence obtain higher field strengths. To make measurements at elevated temperatures, one could use a ceramic or Teflon spacer instead of polystyrene.

Absorption cell windows: A very satisfactory wave-guide window was made by sealing a thin piece of clear mica with beeswax. The following procedure proved to be the best way of making them vacuum-tight: 1. cut a piece of mica about $\frac{1}{32}$ in. or less in thickness to a size so as just to clear the holes in the coupling flanges; 2. paint around the edges with melted wax before applying the mica; 3. hold mica sheet against the flat coupling flange with a slight positive pressure while heating the entire coupling to melt the wax; 4. hold in place until the wax solidifies; and, 5. paint around the edges with melted wax.

2. Electronic Circuits

Filament Power Supply: When the amplifiers were used at highest gain, a rather troublesome 60-cycle ripple was experienced. This was cured by supplying the klystron heater with d.c. voltage. The circuit given in Fig. 5 was built into a 6 in.×6 in.×6 in. metal box and had a range of 3.5 to 9.5 d.c. volts when working into a ten ohm load. The ripple at 6.3 volts is less than 0.1 volt.

Klystron power supply: The power supply for the klystron is necessarily voltage-regulated in order that the operating frequency of the klystron remain steady. The schematic diagram for the supply used is given in Fig. 6 and follows the conventional design. This circuit supplies 1500–2000 volts of regulated voltage with less than 35 millivolts ripple. The controlling potentiometers for the various electrode voltages are sub-mounted as a safety precaution. A five-prong plug provides a ready access to the reflector electrode to superimpose a modulating voltage. When the modulation is not desired, the shorting plug may be inserted. Early models of the

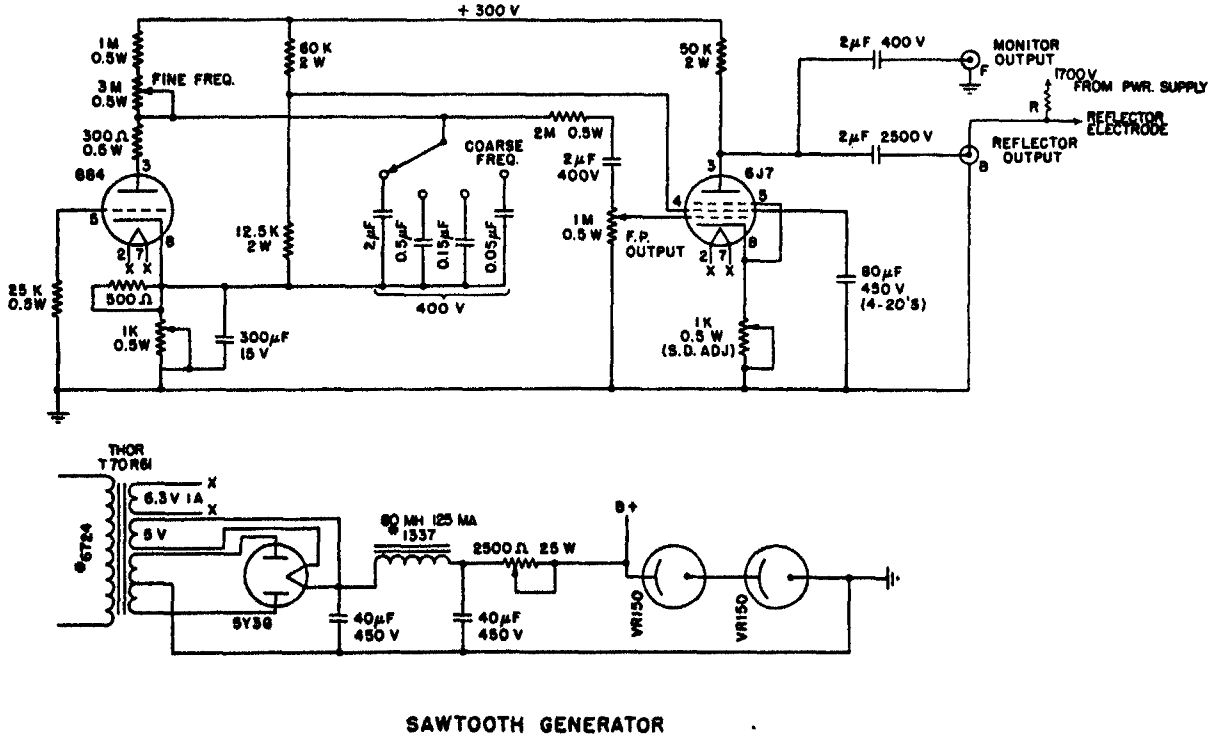

FIG. 7. Sawtooth generator schematic.

Z-668 used a second focus control which accounts for its appearance on the diagram. Furthermore, it is considered good practice to insert 10,000 ohm resistors as current limiters in series with the reflector and focus voltage leads and these have been included in the circuit. The output voltage plug is shown in the circuit schematic for connections to the Z-668. The base connections are different on the 2K33 and hence the connecting cable for this tube will have several transposed leads. (See Table I for base connections.)

Saw-tooth generator: The saw-tooth generator is designed to generate the rather low sweep frequency of two cycles per second. Low sweep rates favor good resolution and more accurate reproduction of the absorption line shapes. Since the band width of the 100-kc amplifier is of the order of 200 c/s (at ten times down in voltage), the lowest sweep rates are necessarily used to avoid amplifier distortion. Suppose, for example, a band 50 mc wide is examined at certain sweep rate f and that an absorption line is 1 mc wide. It would thus require $(1/50)(1/f)$ mc to sweep over a line and the required band width of the amplifier Δf would be of the order $50f$. Equation (6) of Section E shows that Δf should be kept as small as possible for best sensitivity; consequently, the sweep frequency f is adjusted to comply with the narrowest band width attainable. Of course, one could achieve even greater sensitivity by going to a pen recorder where Δf would be of the order of 30 c/s. Although one would have to tune the source through a line at a still slower speed (1/30 sec.), it would only require a minimum of 6 minutes to cover the full range of 10,000 mc.

The reflector electrode, to which the sawtooth output voltage is applied, is at a high potential with respect to ground; consequently, the most convenient way is to couple in with a high voltage condenser or an isolation transformer. Condenser coupling (see Fig. 7) was selected as being the most convenient in this application. Resistor R in Fig. 7 is preferably 1 megohm so as to present a high impedance across the saw tooth generator output, but with some klystrons the gas and leakage reflector current is sufficiently high as to cause the reflector to swing positive with respect to the cathode. This may damage the tube and not permit oscillation. To remedy this, R may be decreased, or, in severe cases, a series connection of three G.E. G-5 germanium diodes has been substituted successfully.

A total range of 2 to 160 c/s is covered with a good wave shape as viewed on an oscilloscope. The output voltage may be varied from zero to 100 volts. In Fig. 7 the circuit is seen to consist of a standard relaxation oscillator with a single stage of amplification.

Sine wave generator: A source of sine wave modulation voltage was designed to give continuously variable voltages from 0 to 1500 volts with a good wave shape. The circuit is given in Fig. 8 and consists of a Pierce crystal oscillator coupled by a cathode-follower circuit to an easily driven 829B beam power tube. The oscil-

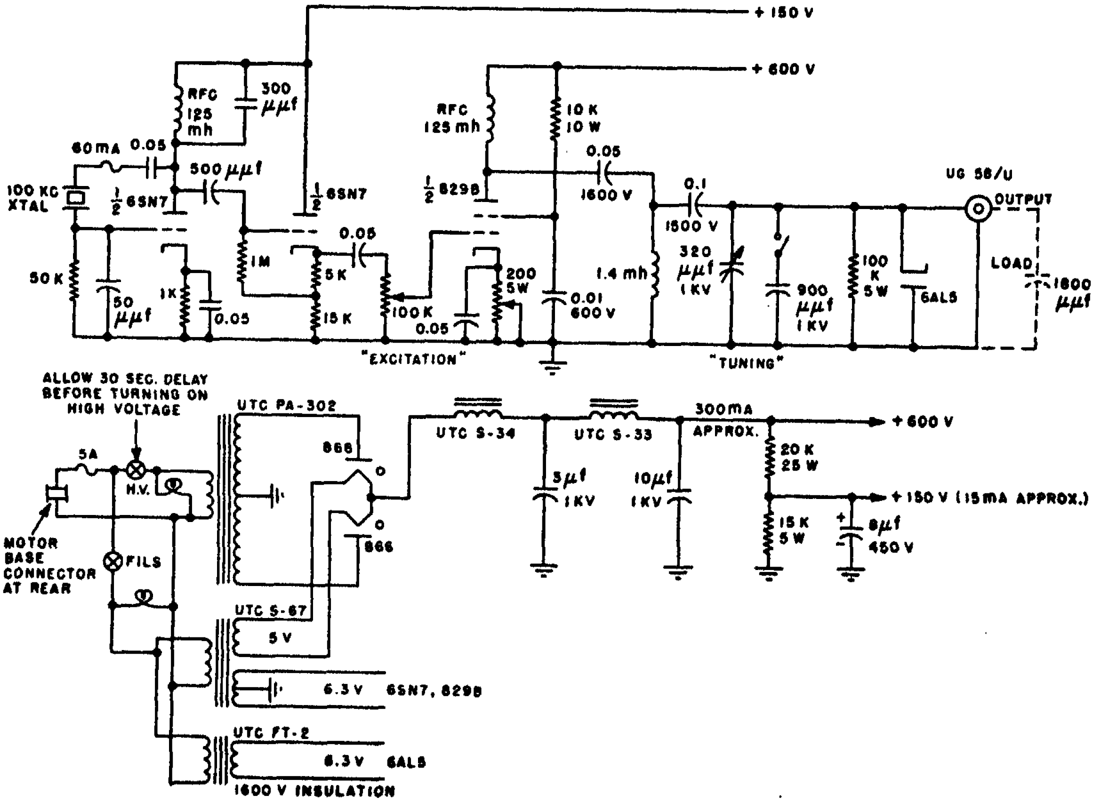

FIG. 8. Sine wave modulation source.

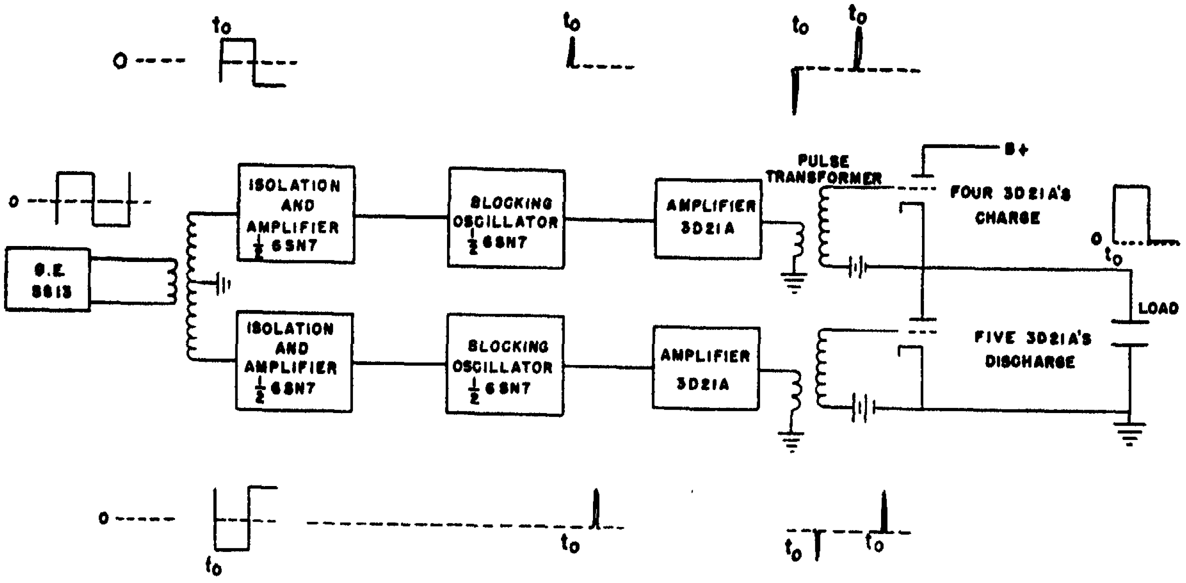

FIG. 9. Block diagram of square wave generator.

lator is crystal-controlled to insure a constant frequency and hence maintain correct tuning of the narrow-band amplifier. It also serves as a convenient source of synchronization voltage to hold the square wave modulation source on frequency. The capacity formed by the Stark electrode and surrounding wave guide serves as the tank capacitor of the 100 kc/*s* amplifier stage. This capacity is shunted with a 320-$\mu\mu$fd trimmer capacity to resonate it precisely and also a fixed capacity equal in magnitude to one of the wave-guide absorption cells. Switching in this latter capacity permits the use of only one of the two wave-guide cells when this is desired. In order to double the available sine wave modulation voltage and to study conveniently Stark effects as a function of voltage, an automatic bias circuit (a 6AL5 tube and 100,000 ohm resistor) was incorporated which always keeps the troughs of the sine wave at zero voltage. It would be necessary to tune the amplifier to twice the modulation frequency if no bias were used.

Square wave generator: If one wishes to make a careful study of line shapes and obtain the Stark effect pattern of degenerate transitions, then it is necessary to use square modulation.[8] The price to pay for a high voltage square wave generator at these frequencies is rather high; consequently, sine wave modulation was used where extremely high fields were required in searching (e.g., on molecules known to have a small dipole moment). Having found a line, one may then switch over to the square wave field for a detailed examination of the Stark pattern. A careful comparison was made between sine and square wave modulation and equivalent shifts of the Stark images were found in the case of the $J=0\rightarrow1$ transition of methyl chloride. However, in the case of more complicated Stark patterns, such as encountered in the $J=1\rightarrow2$ transition of chlorosilane, better resolution and hence more detail was observed when using square wave modulation.

The requirements of the square wave generator are rather stringent; *viz.*, (1) a maximum of 800 volts amplitude based on zero, (2) 50 percent duty cycle at 100 kc/*s* frequency, (3) rise and fall time of less than 0.25 μsec., and (4) a pure capacitative load of about 2000 $\mu\mu$fd. This means that the charging currents are of the order of 6 amperes and the best way to achieve such is to use a bank of high emission tubes to charge the condenser load and another bank to discharge it. To understand more fully the operation of this generator, it will be instructive to refer to the block diagram of Fig. 9 where one complete cycle is traced through the circuit. Referring to the figure, a G.E. SG13 square wave generator is used to trigger a blocking oscillator whose output pulse is amplified and then inverted by a pulse transformer. These positive pulses are fed into the grids of the charge and discharge tubes connected in cascade and alternately charge and discharge the condenser load formed by the Stark electrode. It is seen that the charge and discharge circuits are identical except that the voltage forms are 180° out of phase with respect to each other. The detailed diagram with circuit constants is presented in Fig. 9a where the SG13 triggering generator is to be connected to the input terminals.

A block diagram of the power supply is given in Fig. 10 as an aid in interpreting the detailed schematic diagram of the supply in Fig. 10a. It is to be noted that the charge tubes are self-biased while the discharge tubes use fixed bias from a selenium rectifier. This was done so that the high voltage B^+ would not be shorted through both the charge and discharge tubes when the amplifier was shut down. The 1-V rectifiers are used to

clamp the base line of the square wave on zero, should the square wave trough try to go negative.

In the finished generator the square wave was continuously variable between 25 and 800 volts. For observing first-order Stark effects which require less than 25 volts, a resistance-capacity divider is used which extends the low voltage limit down to about ½ volt. The top of the square wave is flat to less than ½ percent and the bottom edge remains constant to within 2 percent. This sort of performance is obtained over the frequency range 25 to 100 kc/*s*.

Peak voltmeter: Since we are concerned with the peak values of the Stark field when using either sine wave or square wave voltages, it seemed advisable to construct a peak reading voltmeter with a direct reading scale. A 5Z4 tube was used as a diode rectifier as indicated in the circuit of Fig. 11. For calibration at 60 cycles, the 0.1-μfd condenser should be shunted with several microfarads of capacity to increase the time constant of the circuit. The use of a large scale DP2 instrument as indicator facilitated accurate reading of the voltages.

Narrow-band amplifier: A National HRO-5RA receiver is used as the narrow-band amplifier. When the crystal filter is in the maximum selectivity position, little distortion of the lines is noted at sweep rates of 2 cycles per second. At higher sweep rates it is necessary to use wider band widths to avoid distortion and hence a sacrifice in signal-to-noise ratio is made. The input to the HRO receiver was modified to use a shielded coaxial connector to avoid stray pick-up and also the audio stages were by-passed so as to avoid possible distortion. The receiver performs satisfactorily at both 50 kc/*s* and 100 kc/*s* although the gain is considerably higher as the latter frequency.

Oscilloscopes: The output from the narrow-band amplifier is fed into a Dumont 208-B oscilloscope. This instrument is admirably suited for this application because of its high *Y*-axis gain and exceptionally good low frequency response. A long persistent Type P-7 fluorescent screen tube is used which enabled sweep rates of 1–2 *c/s* to be used.

For the monitor oscilloscope, a Dumont 241 instrument is used. There is considerable distortion at sweep frequencies below 30 *c/s*; however, since any curvature of the trace indicates power output from the klystron, it may be satisfactorily used to indicate a state of oscillation. A 450A Hewlett-Packard booster amplifier with 40 db gain was used in conjunction with this oscilloscope. In some respects the Dumont 208-B would be a better choice here, but it is convenient to have on hand an oscilloscope with a good high frequency response (as does the Model 241) with which to check occasionally the 100 kc square and sine waves supplies.

Crystal-controlled frequency standard: If one uses an absorption cavity wavemeter as previously described, the absorption lines may be measured with an error of less than ±7 mc over the range of the spectrometer. However, this is not sufficiently accurately to study fine structure of lines which are spaced only tenths of a megacycle apart. Therefore, a crystal-controlled oscillator is used to produce standard marker pips whose frequencies are known to better than one part per million. These markers are produced by beating the crystal standard output (containing 20, 40, 120, and 360 mc and their harmonics) against a fraction of the klystron power derived from the main wave guide with a directional coupler. A single crystal is used both for mixing and harmonic generation; there being continuous harmonics of the standard signal present in the mixing block at least through *K*-band. Since the standard signal harmonics are fixed in frequency, and the klystron signal is continuously swept in frequency, the mixing action of the crystal will cause a continuum of difference frequencies to be generated as the klystron signal frequency approaches, equals, and then passes the standard marker signal. Referring to the block diagram of Fig. 1a, these difference frequencies are fed into the input of a communications receiver (Hammarlund SPX400), and thence to the presentation oscillo-

scope. When the difference frequency passes through the frequency to which the receiver is tuned, a "pip" occurs on the oscilloscope screen. Thus, for each *K*-band harmonic this gives rise to two markers which are separated by twice the receiver frequency; and by tuning the receiver, a marker may be superposed exactly on an unknown absorption line. The frequency is computed from the relation

$$f=nf_1\pm f_r,$$

when n is an integer, f_1 is the lowest frequency introduced into the crystal mixer; *viz.*, 20 mc in this case, and f_r, the setting of the receiver. In this manner one may continuously interpolate between the standard marker pips. The cavity wave meter is used to determine the value of n in the above equation and so identify the harmonic of the standard generator.

The crystal-controlled standard is similar to one described by Talpey and Goldberg[7] and consists of a crystal-controlled 10-mc oscillator, a buffer stage, two doubler, and two tripler stages with output on 360 mc. As noted on the circuit diagram of Fig. 12, link coupling is made to the 120-mc and 360-mc stages only, but there is sufficient stray coupling to the lower frequency stages to cause harmonics to appear in the crystal harmonic generator every ten megacycles. Since it was difficult to identify positively the markers this close together, a ten megacycle wave trap was incorporated in the output circuit leaving only markers every twenty megacycles.

A frequency trimmer allows the oscillator circuit to be zero heat with *WWV* and the frequency remains constant for days to ±10 cycles or 1 part per million at the used harmonic frequency.

Since the crystal standard output and receiver are in parallel across the crystal, it is desirable to prevent the standard from offering a low impedance to the difference frequencies. A circuit resonating near 4 mc was connected as shown in Fig. 1a and helped to increase the difference frequency signal seen by the receiver. Likewise, the receiver was prevented from absorbing the standard signal by using a quarter wave-length choke. The dimensions of the choke were chosen to present a high impedance at 40, 120, and 360 mc. The multiple shield shown as Detail *A* of Fig. 1a helped to reduce noise pick-up.

Germanium crystals, as expected, were found to be more efficient, harmonic generators than silicon crystals. Their use, combined with the fact that a single crystal was used as both mixer and harmonic generator, probably accounts for the fact that the usual high frequency tripler following the 360-mc stage could be entirely eliminated from the circuit.

More recent experiments show that a butterfly circuit is superior to the lumped constant, 360-mc tank circuit shown in Fig. 12.

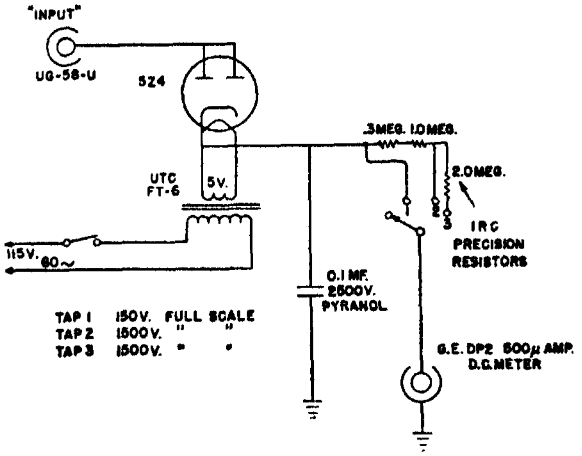

FIG. 11. Peak voltmeter circuit.

3. Vacuum System

A block diagram of the essentials of the vacuum system is shown in Fig. 13. The manifold is equipped with a number of stopcocks for maximum convenience in handling the gases. The remainder of the diagram is self-explanatory. Each sample bulb has a small reservoir for "freezing out" the gas. The stopcocks are all the precision hand-ground variety which insures trouble-free operation.

The circuit diagram for the Pirani gauge is reproduced in Fig. 14. The variable resistance arm in the bridge circuit consists of the G.E. FA-13 tube with a matched FA-14 tube as a compensator. In order to increase the sensitivity, a special low resistance movement micro-ammeter (72 ohms) is used to read the unbalance voltage developed across the bridge as a result of pressure changes. With the circuit constants given, the full scale reading in microns of air is given for the different positions of the sensitivity switch. For greater accuracy at lower pressures a more sensitive meter with still lower internal resistance could be used. Six volts d.c. is normally applied across bridge and may be adjusted with resistor *R*. The other variable resistances are screwdriver adjustable potentiometers which may be permanently set when the meter is calibrated.

The thermocouple gauge circuit is given in Fig. 15. The thermocouple gauge tube may be obtained with either a hard or soft glass bulb. Of course, both of these gauges will respond differently with gases having different convection cooling factors so the pressure readings are only approximate.

D. OPERATIONAL NOTES

The general operating procedure when searching for unknown absorption lines is as follows: The gas sample is "frozen out" with liquid air and pumped down to insure the removal of all the non-condensibles. These non-condensibles tend to dilute the sample and cause a weakening and broadening of any desired lines. The

wave-guide cell is then flushed out three or four times with the gas and between ten and fifty microns finally admitted to the cell. Searching is usually done with about 500 volts of sine wave Stark field and with the smallest band width of the HRO. Having found a line, if it is desired to study its fine structure, then one can optimize the gas pressure and Stark square wave voltage. For linear and symmetric top molecules the approximate expected absorption frequencies may be computed from Eq. (3) and thus guide one as to which region to sweep initially. In searching, it is necessary to tune the tube slowly and maintain a state of oscillation at all times by adjusting the reflector electrode voltage. Oscillation is indicated by the trace on the monitor oscilloscope and by the amount of noise emanating from the receiver crystal. This latter noise appears as "grass" on the Dumont 208 screen when the gain is increased. The edges of the tube mode are also defined by a sharp response on the oscilloscope due to the reception of the 100-kc harmonic component of the sweeping frequency.

The intensity of some weak lines may be enhanced by chilling the guide with dry ice. The expected amount of increase in intensity may be readily computed with the aid of Eqs. (1) and (2).

In order to check the performance of the spectroscope, one may introduce ammonia in the one-foot cell. Since the ammonia spectrum is so rich in accurately known lines, it may be allowed to remain in the cell to provide visual checks over the entire frequency range. However, after the operator becomes familiar with the instrument, it is usually preferable to pump out the ammonia because its lines are so intense that they become annoying when the amplifier is adjusted to a high gain. To help stabilize the oscilloscope trace against sudden large variations in signal input, a crystal diode limiter was connected across the input terminals to the oscilloscope.

One must avoid introducing ammonia gas into the long wave guide cell because it is very difficult to pump out. On one occasion this accidentally happened and ammonia lines appeared for weeks afterward in spite of constant pumping.

In some parts of the tuning range certain rather broad 100-kc responses are obtained which resemble absorption lines in their behavior. They increase in strength with the Stark field and are not present when the Stark field is zero. It has been suggested[8] that this effect may be caused by electric polarization saturation effects in the polystyrene supports for the Stark electrode or of surface deposits on them. If there is any doubt as to whether one has a spurious response or not, the gas may be pumped out (or frozen out) and, of course, a real absorption line will disappear. Conversely, an increase in pressure will cause a broadening of a real absorption line.

Voltage should be removed from the Stark electrodes when the pressure of the gas is being adjusted because of possible arcing in the wave guide. This will cause a decomposition of the gas and hence ruin the sample.

E. USEFUL EQUATIONS

Several general equations which have been found useful in microwave spectrograph studies will be reproduced here without derivation. These will apply only to linear and symmetric top molecules, since the asymmetric cases are usually more complicated and do not reduce to such simple form.

For pure rotational absorption the intensity ration to be expected by changing the gas temperature from T_1 to T_2 may be shown to be:

$$\frac{I_{T_2}}{I_{T_1}}=\left(\frac{T_1}{T_2}\right)^{5/2}\exp\left[\frac{-E_j}{k}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)\right]\quad\text{for linear molecules}\quad(1)$$

$$\frac{I_{T_2}}{I_{T_1}}=\left(\frac{T_1}{T_2}\right)^{3}\exp\left[\frac{-E_j}{k}\left(\frac{1}{T_2}-\frac{1}{T_1}\right)\right]\quad\text{for symmetric top molecules,}\quad(2)$$

where E_j is the energy of the jth rotational state. Thus, if one uses dry ice as a refrigerant ($T_2 \cong 200°\text{K}$) and ($T_1 \cong 300°\text{K}$), for the case of the usual microwave absorptions the exponential will be very nearly unity. For this special case $I_{T_2}/I_{T_1} \cong 2.8$ and 3.4 for linear and symmetric top molecules, respectively. It must also be remembered that in order to keep the number of molecules a constant, the gas pressure must be reduced as the temperature is lowered when comparative intensity measurements are made.

Prediction of Absorption Frequencies

The expected absorption frequencies for both linear and symmetric top molecules are given approximately by[9]

$$\nu=\frac{1010\times 10^3(J+1)}{I_B}\quad(\text{mc}/s,\ \text{atomic wt.}-\text{Å}^2)\quad(3)$$
$$J=0,\ 1,\ 2,\ \cdots$$

$$\nu=\frac{167.8\times 10^{-36}(J+1)}{I_B}\quad(\text{mc}/s,\ \text{g-cm}^2).$$

[9] See for example G. Herzberg, *Infrared and Raman Spectra of Polyatomic Molecules* (D. Van Nostrand Company, Inc., New York, 1945).

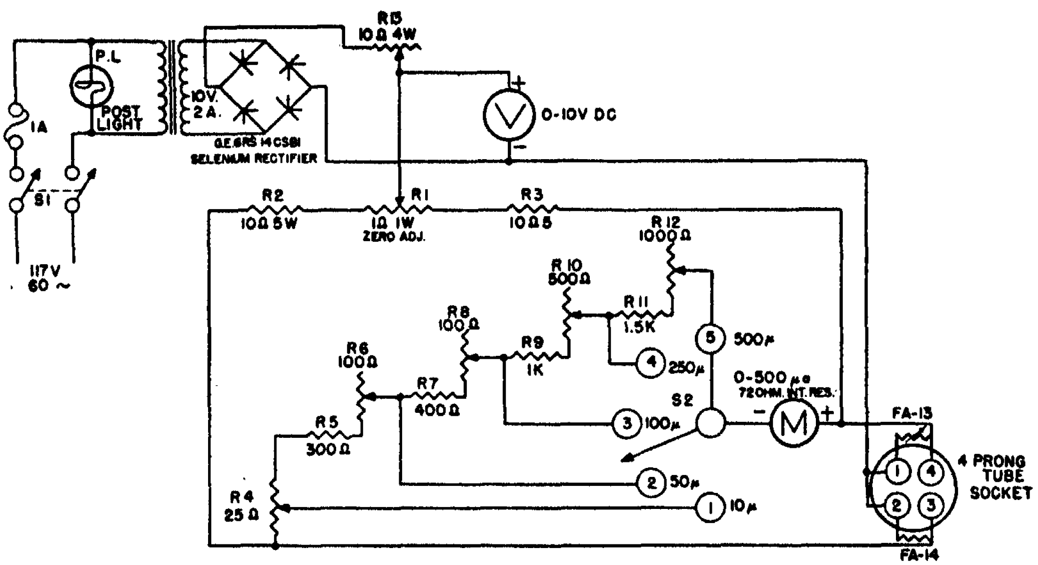

FIG. 14. Pirani gauge circuit diagram.

I_B is the moment of inertia taken about an axis perpendicular to the internuclear or symmetry axis and going through the center of mass. Mathematically it is defined as

$$I_B=\sum_i m_i r_i^2,$$

where r_i is the perpendicular distance of the ith nucleus of mass m_i from the axis passing through the center of mass. Two simple examples will best illustrate the computation of I_B.

For a linear molecule of the X-Y-Z type shown in Fig. 16

$$I_B=M_z(d_{yz}-x)^2+M_yx^2+M_x(d_{yz}+x)^2. \tag{4}$$

The center of gravity is defined by the relation

$$M_x(d_{xy}+x)+M_yx=M_z(d_{yz}-x), \tag{5}$$

where M_i is the mass of the ith atom in appropriate units. The internuclear distances are taken as the sum of the covalent radii as found, for example, in Pauling's book *Nature of the Chemical Bond*.

For symmetric rotor molecules of the type X_3-Y-Z as illustrated in Fig. 17, the computation of I_B may be computed in the following manner: the approximate moment of inertia is obtained by treating the molecule as a linear one with the mass of the three X atoms concentrated at the point defined by the intersection of the symmetry axis and the plane defined by them. In other words, assuming a tetrahedral angle of 110°,

$$d_{y3x}=0.328d_{yx}$$

and Eqs. (3) and (4) are then used as for an X-Y-Z molecule, where M_x is now $3M_x$. When the masses of the X atoms are appreciable, a consideration of the mechanics of this system of point masses shows that I_B may be corrected by adding to it the quantity $1.31M_xd_{yx}^2$. This latter correction is the moment of inertia of two X atoms about the axis aX in Fig. 17.

Computation of Expected Intensity of Absorption

To compute the absolute absorptions, the following equations given by Kisliuk and Townes[10] are useful:

Linear molecules

$$\gamma_{\max}=2.19\times10^{-18}\mu^2\nu^3 \text{ (debye, mc/}s\text{, cm}^{-1}).$$

Symmetric top molecules

$$\gamma_{\max}=4.83\times10^{-22}(A)^{\frac{1}{2}}\mu^2\nu^3\{1-(K^2/(J+1)^2)\}.$$

A is the reciprocal moment of inertia in megacycles

$$A=(10^{-6}h)/(8\pi^2I_A)=(84.0\times10^{-36})/(I_A).$$

J is the quantum number of total angular momentum $=0, 1, 2, 3, \cdots$.

K is the quantum number of the component of angular momentum along the symmetry axis; thus $K=J$, $J-1$, $J-2$, $\cdots$, $-J$.

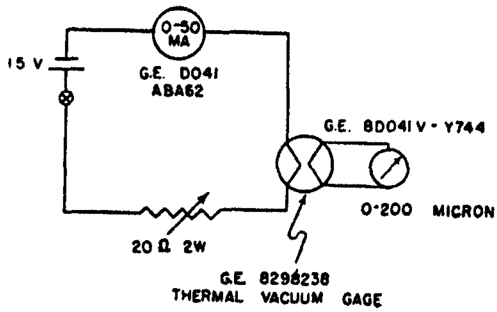

FIG. 15. Thermocouple gauge circuit diagram.

[10] P. Kisliuk and C. H. Townes, "Molecular microwave spectra tables," Nat. Bur. Stand. J. Research (to be published).

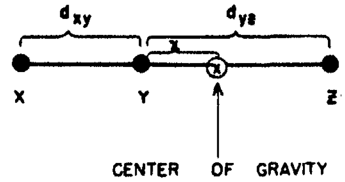

FIG. 16. Linear molecular model.

I_A is the moment of inertia (g-cm^2) about the internuclear or symmetry axis.

Computation of the Optimum Cell Length and Sensitivity[11]

The optimum cell length ($l_{\text{opt.}}$) is given by the simple relation

$$l_{\text{opt.}} = 2/\alpha_c \ (\text{cm}^{-1}).$$

If one uses this optimum length, then the minimum detectable gas absorption coefficient ($\alpha_{0\ \text{min.}}$) is given by

$$\begin{aligned}\alpha_{0\ \text{min.}} &= 2e\alpha_c(2kTN\Delta f/P_0)^{\frac{1}{2}} \qquad (6)\\ &= 50\times 10^{-11}\alpha_c(N\Delta f/P_0)^{\frac{1}{2}},\end{aligned}$$

where e = natural logarithm base = 2.72, α = attenuation coefficient of wave guide (cm^{-1}), k = Boltzman constant = 1.38×10^{-16} (ergs/degree), T = absolute temperature, N = noise figure of detector or receiver, Δf = band width of detector or receiver (c/s), P_0 = power input (watts), 1 neper/cm = 8.7 db/cm = 2 cm^{-1}.

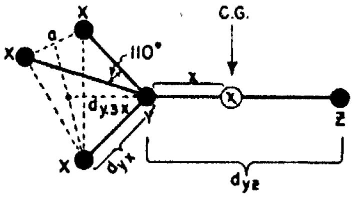

FIG. 17. Symmetric top molecular model.

F. ACKNOWLEDGMENT

The author gratefully acknowledges the assistance of the following rotating engineers, each of which has made many valuable contributions during his assignment to this project: E. Paul Diehl, Robert G. Day, C. Burton Crumly, Richard V. Prucha, Stanley G. Lemon, and John Mattern. I owe thanks also to Frederic C. Billingsley for his cooperation in the construction of the square wave generator and particularly to Dr. Robert Karplus for acquainting me with the field of microwave spectroscopy and rendering invaluable aid during the early stages of the spectroscope construction. I should like to express my gratitude to Dr. A. L. Marshall, director of the Chemical Section of the General Electric Research Laboratory, for his constant interest in the microwave program.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

Vortex Thermometer for Measuring True Air Temperatures and True Air Speeds in Flight

BERNARD VONNEGUT
General Electric Research Laboratory, Schenectady, New York

(Received October 17, 1949)

The aerodynamic heating experienced by thermometers exposed from airplanes can be very nearly eliminated over a wide range of operating conditions by mounting the thermometer in the center of an air vortex created by a simple housing. This method has been found to simplify air temperature measurements over the operating range of a B-17 airplane. The instrument has promise for measuring temperatures in clouds.

True air speeds can be measured by the difference between the temperature of the vortex thermometer and a thermometer exposed in the usual manner. Designs and flight data are presented for several vortex thermometers and a simple true air speed indicator.

INTRODUCTION

THE measurement of true air temperatures from an airplane is greatly complicated by the heating effect of the moving air. At a true air speed of 200 m.p.h., a thermometer exposed to the air stream indicates a temperature that is about three or four degrees higher than the true air temperature. E. Pohlhausen[1] has shown that the temperature correction ΔT which must be subtracted from the reading of a thermometer exposed in the usual way is expressed by an equation of the sort:

$$\Delta T = CV^2 \tag{1}$$

where V is the true air speed. If temperatures are expressed in degrees centigrade and true air speeds in miles per hour, the constant C is about $+0.8\times 10^{-4}$ for the usual thermometer.

K. Terada and G. Yamamoto[2] report that they have succeeded in greatly reducing aerodynamic heating by mounting a thermometer element in the wall of a small venturi tube exposed in the air stream. They found in a flight experiment made with this thermometer at an altitude of 4000 meters that a change of indicated air speed of from 250 to 400 Km/hr. resulted in an increase of the temperature reading of 0.7°C. An ordinary thermometer would be expected to show a temperature increase of about 5°C for the same change of air speed. If their thermometer data can be expressed by Eq. (1), then the constant C should be about $+0.12\times 10^{-4}$ when their air speeds are corrected for altitude and expressed in miles per hour.

In this work, it has been found possible to eliminate the heating effect of the moving air in a somewhat different way by utilizing Ranque's[3] discovery that a temperature lowering occurs in the center of an air vortex.

The refrigeration which is obtained by mounting a thermometer in a vortex can be used to balance out aerodynamic heating in such a way that the constant C in Eq. (1) becomes very nearly zero and large temperature corrections are no longer necessary.

EXPERIMENTAL

Laboratory Tests.—Laboratory experiments were carried out to determine whether the refrigeration obtained in a vortex was large enough to counterbalance aerodynamic heating. These tests were carried out by drawing air with a vacuum cleaner through various simple vortex creating housings and measuring the temperature in the vortex. The temperature lowerings observed in these tests were of the same order of magnitude as the aerodynamic heating effects which might be expected with similar air velocities.

Flight Test, M-2 Housing.—The first flight tests were made on a preliminary design of the housing which was found to reduce aerodynamic heating to about one-third of its usual value. On the basis of the results of these tests, a second unit (designated as M-2) was designed and constructed. This housing, which is shown in Fig. 1, was provided with a valve shown in the drawing which could be used to regulate the air flowing into the vortex. By adjusting this valve, the refrigeration produced by the vortex could be regulated.

The results of a flight made at 3000 feet with this unit are shown in Fig. 2. Two dial-type thermometers were used in this test. One thermometer was mounted in the housing, while the other was exposed at right-angles to the air stream. The data in Fig. 2 have been plotted relative to a true air temperature computed from the readings of the thermometer exposed in the usual fashion. It can be seen that with the valve wide open, the thermometer in the housing reads far below the true air temperature. With this valve setting, the constant C in Eq. (1) has a value of about -0.7×10^{-4}.

The valve was then adjusted to reduce the air flow so that the thermometer read the computed true air temperature. The observed thermometer readings with this valve setting do not vary appreciably with airplane speeds from about 120 m.p.h. to 225 m.p.h.

Flight Test, M-3 Housing.—Following the successful tests with the second housing, it was felt desirable to make direct comparisons between measurements made with the vortex thermometer and those made with a standard airplane thermometer. The ML-313 psychrometer is in general use for measuring air temperatures and humidities from U. S. A. F. airplanes. Accurately calibrated L-shaped mercury thermometers with 0.1°C divisions are used in this apparatus. The M-3 vortex housing shown in Fig. 3, was designed for use with these thermometers. The valve on this housing is controlled by a screw which moves it in or out and permits fine adjustment. Once the valve has been properly adjusted, it is locked permanently in position with a set screw which can be seen in Fig. 3.

[3] G. J. Ranque, Bulletin—Bi Mensuel de la Societe Francaise de Physique, 1125–1155 (June 2, 1933).

In the first flight made with this housing, the valve was adjusted to read a true air temperature computed from the reading of the ML-313 dry bulb thermometer using $C=+0.87\times10^{-4}$ which has been determined for this thermometer. With this valve setting, runs were made at 4000 feet, 8000 feet, and 12,000 feet with two observers taking simultaneous readings, one on the ML-313 and the other on the vortex thermometer. The temperatures measured are shown in Figs. 4 and 5. It was apparent from this data that the valve was in a little too far. A slight adjustment was then made, and a second run was made at 4000 feet which is shown in Fig. 6. The variation of temperature with speed with this setting was very small, and this setting of the valve has been used in all subsequent measurements.

The data taken on the M-3 housing are somewhat anomalous in that the readings taken with the two thermometers do not always extrapolate to the same value at zero velocity. When the thermometers are tested in the laboratory, they agree to within 0.1°C. One possible explanation for this discrepancy which is observed in much of the data is that the vibration of the airplane may cause separation of the mercury column. This separation has occasionally been observed with these thermometers.

Further runs have been made on the M-3 housing to determine how well it operates over the range of speeds and altitudes of which the Project CIRRUS B-17 airplane is capable. Figure 7 shows the results of one of these flights. The data have been plotted to show the departure of the readings of the vortex thermometer from a true air temperature computed from the readings of the ML-313 dry bulb.

The mercury thermometer used in the above tests had a scale which went down to −20°C. For tests at higher altitudes and lower temperatures, it was necessary to use another thermometer with a lower range. The physical dimensions of the new thermometer differed slightly from the old, which might be expected to necessitate a slight adjustment of the valve. However, no changes were made. The data obtained using the new thermometer are shown in Fig. 8. These data do not include simultaneous readings taken with the ML-313 thermometer because its mercury column separated.

The air temperatures at a constant altitude were

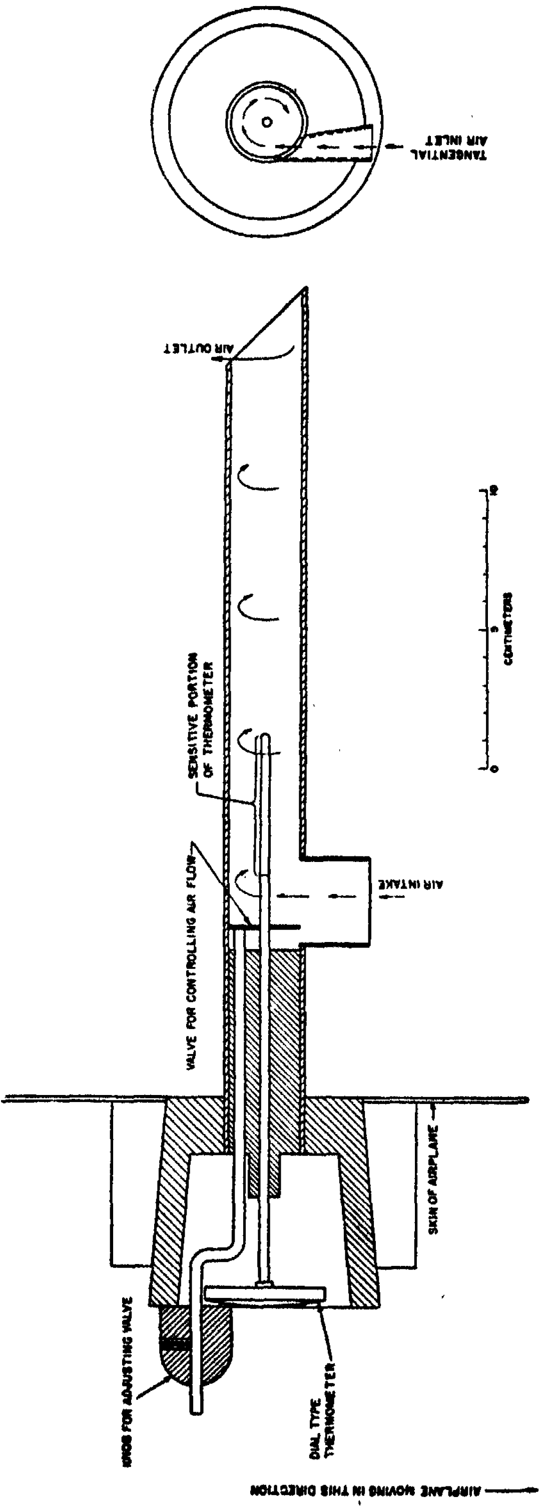

FIG. 1. M2 thermometer housing.

fairly uniform during this flight, and the readings of the vortex thermometer showed a maximum variation of 0.5°C over changes in air speed that would cause the usual thermometer to change at least two degrees. It appears that the vortex housing reduces errors from aerodynamic heating to less than 0.5°, at least up to speeds of 260 m.p.h. and altitudes up to 25,000 feet.

Vortex Thermometer for Measuring True Air Speeds.—Because the aerodynamic heating is a function of the true air speed, it is possible to measure true air speeds by the difference in temperature between a thermometer exposed in the usual way and one exposed in a vortex. In the thermometer tests just described, it was possible to make a fairly close estimate of air speed from the difference in reading of the two thermometers.

A simple true air speed meter was made which consisted of two No. 14B thermistors mounted in a vortex housing. One of these was mounted in the center of the vortex, while the other was mounted on the periphery. The difference in temperature between the thermistors was measured by a microammeter in a simple bridge circuit. A flight was made in which the readings of the microammeter were compared with the true air speed computed from the readings of the usual air speed indicator. The results of this flight show that the instrument may have promise as a true air speed indicator.

SIMPLIFIED THEORY

An adequate theoretical treatment of the vortex would be a formidable task. It is possible, however, to make some simplifying assumptions and arrive at an approximation of what may be the true state of affairs.

If one assumes that the air in the vortex is rotating with uniform angular velocity and that its periphery is moving with the true air speed of the plane, one finds that at 200 m.p.h. the air is revolving at about 45,000 r.p.m. in a $1\frac{1}{2}$-inch diameter tube.

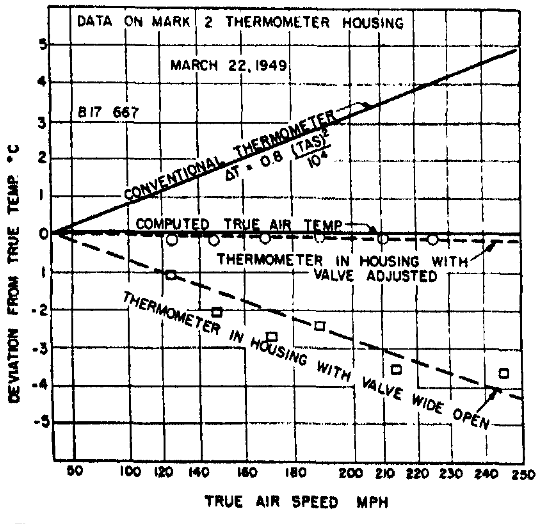

FIG. 2. M2 housing flight data taken at 3000 ft. altitude.

This high speed of rotation sets up a pressure difference between the center and outside of the revolving air. One can regard the temperature lowering in the center of the vortex as being produced by the adiabatic expansion of the air as it passes from the periphery to the center. On the basis of the above assumptions, it can be shown that the difference in pressure, Δp, between the outside and the center of the vortex is given by

$$\Delta p = p(mw/RT)\cdot V^2/2, \tag{2}$$

where p is the pressure of the atmosphere, mw is the molecular weight of the air, R, the gas constant, T the absolute temperature, and V, the true air speed of the airplane. This is the identical expression for the increase in pressure caused by the motion of the airplane through the air. Aerodynamic heating can be regarded as resulting from an adiabatic compression of the air. The vortex can be looked upon as a simple method by which air from the atmosphere is accelerated to the speed of the airplane and adiabatically expanded to its original pressure and temperature. The air in the center of the vortex is at true air temperature and pressure, and because it is moving along with the airplane, its temperature can be easily measured without need of corrections.

If the pressure difference available from the motion of the airplane were limited to the pitot static difference, it is doubtful whether the air could be cooled all of the way back to its original temperature by this system. A certain amount of frictional heating must take place. Fortunately, about double the pitot static pressure difference is available between the ram air pressure and a tube opened downstream, and, therefore, ample cooling is available.

Temperature Measurements in Clouds.—It is believed that the vortex thermometer will be of value in measurements in clouds. The rotational velocities are sufficiently large that it is believed that the high centrifugal force will prevent cloud particles from depositing on the thermometer in the center of the vortex. This would eliminate any errors which might be caused by evaporation or freezing of water on the thermometer. Should any cloud-water drops deposit on the thermometer bulb, they would not be expected to cause evaporation cooling such as is experienced with the usual thermometer. Because the thermometer in the vortex and the air around it are at the true temperature of the cloud, any water on the thermometer would be in equilibrium with the saturated air around it and could not evaporate. When the airplane flew out of the cloud into unsaturated air, measurements would, of course, be in error until the water dried off.

The flights which have thus far been made in clouds have been of such short duration that the thermometers have not had time to reach equilibrium. These flights have shown that the temperature difference between

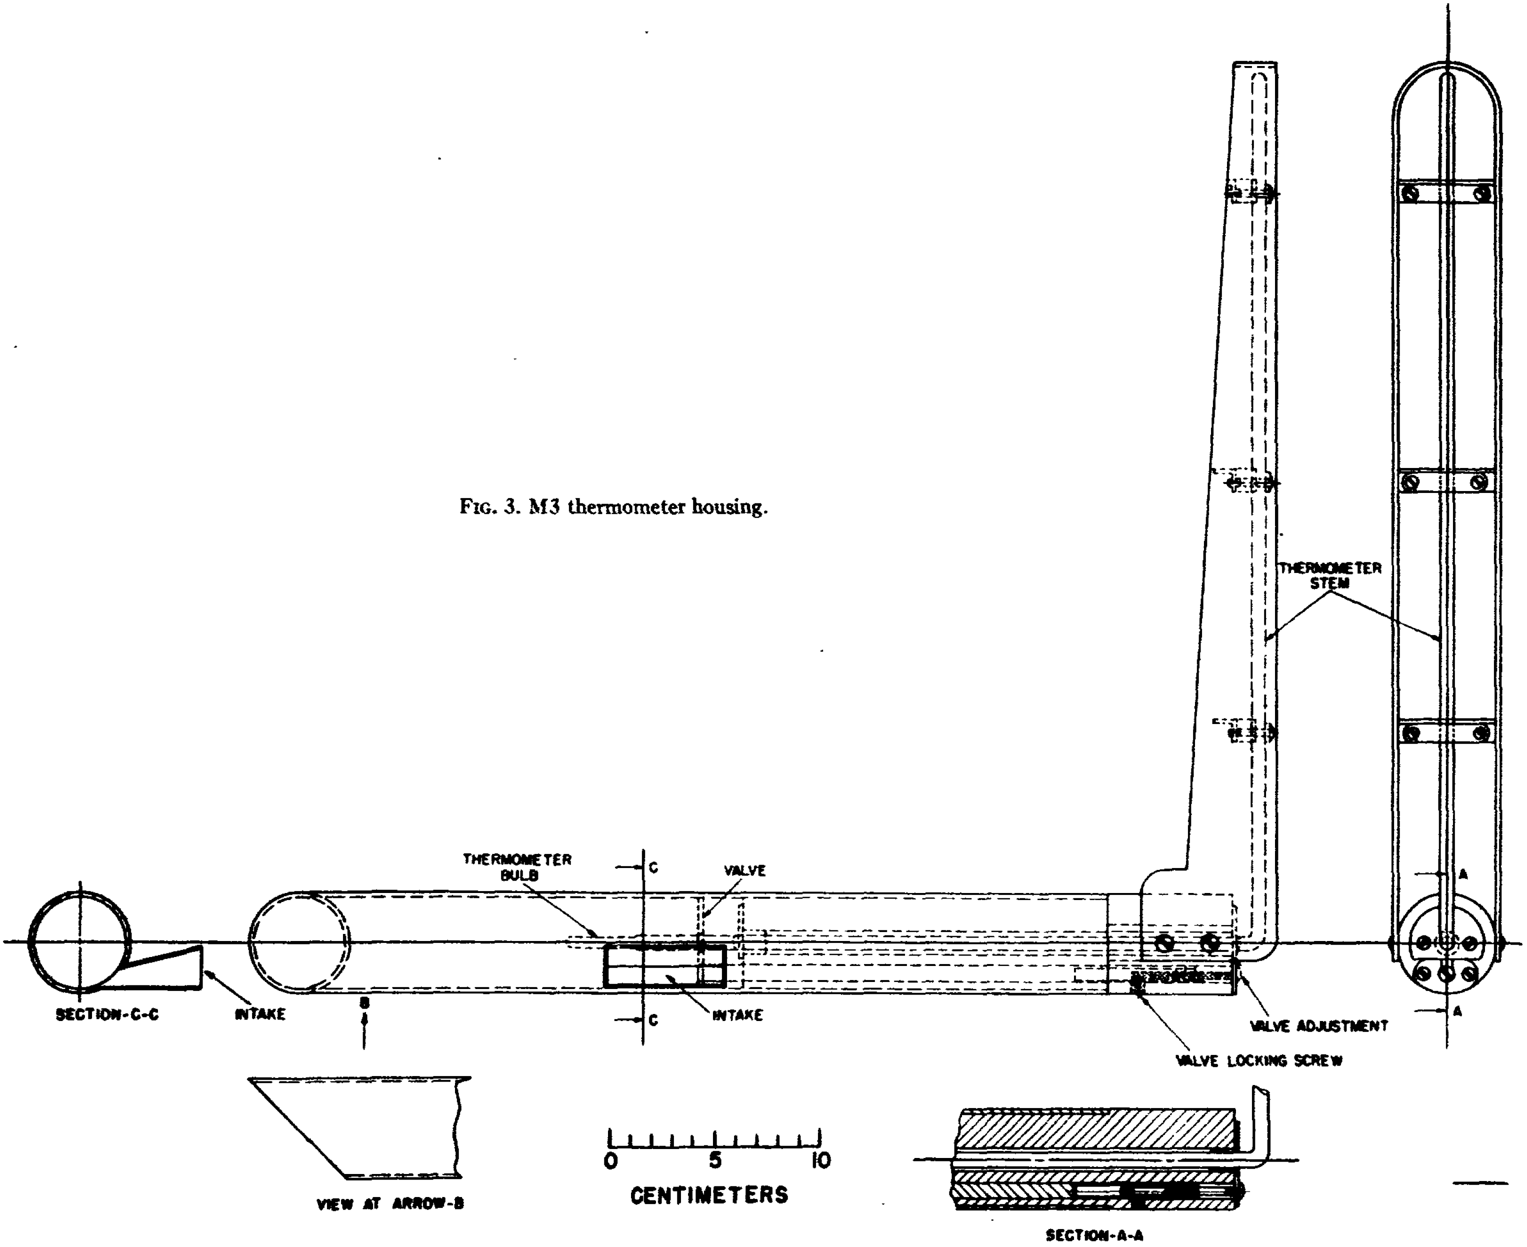

Fig. 3. M3 thermometer housing.

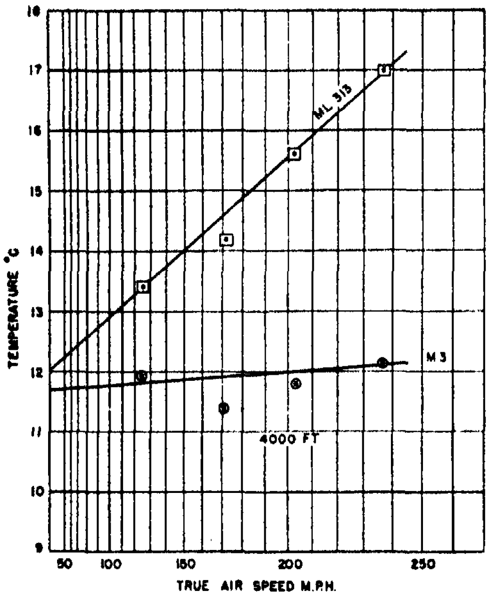

FIG. 4. Data taken with M3 housing at 4000 ft. altitude using preliminary valve setting.

the thermometers decreases somewhat as would be expected.

In the few flights which have been made in icing conditions, rime ice was observed to build out on the leading edges of the air intake of the housing. This deposition of ice did not appear to have any marked effect. It should be possible to use some non-volatile deicing liquid to prevent the formation of ice on the housing.

Effect of Clouds on True Air Speed Meter.—A short flight through clouds has been made using the true air speed meter which has been described. Upon flying into a cloud at constant air speed, the meter reading dropped by a factor of two and upon leaving the cloud, returned to its normal value. This was doubtless caused by deposition and evaporation of water on the high temperature thermistor.

Inasmuch as the air speed is to be measured by the temperature *difference* between the thermistors, there is no reason why the liquid water cannot first be removed either by a system of baffles or by heating and evaporation. This should enable the air speed meter to operate satisfactorily even in clouds.

When the vortex thermometer is used to measure air speed, there is no particular reason that the cold thermistor should be exactly at the true air temperature. It is important, however, that the cold thermistor always be operated above the dew point of the air. At temperatures below the dew point, heating takes place because of condensation of the water to form a cloud. This heating would, of course, make the instrument very unreliable.

CONCLUSIONS

The tests thus far indicate that the vortex thermometer should be quite useful in temperature measurements made from airplanes. There is little doubt that readings obtained with the thermometer deviate to some extent from the true air temperature depending on altitude, pressure, and air speed.

However, from the data obtained thus far, it can be seen that in the range of conditions investigated these corrections are quite small. The data are not sufficiently accurate to give a clear indication whether the thermometer adjusted at low altitude reads too high or too

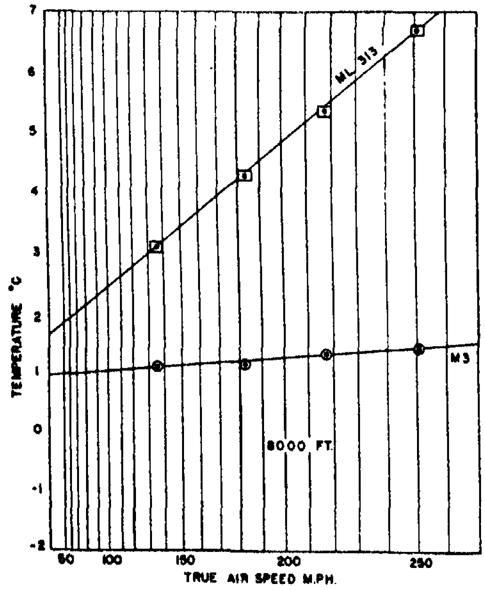

FIG. 5. Data taken with M3 housing at 8000 ft. altitude using preliminary valve setting.

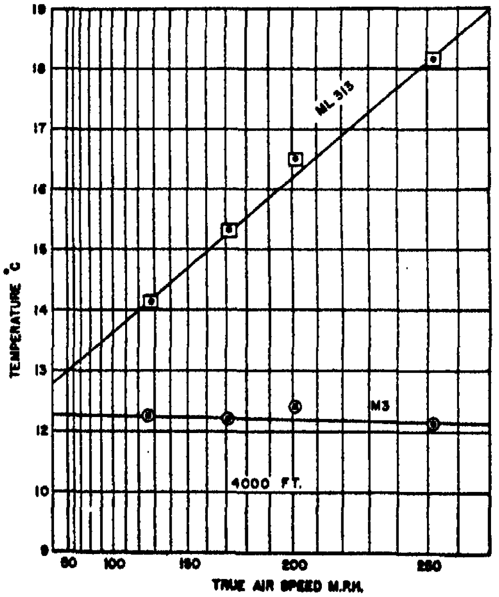

FIG. 6. Second run at 4000 ft. altitude with M3 housing after making slight adjustment of valve.

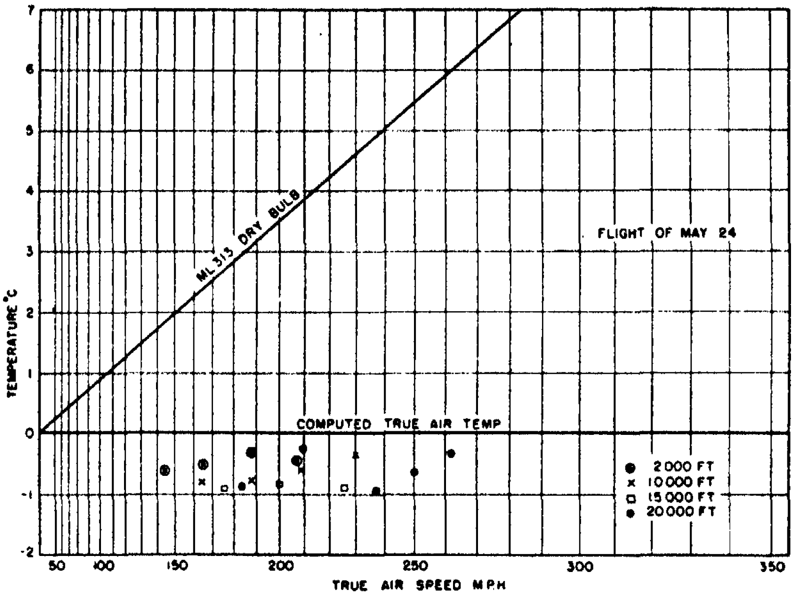

FIG. 7. Deviation of temperatures measured with M3 housing from true air temperature computed from ML313 dry bulb readings.

low at high altitude. The data of Fig. 8 give a slight indication that at high altitude, because of low pressures or temperatures, the vortex may slightly overcompensate for aerodynamic heating by a small fraction of a degree.

Measurements made at higher air speeds and greater altitudes will give a much better picture of the limitations of the device.

The design of the housing does not seem to be at all critical in the range of conditions which have been investigated. Because of this latitude in design, it may be possible by changing the housing to reduce any deviations which may be found to exist.

ACKNOWLEDGMENTS

The author wishes to thank the following for their invaluable cooperation in this work: Mr. A. Parr, who constructed the thermometer housings; Mr. T. Rich and Mr. J. E. Bigelow of the General Electric General Engineering and Consulting Laboratory, who suggested and built the thermistor temperature measuring device on the air speed indicator; S. Rush and associates who prepared the drawings; U. S. N. aerographers, C. Remscheid and R. F. Ryan, and D. Blanchard of the General Electric Research Laboratory who took much of the flight data; and the personnel of Project CIRRUS who cooperated in organizing and carrying out the flight tests.

Wire Recorded Magnetic Pulse Timing Circuit*

C. R. EMIGH
Physics Department, University of Illinois, Champaign, Illinois

(Received August 29, 1949)

A time delay circuit is described for timing and sequencing the operations of a cloud chamber. By magnetizing a moving section of recording wire and at a later time using the magnetized section to actuate a sensitive relay, delays from 0.01 to 0.25 second are obtained. The delay can be adjusted visually to an accuracy of 0.001 second.

INTRODUCTION

THE magnetic pulse timing circuit was developed to synchronize accurately the operations of a cloud chamber to the 80-Mev University of Illinois pulsed betatron.[1,2] This report concerns itself only with the initiation and subsequent operation of the timing circuit. The general operation of cloud chambers in relation to their timing circuits has been described adequately in previous articles.[3,4]

The range of the magnetic pulse timing circuit is from 0.01 to 0.25 second delay with a variation of less than 0.001 second as determined by an oscilloscope. The variation is independent of the delay.

The magnetic pulse timing circuit has several advantages over previously reported cloud-chamber timing circuits.[3–6] It may be initiated by a trigger signal at any arbitrary time, which for the present application is a necessary advantage over the mechanical cam type of timing circuit. The mechanical system, consisting of cam operated micro-switches, has in addition the disadvantages that the time delay is somewhat dependent on the mechanical wear of the cam and the desired delay can be adjusted to an accuracy of ±0.01 second only by an auxiliary timing circuit. The electronic type timing circuit usually incorporates either an RC or R/L type time delay, which is to be preferred for delays less than 0.01 second. However, for delays of the order of 0.01 to 0.25 second the magnetic pulse timing circuit offers greater accuracy and ease of adjustment. Once the pulse timing circuit is calibrated, the magnitude of delay may visually be set to an accuracy of approximately ±0.001 second without any auxiliary equipment. The pulse timing circuit also inherently incorporates a second time delay which allows the cloud-chamber controlling relays to stay energized for a prescribed length of time. The second delay is also variable. The apparatus has the disadvantage of obtaining accuracy and simplicity of operational alignment at the expense of simplicity of construction.

BASIC OPERATION

The cloud-chamber magnetic field coils are energized periodically with a cycle time of the order of 10 seconds, depending on the recovery time of the cloud chamber used. As the current builds up in the field coils, the magnetic field rises proportionally. When the magnetic field passes through a predetermined value, a proton magnetic moment detector[7] (see Fig. 1) produces a signal which is amplified and channeled to the magnetic pulse time delay circuit. (By the use of the proton magnetic moment detector the field can be determined in time to an accuracy of ±0.1 percent at the probe.)

At the pulser unit the signal from the proton magnetic moment detector connects a charged condenser across an inductance. The unidirectional pulse field produced in the iron core of the inductance is used to magnetize horizontally a section of magnetic recording wire wound on the periphery of a disk. The disk is driven by an a.c. synchronous motor and gear reducer such that one revolution of the disk represents 0.267 second.

Located on a platform around the disk are six small pick-up coils. As the magnetized portion of the recording wire passes near a pick-up coil, a voltage signal is induced across the terminals of the coil. The signal triggers a one-shot multivibrator delay circuit which in turn energizes a high sensitivity relay for a period depending on the cycle time of the multivibrator. The relays control the cloud-chamber expansion, turn off the sweep field, trigger the pulsed betatron, open the camera shutters and trigger the pulse lights in their properly timed sequence. At the completion of one revolution of the disk, with respect to the triggering of the pulser unit, the magnetized wire is demagnetized by a d.c. magnet.

The amount of time delay depends on the number of degrees the pick-up coil assembly is rotated about the center of the disk from the pulser unit. The platform is graduated every 13½° (0.01-second intervals). Interpolation between 0.01-second interval marks is done visually.

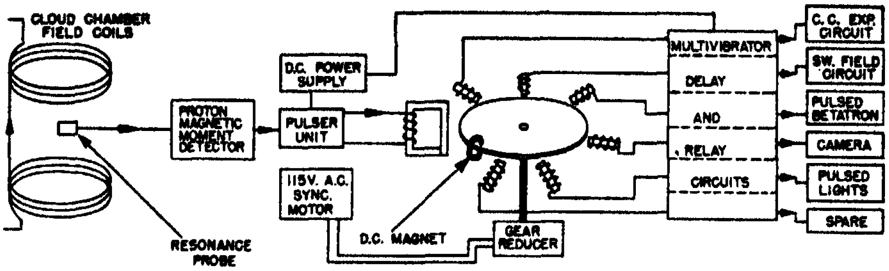

FIG. 1. A block diagram showing the general layout of the delay system as used for cloud-chamber operation.

CIRCUIT DETAILS

Power Supply

The power supply is shown in Fig. 2. It is designed to supply power to the pulser unit and the multivibrator circuits. The power supply is a full-wave bridge type rectifier with one corner of the bridge grounded. Therefore, between ground and the center-tap of the power transformer, approximately +450 volts d.c. are developed by ordinary full wave rectification. The 5W4 in the pulser unit acts as a conventional cascade doubling circuit with the full wave rectifier and supplies the pulser unit at +900 volts d.c.

Pulser Unit

The 16-μfd capacitor is charged by the cascade doubling circuit to +900 volts through a 0.1-megohm resistor and the 4.4-millihenry inductance. The inductance consists of 150 turns of No. 16 enameled copper wire wound on a core of laminations stacked to a cross section of $\frac{3}{4}$ in. by $\frac{1}{2}$ in. The laminated core is shaped such that its ends do not butt up against each other, but overlap by $\frac{3}{4}$ in. (Fig. 2). The overlapping portions are separated by a $\frac{1}{8}$-in. copper sheet. This thickness is of the same order of magnitude as the skin depth of copper at the frequency of operation

$$f=\frac{1}{2\pi(LC)^{\frac{1}{2}}}\quad(C=16\ \mu\text{fd},\ L=4.4\ \text{mh}).$$

When the 4C35 hydrogen filled triode is triggered by the signal from the proton magnetic moment detector, the charged 16 μfd capacitor is essentially shorted across the 4.4-millihenry inductance. The resulting current through the inductance has a sinusoidal wave shape for the first half-cycle. At the end of the half-cycle the 4C35 is extinguished and no further current flows through it. Because of the copper shield between the poles of the core, the sinusoidally varying flux is forced from one pole face around the shield to the other pole face, which produces a concentration of horizontal flux in front of the poles. The peak value of current is roughly 50 amperes, corresponding to an estimated 4000 gauss of horizontal magnetizing field produced at the magnetic recording wire.

Disk and D.C. Magnet

The disk is a 12 in. diameter $\frac{3}{8}$ in. thick piece of red Bakelite with a $\frac{1}{4}$ in. wide, $\frac{3}{16}$ in. deep slot machined around the circumference. All of a commercial 30-minute spool of recording wire is wound in the slot.

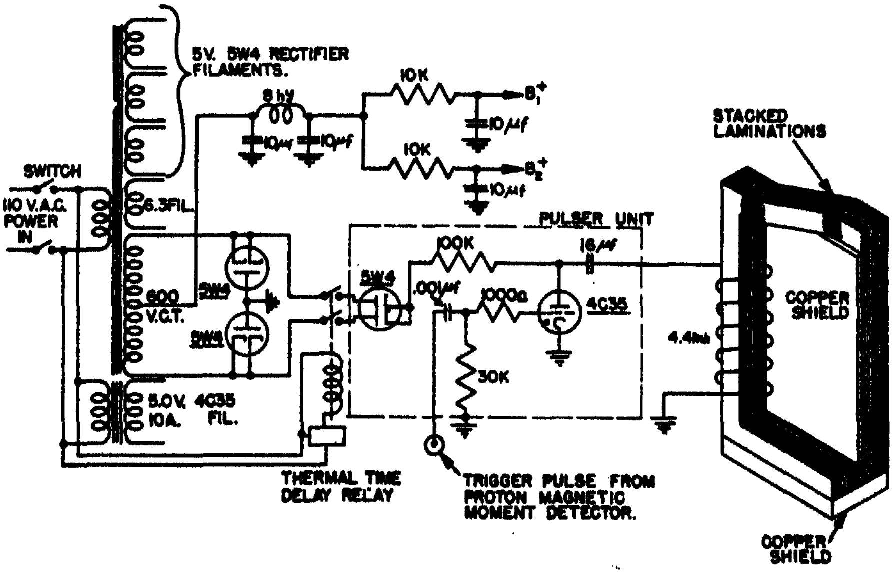

FIG. 2. Power supply and pulser unit.

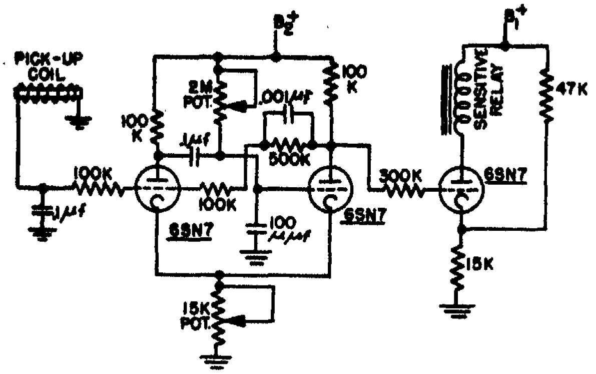

FIG. 3. Multivibrator and sensitive relay circuit.

The above described horizontal pulse field magnetizes a 13° arc of the recording wire (magnetized along the wire's length). After the magnetized section completes nearly one revolution, a d.c. magnet of 5000 gauss magnetizes the wire in a vertical direction (magnetized in the direction of the wire's vertical diameter), thus demagnetizing the horizontally recorded pulse.

Multivibrator Delay Circuit and Relay

The circuit shown in Fig. 3 is a conventional type one-shot multivibrator. The first grid circuit contains the pick-up coil which consists of 10,000 turns of No. 38 wire wound on a solid iron core. The inductance of the coil is 1.5 henry. The resistor in the cathode circuit is adjusted so that the grid containing the pick-up coil is biased below cut-off. Therefore, a 10-volt positive signal from the pick-up coil will trigger the multivibrator. The cycle time of the multivibrator is varied by the potentiometer in the second grid circuit.

The plate of the second section of the multivibrator is coupled through a resistor to the grid of the relay switch tube. Thus the relay is energized during the cycle time of the multivibrator. The relay used is a high-sensitive relay rated at 0.005 ampere for closing. By exceeding this value appreciably for short times, the mechanical delay due to the relay can be reduced to less than 0.002±0.0005 second.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

A Wide-Band Audio Phasemeter

JOHN R. RAGAZZINI AND LOTFI A. ZADEH
Columbia University, New York, New York

(Received August 8, 1949)

The problem of measuring the phase angle between two sinusoidal voltages is an important one in laboratory procedure. Phasemeters which can make this measurement accurately over a substantial frequency range have heretofore been bulky and relatively stationary. This paper describes a circuit which results in a phasemeter which is accurate to about 30 minutes, has a dial adjustment which is independent of frequency, operates over a range of from 20 c.p.s. to 100 kc and is relatively small and inexpensive. The principle used is to match the phase shift between the unknown voltages with a calibrated phase shift in the meter channel. This phase equalization is observed on a standard oscillograph which is used only as a comparison instrument. The oscillograph amplifier phase shifts are balanced out with an uncalibrated phase shifter cascaded in the meter channel and do not affect the measurement.

1. INTRODUCTION

An increasingly common and yet difficult problem that confronts one in the laboratory is that of measuring the phase difference between two sinusoidal voltages. Many methods have been devised for this purpose but few, if any of them, are satisfactory for accurate measurement of phase angles over a wide range of frequencies with relatively simple circuits and equipment. Some are highly accurate but operate over a restricted range of frequencies, while others are of the convenient direct-reading type but lack accuracy. A few such as the ones constructed at the Royal Institute of Technology in Sweden,[1] L. M. T. Laboratories in Paris,[2] Post Office Research Station in London[3] and the Bell Telephone Laboratories in New York[4] combine high accuracy with width of operating range. These, however, are usually very bulky and should be classified as stationary equipment. Few phasemeters except those of the stationary type are commercially available at present.

To be useful in the laboratory as an instrument, a phasemeter should have none of the deficiencies mentioned above and should be relatively simple and inexpensive. A design has been devised and is described in this paper which fulfills the following specifications:

1. The phasemeter should be operative over a frequency range of from 20 c.p.s. to 100 kc.
2. The error should not be in excess of 30 minutes of arc over the entire operating range.
3. The burden of accuracy of the meter should be placed on a few non-inductive linear circuit elements.
4. The dial indication of the meter should be independent of frequency.
5. The meter and associated equipment should be relatively simple and inexpensive.
6. The power supply for the meter should operate from a.c. mains.

A meter has been constructed in accordance with these specifications by the authors. A detailed description of this phasemeter is given in the following sections.

2. PRINCIPLE OF MEASUREMENT

Referring to the block diagram of Fig. 1, it is seen that the phasemeter consists essentially of two channels, C_1 and C_2. The first channel contains two phase shifters, P_c, which is calibrated, and P_{nc}, which is uncalibrated. The calibration of P_c is independent of frequency over the range of operation of the meter (20 c.p.s. to 100 kc). The second channel is a direct connection and is inserted only for convenience in making connections. The output voltages of the phasemeter are connected to the horizontal and vertical inputs of a standard oscillograph.

The meter will measure the phase angle between the voltages E_1 and E_2 by observing the trace on the oscillograph. The general process of measurement consists of first setting the calibrated phase shifter, P_c, to zero and applying the same voltage E_1 to both channels. The uncalibrated phase shifter, P_{nc}, is then adjusted until the oscillograph indicates by its trace that the

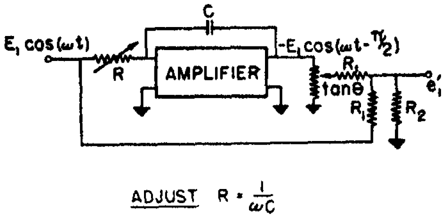

FIG. 2. Block diagram of calibrated phase shifter.

phase shift of both channels is equal. The null indication consists of reducing the ellipse which appears on the screen to a straight line. High degrees of accuracy can be achieved by this process if the trace is amplified so that only a small part of the ellipse actually falls on the screen. Under these conditions, the process of collapsing the ellipse is observed as the bringing together of two straight lines, the remainder of the trace being off the screen.

After the channel phase shifts have thus been equalized, the switch S_1 is thrown to a position which impresses E_1 on channel 1 and E_2 on channel 2. The oscillograph will now indicate a phase shift between the two voltages. This is once again brought to zero only this time by adjustment of the calibrated phase shifter P_c. The reading of this phase shifter dial is the phase angle between the two voltages E_1 and E_2. The measurement is seen to be essentially a null technique and the oscillograph is used only as an indicator to show phase coincidence. The phase shift in each of the channels or associated equipment is cancelled so that inequality in the amplifiers of the oscillograph has no effect.

3. CIRCUIT DETAILS

The basic unit in the calibrated phase shifter P_c is required to shift an applied voltage by an adjustable angle θ. Thus, if the input voltage has the form:

$$e_1=E_1\cos\omega t, \qquad (1)$$

the output voltage should have the form:

$$e_2=E_1'\cos(\omega t+\theta), \qquad (2)$$

where the magnitude is of no consequence but the phase angle θ must be known and should have a value ranging from 0 to 45 degrees. This range, in conjunction with certain switching arrangements shown in Fig. 3, is sufficient to accommodate all possible phase relationships between the unknown voltages.

The method used to transform e_1 into e_2 is summarized in the trigonometric relation:

$$E_1\cos(\omega t)+[E_1\tan\theta]\cos(\omega t+\pi/2)$$
$$=\left[\frac{E_1}{\cos\theta}\right]\cos(\omega t+\theta). \qquad (3)$$

The operations called for in Eq. (3) are mechanized in the following steps:

a. Generation of a voltage $E_1\cos(\omega t+\pi/2)$ which is in quadrature with the voltage $E_1\cos(\omega t)$.

b. The adjustment of this voltage to a magnitude $E_1\tan\theta$ by means of a calibrated linear potentiometer.

c. The addition of the two components in Eq. (3).

The first operation involving a shift of phase of 90 degrees is accomplished by a stabilized feed-back amplifier as shown in Fig. 2. The feed-back amplifier shown is an integrator whose gain is very closely $-1/j\omega RC$ if the gain of the base amplifier is high. If R and C are interchanged, a differentiator results whose gain is $-j\omega RC$. In practice, the latter has been found more desirable and is the type incorporated in the meter.

In the actual circuit shown in Fig. 3, this unit is seen to consist of tubes V_2, V_3, and V_4, capacitances C_6, C_7, C_8, and C_9 and resistors R_5, R_6, and R_7. In the actual unit, a gain of well over 1000 is maintained in the base amplifier over a frequency band of from 20 c.p.s. to 100 kc so that a very accurate 90-degree phase shift is obtained over this band width.

It is evident that, as in the case of any minimum phase shift network, the amplifier produces a gain rise (or loss) with frequency of 6 decibels per octave of frequency. To prevent the gain (or loss) of the amplifier from ranging over too wide limits, a switch S_3 is used to choose the value of capacitance which, in combination with the adjustable bridging resistor R_6, will result in an over-all gain of unity at the frequency of the test voltage. In this manner, the voltages at the input and output of the feed-back amplifier are equal in magnitude but have a phase angle between them of exactly 90 degrees.

The second step in the mechanization is carried out by means of the potentiometer R_{16} whose output has the magnitude $E_1\tan\theta$. This potentiometer is a linear wirewound unit with a dial whose face is calibrated in angle θ, the phase angle which is being measured. Finally, the third step is carried out by the simple adder circuit consisting of two precision resistors, R_{18} and R_{19}, and the common resistor R_{20} across which appears the sum of the two components in Eq. (3). With this circuit, therefore, the operations called for in Eq. (3) are carried out and a voltage which has been shifted by an angle θ with respect to the input voltage is available. The burden of accuracy is placed on resistive components and since the calibration is carried out only to 45 degrees, the dial scale is nearly linear.

The uncalibrated phase-shifter for channel equalization is made up of the subtractor tube V_6 and the RC bridge made up of R_{25}, R_{30}, C_{16}, C_{20}, and the other condensers in the same switching circuit. The switches S_6 and S_7 are used to obtain easily adjustable phase shift at the various frequency ranges. With the calibrated phase-shifter, whose maximum phase shift is only 45 degrees, the switching system made up of S_2, S_3, S_4, S_6, and S_7 makes possible the measurement of

phase angles over a range of ±90 degrees. To cover the remaining 180 degrees, the slant of the collapsed ellipse is noted. If, after adjustment with the calibrated phase-shifter, the slant of the line changes from that noted at the time of channel equalization, 180 degrees is added to the dial reading. As constructed, the phase-meter gives consistent precision of 30 minutes over a frequency range of from 20 c.p.s. to 100 kc.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

Positive Displacement Pump for Corrosive Fluids

E. E. Glenn, Jr. and Norman Hackerman
Department of Chemistry, The University of Texas, Austin, Texas

(Received September 14, 1949)

A positive displacement-type pump in which there are no metal parts exposed to the fluids has been built and tested. Gases, liquids, or mixtures of both can be pumped without any corrosive effects on the pump.

In the course of a laboratory investigation of the corrosion of metals, the need arose for a positive displacement-type pump which could circulate mixtures of corrosive gases and liquids. It was necessary that the pump operate continuously over relatively long periods of time. Several types of commercial pumps were considered. A positive displacement pump using a rubber impeller presented internal lubrication problems; for example, lubrication of the contact between the pump housing and the impeller by the liquid being pumped. This was undesirable since a high gas to liquid ratio in the pumped fluid was required. A liquid by-pass line from the discharge to the suction side of the pump could be used in order to furnish this lubrication, but this was not acceptable since the volume of gas pumped would be greatly reduced. To overcome this, the pump speed could be increased, but this would cause excessive wear of the rubber impeller, housing, and bearings, since tolerances are small in positive displacement pumps. Gear-type pumps were considered, but again, lubrication of the gears by the fluids being pumped presented a problem.

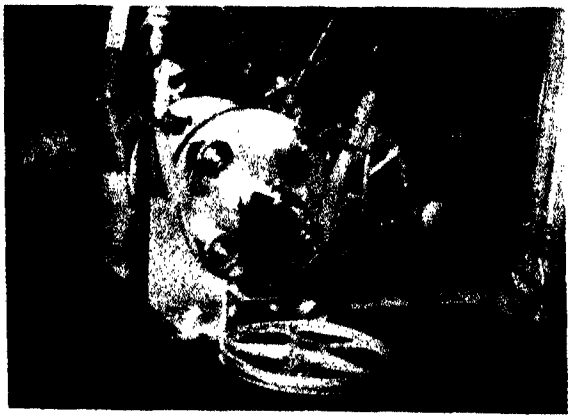

Fig. 1.

A major complication arising from contact of metal pump parts with the fluids was the corrosive attack which not only increased the likelihood of failure of the pump parts, but also introduced undesirable contaminants into the fluid. Neoprene was substituted for the rubber impeller mentioned above, but was unsatisfactory because it was extracted by liquid hydrocarbons in the system. It also swelled sufficiently to cause binding in the pump housing.

Since none of the types of pumps considered showed promise of withstanding deterioration because of the corrosive fluids and long operating periods, a pump to meet these qualifications was designed and built. Figure 1 is a photograph of the pump and Fig. 2 shows the principal components schematically.

The principle of operation of the pump is simply the squeezing of a flexible tube to cause the discharge of its contents. As shown in the diagram this was done by causing four rollers, mounted on a disk, to roll along a flexible tube lying in a semicircular track. As each roller moves along the tube, the fluids contained therein are forced ahead, since the rollers are so mounted as to cause complete flattening of the tube. After a roller passes any point, the tube returns to its circular cross-sectional shape, the volume increase causes a pressure drop, and the pressure gradient so produced forces additional fluids into this portion of the tube. The sizes of the rollers, disk, flexible tubing, and track are purely arbitrary, depending only on the volume to be pumped. In general, only one size tubing can be used with one particular size track and roller mounting; however, volumes may be varied by varying the disk speed.

Tygon tubing, ½ in. i.d., was selected for the system being studied, since it was found to be resistant to the corrosive fluids and to extraction by the hydrocarbons. The Tygon tubing was slipped into a ⅝-in. i.d. rubber tube. The rubber case takes the wear of the rollers and helps the Tygon return to its normal shape after the passage of a roller. The recovery time for Tygon is slower than that for rubber, so use of the latter increases the efficiency of the pump.

The rollers were made of brass, 2 in. in diameter, and mounted on a shaft through double-sealed ball bearings. These roll freely during their period of travel when not in contact with the tube and thus do not cause excessive wear at the point of first contact at the suction end of the tubing. These rollers were mounted perpendicular to and ½ in. inside the periphery of a 10-in. diameter steel disk.

Clamps were mounted on the suction and discharge ends of the tube. The suction end clamp held the tubing to prevent creep along the track in the direction of motion of the main disk, while the discharge end clamp served merely to hold the tube aligned with the rollers.

The flow was, of course, pulsating, which may prove advantageous in many cases. The system for which the pump was designed included a hydrocarbon-water mixture which had to be in the form of an emulsion immediately after it left the pump. By extending the discharge tube upward about 2 ft. the pulsating action, together with the large gas volume, caused sufficient agitation to emulsify the mixture at the desired point in the system.

This design may also be used to feed a given quantity of liquid or gas into a system at definite intervals of time, by regulating the speed of the main disk and the number of rollers mounted thereon. Perhaps the use of a check valve on the discharge end of the pump would be necessary in this case. With the design in the diagram, the rollers act as their own check valve, and, therefore, flow can be only in one direction.

The main disk was mounted on a shaft in such a manner that the rollers moved over the tubing track with just sufficient clearance to allow for the thickness of the flattened tube. The shaft was driven by V-belts and pulleys arranged to give a disk speed of about 100 r.p.m. Various arrangements of pulleys and motor speed could be made to yield almost any speed desired.

The tubing track was a semicircle of such dimensions that the rollers compressed the tubing at all points of contact. In cross section the track resembled a shallow channel iron, the lips preventing sideward movement of the tubing.

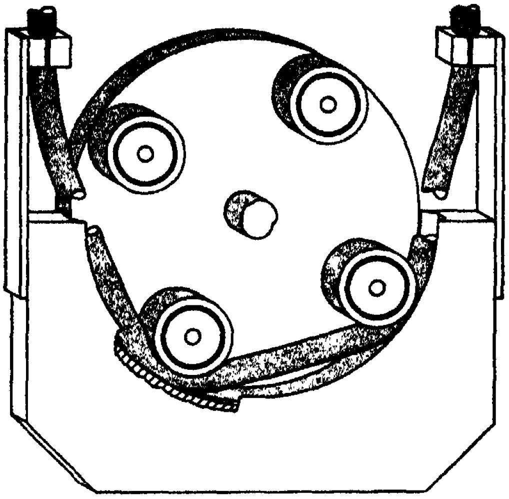

FIG. 2.

Some of the characteristics of the pump are:

(1) Speed—1 g.p.m. of water against a 3-ft. head.
(2) Pressure ratio achieved—pump suction at 14.7 p.s.i.a. discharge at 36.7 p.s.i.a.
(3) End vacuum achieved—0.83 p.s.i.a. (43 mm Hg).
Time to produce end vacuum—1 min.
Lowest end vacuum possible—0.58 p.s.i.a. (30 mm Hg) since water was used to wet the tube.
(4) Average tubing life under given conditions—about 120 hr. continuous operation.

The pump can be used for gas as well as liquid, so long as the tubing is first wetted by liquid. Thus, as a gas pump, some inert liquid would be required as the wetting fluid to provide complete sealing as the roller flattens the tubing. It seems probable that even liquids of fairly high viscosity could be pumped with this design. Solid particles should be avoided because of erosive effects on the tubing.

A Frequency Modulation Pressure Recording System*

J. H. Hett and R. W. King, Jr.
Research Division, New York University, University Heights, New York

(Received September 23, 1949)

A simple frequency-modulated pressure gauge employing a variable capacity pick-up element has been devised to measure the oscillating pressures of burning gases. It has been used to measure pressures in pulse jet engines ranging from −5 to +60 p.s.i. gauge, under conditions where the gas temperatures ranged from approximately 300°K to 2450°K and the gauge mount vibrated with an amplitude of approximately 0.125 inch. The fundamental frequencies of temperature variation, pressure variation and mechanical vibration were 40 cycles and 220 cycles per second. Under these conditions the pressure response is essentially linear from 0 to 5500 cycles per second.

INTRODUCTION

THE pressure recording system described in this paper was devised to fulfill the following conditions:

1. To give a frequency response extending from static to at least 5000 cycles/sec.
2. To obtain a high stability to take advantage of static response.
3. To respond linearly over selected pressure range.
4. To operate in flame temperatures rapidly fluctuating over a range of 2000°K.
5. To operate with as few microphonics as possible in very high noise fields, and at vibration amplitudes of 0.125 inch, frequency of vibration 40 to 220 cycles/sec.
6. To obtain an apparatus which is electronically simple, easily portable and rugged enough for field use.

Many different systems have been investigated and have failed to fulfill these specifications for the reasons indicated as follows;

The tourmaline crystal gauge has a very high temperature response.

The quartz crystal gauge does not give a static response and for use with cables has a low ratio of signal to cable noise in the range of pressures of interest here.[1]

The various types of strain gauges suffer either from temperature dependence or low frequency response.

The frequency response of the variable inductance gauge is limited by the necessity of using a relatively low carrier frequency.

Magnetostriction gauges have no static response.

The work of various investigators since 1940 indicated that a condenser-type gauge, when used with a suitable circuit, would fulfill our conditions.[2] During the war, many special applications of condenser gauges were devised in this country and in England but references to this literature are still classified.

The general operation of our system is as follows: A pressure sensitive condenser element, shielded from high temperatures by placing it behind a specially designed cooling chamber is part of a tuned circuit which controls the frequency of an oscillator. The output of the oscillator is fed through a cathode follower to the receiver, which contains a "frequency discriminator" consisting of a fixed tuned resonant circuit combined with a phase detector. Changes in the oscillator frequency due

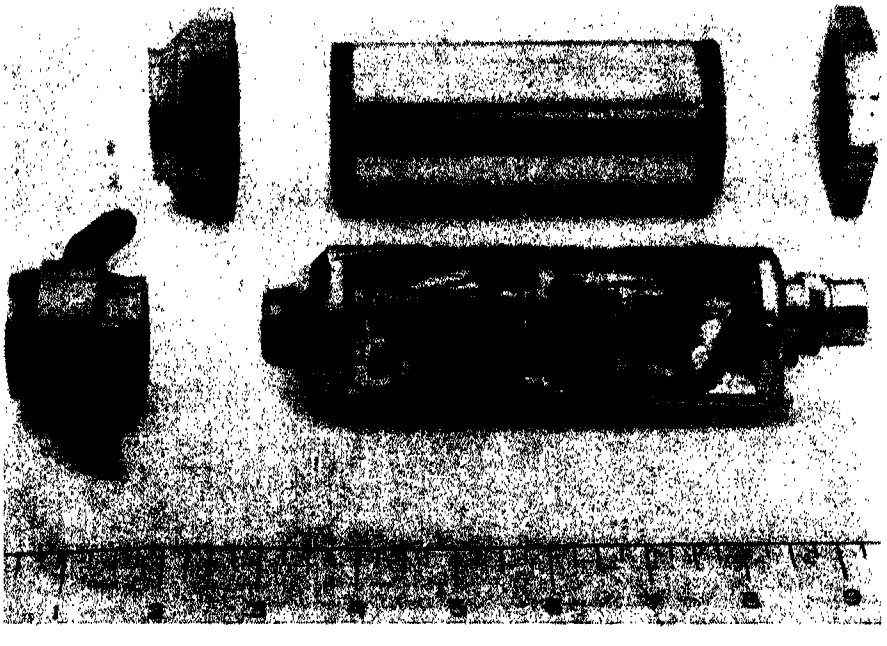
to changes in condenser capacity cause a relatively large shift in phase between the voltage and the current in the fixed tuned circuit. This phase difference is detected by the phase detector and the resulting signal is fed through another cathode follower to the recording equipment. The transmitter and receiver are connected by a cable 75-feet long. In the following the circuit, consisting of the oscillator and cathode follower, is called the transmitter, and the circuit consisting of frequency converter, amplifier, discriminator, and cathode follower is called the receiver.

THE GAUGE HEAD AND COOLING CHAMBER

The gauge head is a carefully machined unit containing the pick-up element, which is essentially an elastically deformable Invar diaphragm attached to a threaded hollow Invar cylinder which forms the main body of the gauge head. Two different gauge heads are shown in exploded view in Fig. 1. Model *A* shows a gauge head in which the diaphragm is an integral part of the main body. Model *B* shows a gauge head in which the diaphragm and the main body are separable. The diaphragm is 0.500 inch in diameter and 0.020 inch thick for the pressure range −5 to +60 p.s.i. Its interior surface is ground and polished and is spaced 0.001 inch from the end face of a central electrode which fits into, but is insulated from, the main body. A mica disk 0.0007 inch thick is cemented to the end face of the electrode. The condenser element is thus made up of the diaphragm, air space, mica and the central electrode. The use of mica produces a smaller equivalent air gap thereby increasing the electrical sensitivity. This permits the use of a smaller diaphragm movement to obtain the same signal for the same pressure, and thus improves the linearity of response. The natural frequency of the diaphragm is 25,000 cycles per second as determined by bouncing a small steel ball off the diaphragm and observing the resulting vibrations. The sensitivity of the condenser element is about 0.25 mmf/p.s.i., but the sensitivity of the gauge as a whole can be varied over a considerable range by changing the shunted capacity across the condenser element.

When measuring the pressures of hot gases, the gauge is screwed down into a water-cooled chamber, one design

FIG. 4. Gauge head, Hartley oscillator and cathode follower mounted integrally with the cooling chamber.



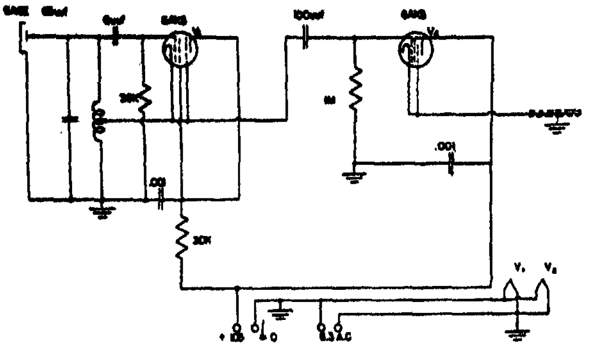


FIG. 5. The transmitter unit circuit diagram.

of which is sketched in Fig. 2. Note that this design of the cooling chamber gives direct water cooling of the perimeter of the diaphragm, as well as cooling of the gases passing through the fire tubes. When the fire tubes are ½ inch in length, the response is essentially linear from 0 to 5500 cycles per second. Figure 3 shows a comparison of the effectiveness of this type chamber with both another N. Y. U. cooling chamber, which did not have direct water contact with the diaphragm, and a cooling chamber and pressure gauge made by Southern Instruments, England.

THE TRANSMITTER UNIT AND RECEIVER

When low pressures are to be measured and maximum sensitivity is necessary, the transmitter unit is mounted directly on the gauge head. A view of the oscillator side of the unit and the mounting case is shown in Fig. 4. When very high shock and vibration are present, the transmitter may be separated from the gauge head by a five foot cable. Either type of transmitter is usually connected by a 75-foot coaxial cable to the receiver.

A circuit diagram of the transmitter is given in Fig. 5. The circuit is a conventional grounded-plate Hartley oscillator capacitively coupled to a cathode follower output tube. The cathode resistor of the cathode follower is located in the receiver. The tubes used are 6AK5's chosen for their relatively low microphonics and long life.

A diagram of the receiver circuit is shown in Fig. 6. The receiver is designed to accommodate signals of frequencies from 2 to 4 megacycles. The intermediate frequency amplifier operates at a center frequency of 430 kilocycles, with a band width of 80 kilocycles. The discriminator is linear within 2 percent over 40 kilocycles and the output voltage varies by 100 volts for this frequency deviation.

The input circuit of the receiver approximately matches the cable impedance of 50 ohms to the grid of the converter stage. The series condenser C_4 and shunt resistor R_2 provide grid leak bias and a certain amount of limiting for large input signals. The first two grids of the converter stage act as a grid and anode of a Hartley oscillator which modulates the space current in the tube. The incoming signal on the third grid further modulates the electron stream. The net current flows from the plate through the resonant load which is tuned to the difference between the local oscillator and signal frequencies. The signal is further amplified by the second tube which drives the discriminator.

The coefficient of coupling of the input intermediate frequency transformer is increased beyond the manufacturer's critical value by sliding one winding along the form closer to the other. The Q of the output winding is reduced with the 33K resistance R_5. This gives 80 kilocycles band width. Amplitude limiting in the intermediate frequency amplifier removes the peaks and gives uniform response. The resistor, R_5, in conjunction with the condenser C_7, in the grid of the intermediate frequency amplifier V_2, causes grid leak biasing in proportion to the incoming signal level. This process provides much of the limiting action of the stage to

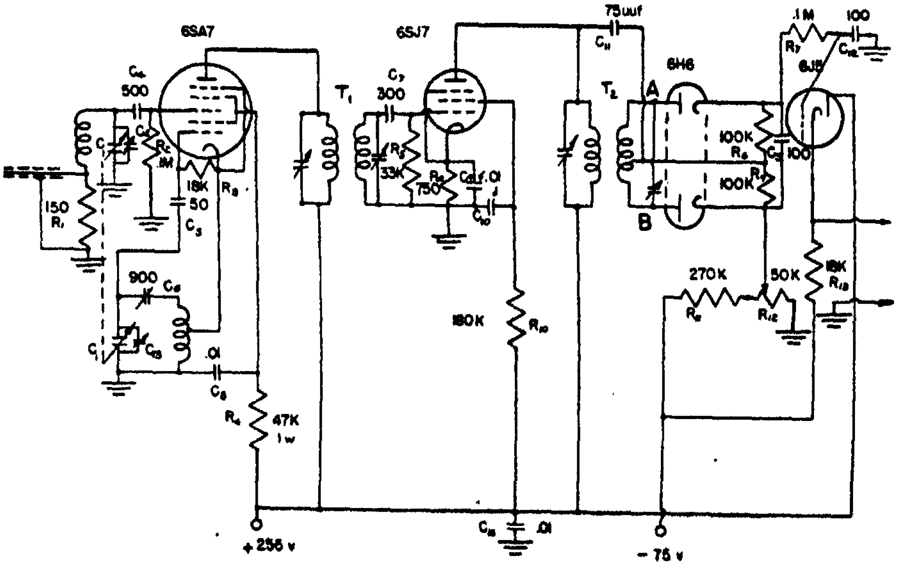

FIG. 6. Receiver circuit diagram.

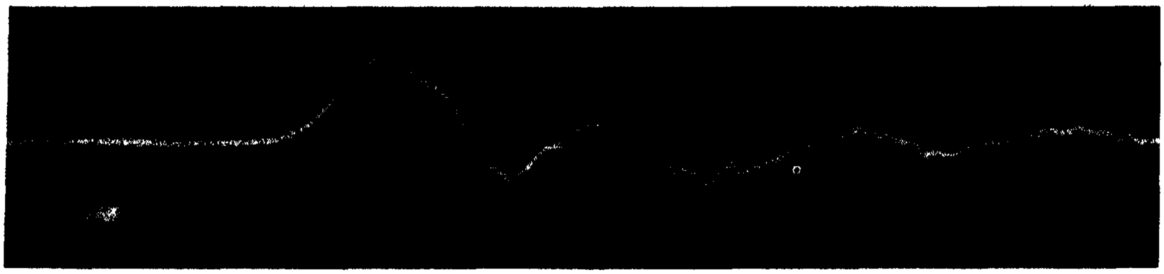

FIG. 7. Low pressure response of the gauge without the use of a cooling chamber. Range +3½ to −1½ p.s.i.

FIG. 8. Response of the gauge to pressures +12 to −7 p.s.i. with a cooling chamber without edge cooling. The horizontal line represents the pressure level of the atmosphere.

which the low screen voltage also contributes. The plate circuit contains a Seeley-Foster discriminator. The output of this discriminator goes to the cathode follower which provides a low impedance source feeding the signal into the recording equipment. The recording is done by a strip camera from a cathode-ray tube.

TYPICAL PRESSURE RECORDS

Figure 7 shows a low pressure record obtained with the circuit adjusted for high sensitivity. This is the record of the pressure near the closed firing end of a 6-foot, half-open flame tube, taken without using the cooling chamber. The first peak and valley measure respectively +3½ p.s.i. and −1½ p.s.i. The length of the trace shown represents 70 milliseconds.

Figure 8 shows 6 pressure cycles recorded 6 inches downstream from the valves in the 21-inch diameter combustion chamber of a large pulse jet. Peaks are +13 p.s.i. and −7 p.s.i. for a low throttle setting of the fuel control. The horizontal line gives the atmospheric pressure level. The superposition of three cycles on the other three is achieved by allowing the oscilloscope recording camera to rotate more than one revolution. It is reasonably certain that there is no appreciable drift during the observation since the atmospheric level was recorded just before the run and coincides with the level of the steps in the pressure cycles which indicate the closing of the valves.

ACKNOWLEDGMENT

The original development work on this instrument was suggested by the late Dr. J. K. L. MacDonald who had a keen interest in the theory and instrumentation of pulse jets.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

Analog Computers for Servo Problems

DONALD McDONALD*
Aeronautical Research Center of the University of Michigan, Ypsilanti, Michigan

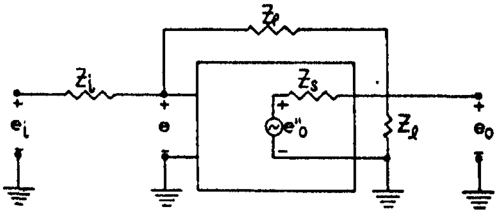
(Received September 26, 1949)

The exact equations are derived for operational amplifiers used in analog computers. These exact equations are replaced by simpler equations based upon certain approximations. These approximations are discussed and it is shown, when applied to servo mechanism problems, the operational amplifiers may be designed with greater ease and less complexity than those to be used for more general problems.

INTRODUCTION

IN the last few years, a great deal of interest has been centered on the use of high gain, operational amplifiers in analog computers for the study of dynamic problems.[1-4] One of the major applications for such analog computers has been in the field of servo mechanisms. The transient equation of motion of even the simpler servo mechanisms is difficult and tedious to solve, and therefore, analogs of servo mechanism systems are being used extensively to facilitate the study and design of such systems.

Analog computers for general dynamic studies normally use operational amplifiers having very high gain, some as high as one million. When analog computers are applied to servo mechanism problems, certain important characteristics of the servo problem tend to reduce the required gain and the resulting complexity of the operational amplifiers and power supplies used in the computer. Gains as low as several hundred yield very satisfactory performance for servo problems. In the analysis and synthesis of servo mechanisms, the dynamic response and stability and the steady-state response are the major factors to be determined. The differential equations of motion of the servo mechanism, which are needed to set up the servo analog on the computer, yield the steady-state response quite easily without the aid of the computer. Hence, only the dynamic response of the servo mechanism need be determined with the computer. As will be shown, the dynamic response accuracy of analog computers can be made much higher than their steady-state response accuracy for comparatively low values of the operational amplifier gain.



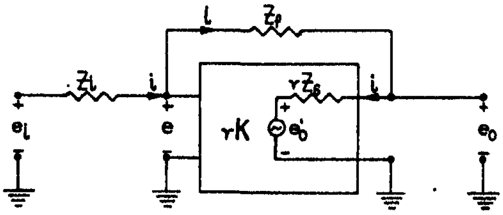
Z_i = input branch impedance.
Z_f = feed-back branch impedance.
Z_s = output stage source impedance.
Z_l = output load impedance.
K = amplifier internal gain.
e_i = input signal voltage.
e = amplifier input voltage.
e_0 = output voltage.
e_0'' = open circuit or no load output voltage, i.e., if $Z_f=\infty$ and $Z_l=\infty$ then $e_0''=e_0$.

FIG. 1(a).

BASIC OPERATIONAL CIRCUITS

Figure 1(a) is a schematic diagram of the basic operational amplifier circuit. In order to more easily analyze the operation of this circuit, it has been transformed by the use of Thevenin's theorem as shown in Fig. 1(b).** Equation (e) of Fig. 1(b), which is obtained by the simultaneous solution of Eqs. (a)–(d), of Fig. 1(b) states the response of the operational circuit. This basic circuit, when employed in analog computers, is usually required to perform the three operations of differentiation, integration, and addition.

Differentiation is achieved by setting Z_i and Z_f equal to $1/jwC_i$ and R_f, respectively; Eq. (e) of Fig. 1(b)



$r=Z_l/(Z_s+Z_l)$; rK = equivalent amplifier internal gain.
The equations for this system are

$$e_i=iZ_i+e \tag{a}$$
$$e=iZ_f+e_0 \tag{b}$$
$$e_0=irZ_s+e_0' \tag{c}$$
$$e_0'=-rKe. \tag{d}$$

Solving these equations simultaneously for e_0/e_i yields:

$$\frac{e_0}{e_i}=-\frac{Z_f}{Z_i}\left[\frac{rK}{rK+1}\right]\left[\frac{1-Z_s/KZ_f}{1+(Z_f+rZ_s)/(rK+1)Z_i}\right]. \tag{e}$$

FIG. 1(b).

[4] Hagelbarger, Howe, and Howe, "Investigation of the utility of an electronic analog computer in engineering problems," University of Michigan Engineering Research Institute, External Memorandum No. 28 (April 1, 1949).

[**] Equation (d) of Fig. 1(b) infers that an odd number of phase inversions take place in the amplifier. The use of the same circulating current i in all branches of the circuit implies the input impedance of the amplifier is infinite.

becomes

$$\frac{e_0}{e_i}=-jwR_fC_i\left[\frac{rK}{rK+1}\right]\times\left[\frac{1-R_s/KR_f}{1+jw(R_f+rR_s)C_i/(rK+1)}\right]. \quad (1)$$

In Eq. (1) and in all later equations, Z_s has been set equal to R_s.

If the input and feed-back branches are a resistor and a condenser, respectively, then

$$Z_i=R_i \quad \text{and} \quad Z_f=1/jwC_i,$$

and the operational circuit becomes an integrator. For an integrator Eq. (e) becomes:

$$\frac{e_0}{e_i}=-\frac{1}{jwR_iC_f}\left[\frac{rK}{rK+1}\right]\times\left[\frac{jw(rK+1)R_iC_f(1-jwR_sC_f/K)}{1+jw[(rK+1)R_i+rR_s]C_f}\right]. \quad (2)$$

The operation of addition or summation implies the existence of two or more input signals; hence the circuit of Fig. 1(b) is shown modified in Fig. 2 with three separate inputs. In Fig. 2, the input and feed-back branch impedances have been made resistive and Eq. (h) of Fig. 2 demonstrates the summation properties of the circuit.

It may be noted, if only one input is used and $R_f/R_1=1$, the circuit of Fig. 2 degenerates to the special case of a sign changer. Of course, the differentiating, integrating, and adding circuits in their most general form also perform a sign change.

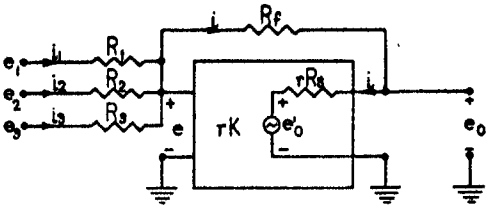
DISTORTIONS OF THE EXACT OPERATIONS

The three basic Eqs. (1) and (2), and (h) of Fig. 2 for the operations of differentiation, integration, and addition all have the same general form and all are composed of three similar terms. For each of these equations the first term represents the exact operation while the remaining two terms in brackets distort the exact operation. The first of these distortion terms is common to all of the basic operation equations and will be denoted by A. A may be rewritten as follows:

$$A=rK/(rK+1)=1-1/(rK+1). \quad (3)$$

The distortion produced by A is simply that of multiplying the basic operation by a scale factor dependent only upon the effective gain rK.

The second distortion term is different for each operation and therefore shall be denoted by B_d, B_i, and B_a for differentiation, integration, and addition, respectively. For the case of addition, B_a is also only a scale factor but it is dependent upon all the parameters of the operational circuit as follows:



$$e_1=i_1R_1+e \quad (a)$$
$$e_2=i_2R_2+e \quad (b)$$
$$e_3=i_3R_3+e \quad (c)$$
$$i=i_1+i_2+i_3 \quad (d)$$
$$e=iZ_f+e_0 \quad (e)$$
$$e_0=irZ_s+e_0' \quad (f)$$
$$e_0'=-rKe. \quad (g)$$

Solving (a)–(g) inclusive simultaneously yields:

$$e_0=-\left(\frac{R_f}{R_1}e_1+\frac{R_f}{R_2}e_2+\frac{R_f}{R_3}e_3\right)\left[\frac{rK}{rK+1}\right]\left[\frac{1-R_s/KR_f}{1+R_f+rR_s/(rK+1)R_p}\right] \quad (h)$$

where

$$R_p=R_1R_2R_3/(R_1R_2+R_1R_3+R_2R_3)$$

and is the resistance of all three input resistors in parallel.

FIG. 2.

$$B_a=\frac{1-R_s/KR_f}{1+(R_f+rR_s)/(rK+1)R_p}. \quad (4)$$

For differentiation, B_d has both magnitude and phase:

$$|B_d|=(1-R_s/KR_f)\times[1+(wC_i)^2(R_f+rR_s)^2/(rK+1)^2]^{-\frac{1}{2}} \quad (5a)$$

$$\angle B_d=-\tan^{-1}[w(R_f+rR_s)C_i/(rK+1)]. \quad (5b)$$

Similarly, for integration, B_i is

$$|B_i|=w(rK+1)R_iC_f[1+(wR_sC_f/K)^2]^{\frac{1}{2}}\times\{1+(wC_f)^2[(rK+1)R_i+rR_s]^2\}^{-\frac{1}{2}} \quad (6a)$$

$$\angle B_i=\tan^{-1}\{1/wC_f[(rK+1)R_i+rR_s]\}-\tan^{-1}[wR_sC_f/K]. \quad (6b)$$

For satisfactorily designed operational amplifiers, some of the quantities in the distortion terms may be small compared to other quantities in the distortion terms. If the amplifier gain is above several hundred and the input, feed back, and load impedances are large compared to the source impedance, the following approximations in the distortion terms may be made:

$$A\cong 1-1/K \quad (7)$$

$$B_a\cong 1-R_f/R_pK \quad (8)$$

$$\angle B_d\cong-\tan^{-1}[wC_iR_f/K]\cong-wC_iR_f/K \quad (9a)$$

$$|B_d|\cong[1+(wC_iR_f/K)^2]^{-\frac{1}{2}}\cong 1-(1/2)(wC_iR_f/K)^2=1-(1/2)(\angle B)^2 \quad (9b)$$

$$|B_i|\cong KwR_iC_f[1+(wC_fR_s/K)^2]^{\frac{1}{2}}\times[1+(KwR_iC_f)^2]^{-\frac{1}{2}} \quad (10a)$$

$$\angle B_i\cong\tan^{-1}[1/wKR_iC_f]-\tan^{-1}[wR_sC_f/K]\cong 1/KwR_iC_f-wC_fR_s/K. \quad (10b)$$

OPERATIONAL AMPLIFIER

Figure 3 is a schematic diagram of an operational amplifier designed for servo application.† It uses only two tubes, two regulated B supplies, and an a.c. filament supply regulated by a conventional constant voltage transformer. The first stage of the amplifier is a twin stage with the amplification of one-half of a 6SL7. This twin stage has been used primarily to minimize the drift produced by variations in cathode emission. The second stage operates at higher voltage levels and thus is a simple amplification stage. The third and last stage is a cathode follower stage used to minimize R_o. This circuit shows an equivalent input drift of the order of 1 millivolt over four to six hours.

For the circuit of Fig. 3, $K \cong 700$, $R_o \cong 700$, and the output stage has been designed to deliver ±40 volts to a load having a resistance not less than 25,000 ohms. Hence the minimum value of r is $r = 0.97$ or $1 > r > 0.97$ and for all practical purposes $r = 1$.

The circuit of Fig. 3 is only one example of a number of elementary basic circuits which may be used to obtain medium gain amplification.

If the power output of this circuit is not sufficient, a 7F8 may be substituted for the second 6SL7.‡ This substitution will result in approximately a 30 percent reduction in K and an increase in power output by a factor of 2.

The amplifier of Fig. 3 has been designed for values of R_f, R_i, C_f, and C_i, as follows:

$$100{,}000 \text{ ohms} < R_f < 1{,}000{,}000 \text{ ohms}$$
$$100{,}000 \text{ ohms} < R_i < 1{,}000{,}000 \text{ ohms}$$
$$0.1\ \mu f < C_f < 1\ \mu f$$
$$0.01\ \mu f < C_i < 1\ \mu f.$$

Therefore

$$R_f \gg R_o \quad \text{and} \quad R_i \gg R_o.$$

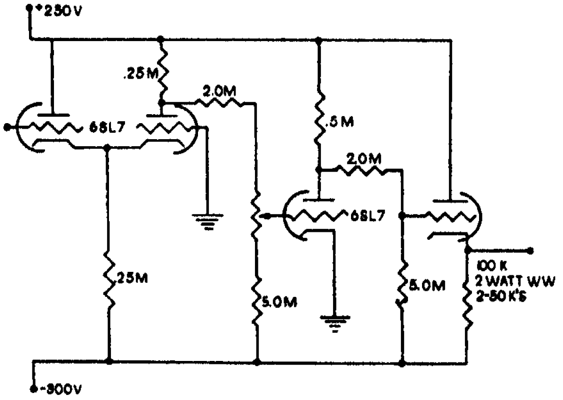


Fig. 3.

EVALUATION OF THE DISTORTION TERMS FOR THE AMPLIFIER OF FIG. 3

Using the values of K, R_o, and r given for the amplifier of Fig. 3, the approximate distortion terms can be evaluated as follows.

The distortion term A, which is common to all of the operations, affects only the magnitude of the exact operation reducing it by one-seventh of one percent.

For the case of addition, if the several inputs are summed but not amplified, the ratio R_f/R_p will have a maximum value equal to the number of input signals summed. Attenuation of the sum will reduce this ratio. Amplification of the sum will increase R_f/R_p but it is not necessary that amplification be done in the summing amplifier. Consequently, B_a, which also affects the magnitude of the exact summation, reduces it by less than one-seventh times the number of input signals times one percent.

In differentiation, B_d produces a negative phase shift as well as a reduction in the magnitude of the exact operation. This phase shift is more important than the magnitude change and for satisfactory servo applications should not exceed a maximum value $\angle B_{d_m}$ for all frequencies below a certain frequency w_c. Therefore, from Eq. (9a)

$$R_f C_i < 700/w_c \angle B_{d_m}. \tag{11}$$

For example, if $\angle B_{d_m}$ is to be kept less than 3° or 1/20 radian up to 50 c.p.s., then

$$R_f C_i < 0.1$$

will satisfy this requirement. This restriction on $R_f C_i$ is very easy to achieve because R_f is usually chosen around 100,000 to 500,000 ohms and hence, C_i must be less than about 1 to 0.2 μf. The choice of 3° for $\angle B_{d_m}$ also limits the magnitude reduction produced by $|B_d|$ to less than one-eighth of one percent.

For the case of integration, there are two phase shifts in B_i, one a positive phase shift occurring at low frequencies and the second a negative phase shift occurring at relatively high frequencies. These two phase shifts occur at such widely separated frequencies that they may be considered separately. The maximum permissible value of $\angle B_i$ at low frequencies and at high frequencies will be denoted by $\angle B_{i_l}$ and $\angle B_{i_h}$, respectively. The frequencies corresponding to these two values of $\angle B_i$ are w_l and w_h, respectively. From Eq. (10b)

$$\angle B_{i_l} \geq 1/700 w_l R_i C_f \tag{12a}$$

$$\angle B_{i_h} \geq w_h C_f. \tag{12b}$$

If the same high frequency specifications are imposed upon the integrator phase shift as upon the differentiator and $C_f < 1\ \mu$f, then

$$w_h \leq 50{,}000 \text{ rad./sec.}$$

or

$$f_h \leq 8000 \text{ c.p.s.}$$

---

† Mr. K. C. Mathews, a member of the Controls Group of the Aeronautical Research Center of the University of Michigan, was responsible for the design and development of these amplifiers.

‡ Usually the loads requiring appreciable power are the multiplier servo potentiometers in the analog computer. Precise potentiometers for such purposes are commercially available with at least 25,000 ohms resistance.

Reasonable maximum values for R_i, C_f, and R_iC_f are 1,000,000 ohms, 1 μf, and 1, respectively.¶ Consequently, if $\angle B_{il}$ is also chosen to be less than 3°

$$w_l \geq 1/35 \text{ rad./sec.}$$

or

$$f_l \geq 1/200 \text{ c.p.s.}$$

Thus from 1/200 c.p.s. to 8000 c.p.s., the phase shift of the distortion term B_i will be less than 3°.

Substitution of Eqs. (12) into Eq. (10a) yields the following form for $|B_i|$:

$$|B_i| \cong w/w_l 1/\angle B_{il}[1+(w/w_h \angle B_{ih})^2]^{\frac{1}{2}} \times[1+(w/w_l 1/\angle B_{il})^2]^{-\frac{1}{2}}. \quad (13)$$

From Eq. (13) it can be shown that $|B_i|$ reduces the magnitude of the exact operation by less than one-eighth of one percent over a frequency range from 1/200 c.p.s. to 8000 c.p.s.

The fractional reduction in magnitude and the phase shift caused by the several distortion terms may be summarized as follows:

Summation:

$$1-AB_a \leq 1/700 \text{ (1+number of inputs).}$$

Differentiation:

$$1-A|B_d| \leq 1/400 \quad 0<f<50 \text{ c.p.s.}$$
$$\angle B_d \leq 3°.$$

Integration:

$$1-A|B_i| \leq 1/400 \quad 1/200<f<8000 \text{ c.p.s.}$$
$$\angle B_i \leq 3°.$$

The reduction in the magnitude of the exact operations produced by the distortion terms of the operational amplifier of Fig. 3 is comparable to the error produced in the exact operation by the use of 0.1 percent resistors and condensers in the input and feed-back branches. For integration, differentiation, and addition, 0.1 percent resistors and condensers will produce an error of as much as 1/500 in the quantities R_iC_f, R_fC_i, and R_f/R_i in the exact operation terms.

Thus low gain operational amplifiers have more than satisfactory dynamic accuracy for servo problems and are less sensitive to drift, are simpler in construction, and require fewer and less regulated power supplies than do high gain operational amplifiers. The magnitude errors in the dynamic response of the operations are less than those obtained (1) in measuring or estimating the coefficients of the differential equations of motion of the servo and (2) in recording the solution of the problem. Similarly, the small distortion phase shifts produced by the integrator and differentiator occur at frequencies which have negligible effect upon the dynamic response, i.e., the effective natural frequency, damping ratio, etc.

On the other hand, the steady-state or zero frequency accuracy of integrators is lower for the low gain operational amplifiers.

STEADY-STATE ACCURACY OF INTEGRATORS

The zero frequency responses of an integrator for different values of operational amplifier gain may be compared by studying its response for a step input

$$e_i = 1. \quad (14)$$

Equation (2) may be rewritten as follows:

$$e_0/e_i \cong -K/1+pKR_iC_f, \quad \text{where} \quad p=d/dt. \quad (15)$$

The approximations used in (15) are the same as used in the previous section with the additional approximation that

$$1-jwR_iC_f/K \cong 1$$

at the frequencies under consideration.

Substituting (14) into (15) and integrating yields

$$e_0 = -K(1-e^{-t/T}), \quad (16)$$

where

$$T = KR_iC_f. \quad (17)$$

Substituting a power series in t/T for $e^{-t/T}$ into Eq. (29) and rearranging terms gives

$$e_0 = -t/R_iC_f[1-1/2(t/T)+1/6(t/T)^2-\cdots] \quad (18a)$$

or

$$e_0 \cong -t/R_iC_f[1-1/2(t/T)] \quad \text{for} \quad t/T \ll 1. \quad (18b)$$

An ideal integrator would have an output $-t/R_iC_f$. Hence the term $1/2(t/T)\times 100$ is the percentage by which the output of a real integrator deviates from the output of an ideal integrator for short periods after being subjected to a step input of voltage. In other words, $50/T$ may be referred to as the initial rate of percent deviation of an integrator. This rate of deviation is dependent upon T. Inasmuch as the maximum value of R_iC_f is essentially independent of amplifier gain K, the minimum initial rates of percent deviation of integrators is dependent upon only K. Therefore, higher gain operational amplifiers will have a smaller rate of deviation than have low gain operational amplifiers. This smaller rate of deviation is very important in many studies such as trajectory studies and requires gains as great as 1,000,000. Such high values of gain increase the number of tubes, power supplies, components and the care that must be exercised in the design of them to minimize drift effects.

¶ These values of R_f and C_i can be increased several-fold but have been chosen for convenience.

Gas Phase Counting of Low Energy Beta-Emitters*

W. Bernstein and R. Ballentine†
Brookhaven National Laboratory, Upton, New York and Rutgers University, New Brunswick, New Jersey

(Received October 4, 1949)

A proportional counter has been designed to detect soft beta-emitters in the gas phase. Data is presented to illustrate the applicability of the counters to the detection of C^{14}, S^{35}, and H^3. Various partial pressures of $C^{14}O_2$ have been investigated to determine the effects on the counter properties. Corrections have been made for the counter ends and the memory effects are described. An energy spectrum is presented for H^3 to determine the low energy limit of the instrument.

THE radioactive assay of very soft beta-emitters such as H^3, C^{14}, and S^{35} is an important problem in both chemical and biochemical research. Assay of solid samples is difficult because of the self-absorption of the samples, and the absorption by the windows or walls of the detector. In the case of tritium, with a maximum energy of 18.9 kev, no practical method of solid counting is available.

Both of these difficulties can be avoided if the samples are counted in a gas phase as part of the counter filling. Such procedures have been developed in the past, using ion chambers[1] or gas filled Geiger-Müller tubes.[2] The G-M tube technique, developed by Brown and Miller, provides the most practical method for the detection of C^{14} (as CO_2) to date, but has the disadvantage of using G-M tubes with a variable filling. The difficulty in obtaining reproducible behavior of G-M tubes under varying conditions is well known.

The ionization chamber method possesses the advantage of handling a relatively large amount of gas sample in the event that the specific activity is low. Also, the background contribution from high energy particles (cosmic rays) is less than in a counter which detects individual events. However, there are statistical fluctuations of both energy and events in an ionization chamber, and, in general, the detection of individual events is preferable.

Counting in the proportional region appears to be a method which can avoid many of these disadvantages. With proper circuits, proportional counters can count extremely active samples accurately, and with negligible coincidence losses. They are also preferable to G-M tubes at low counting rates because there are no spurious counts originating in the detector and the background counting rate is low because they are less sensitive to gamma-rays. Spurious counts may come from the amplifier or high voltage supply but can be eliminated without too much difficulty.

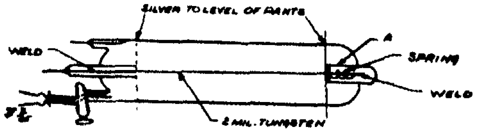

FIG. 1. Cylindrical proportional counter with one end which may be immersed in liquid air.

Proportional counters are also only moderately sensitive to changes in the filling mixtures.[3] This permits a simple, rapid filling technique, and the samples may be counted in different gaseous states. For instance, tritium may be counted as hydrogen gas, sulfur as hydrogen sulfide, carbon as carbon dioxide, acetylene and presumably carbon monoxide. The stability, with respect to the character of the filling, permits a wide range of sample sizes without any serious effect on the counter properties.

The design of the standard counter used in these investigations is shown in Fig. 1. The dimensions may be varied over wide limits. The counter radii vary from 2½ to 10 cm, and the cathode lengths from 10 cm to one meter. The standard counter is 2 cm in diameter and 30 cm long. These counters all show similar operating characteristics, although they have different thresholds. The cathode material used for most of this work is chemically deposited silver, although evaporated chromium or gold cathodes may be used. The center wire is 2-mil tungsten. Since the filling procedures require that one end of the counter be immersed in a liquid nitrogen trap, this end is kept free of glass to metal seals, as shown by *A* in Fig. 1. The successful use of the counter[4] shown in Fig. 2 indicates that the technique is not limited to counters of cylindrical geometry. This spherical cathode is chemically deposited silver and the center wire consists of a 2-cm loop of 2-mil tungsten. The other features of the design of this counter are adapted for a special sampling technique which will be described more fully elsewhere.[5]

[3] The introduction of electronegative gases, in very small amounts, results in a marked distortion of the output pulse heights as a function of energy. Such counters are impractical for energy measurements, but are satisfactory for use as relative activity detectors. At high amplifier gain and high gas multiplication factors, total activity measurements can be made.

[5] R. Ballentine and W. Bernstein, "Method for monitoring $C^{14}O_2$ air contamination," Brookhaven National Laboratory report, BNL T-5.

$C^{14}O_2$ or H_2S^{35} gas samples are obtained with the vacuum system shown in Fig. 3 and the procedure described below. Either barium-carbonate precipitates or sodium carbonate solutions are converted to carbon dioxide gas by adding 40 percent lactic acid under vacuum. H_2S is obtained from sodium sulfide solutions by adding saturated magnesium chloride. The gas sample, after generation, is dried with a dry-ice chilled trap which removes water from the gas stream. The gas is then separated from any carrier air which may be present by freezing out the sample in a trap chilled with liquid nitrogen. At this temperature only a negligible fraction of the gases present in the air are condensed and consequently the separation is quantitative. After collection in the liquid nitrogen trap, the sample is transferred to the evacuated counter by distillation with liquid N_2 on the counter. The counter is then cut off from the gas line, the gases allowed to expand by warming to room temperature, and the counter is filled to about one atmosphere with tank methane. The total elapsed time for the preparation of the gas sample and filling of the counter for either CO_2 or H_2S is about seven minutes. A vacuum line, giving pressures of ten to one hundred microns, available from an ordinary mechanical pump, is satisfactory.

In the case of tritium, the sample is transferred to the counter tube with a Töpler pump, as shown in Fig. 4. Following the complete transfer of the sample into the counter, the pressure in the counter is brought to one atmosphere with tank methane.

Methane is selected as the counter gas to permit rapid recovery of the samples for later gravimetric analysis. This is not possible if argon-CO_2 fillings are used, or if the counters are filled to a predetermined carbon dioxide pressure by adding carrier CO_2. Therefore, the counting gas contains only the analytical sample, together with the added methane. Argon-methane or neon-argon-methane mixtures might reduce the operating voltage, but have not been investigated to date.

The electronic equipment used in this work consists of the Nuclear Instrument and Chemical Company Model 162 Scaler and Model 1092 5000 volt power supply. This scaler has an amplifier with a gain of 1000, an attenuator, and a pulse height discriminator with a maximum sensitivity of 1 volt. Some difficulty was encountered with multiple pulses caused by overloading the amplifier with large input signals. A 1N34 crystal diode, used to clip positive overshoots, at the input to the second loop eliminated this problem. Spurious counts are encountered now only when the first loop is overloaded. The pulse is differentiated with a 1-μsec. time constant at the input to the amplifier which reduces the duration of the overshoot and gives a shorter dead time. The presence of double counts may be checked with a synchroscope.

A non-overloading amplifier, designed by the late H. G. Brewer, Jr. at this Laboratory, which can handle an input pulse height distribution of 7000 to 1 without overloading, has also been used in this investigation.

Figure 5 is a plot of counts per minute against counter voltage for three samples of identical activity, but with different partial pressures of inert CO_2 added. It is apparent that high partial pressures of CO_2 raise the threshold of the proportional region and broaden the pulse height distribution. At 3900 volts the results are summarized in Table I.

The slope of the operating region is not over 3 percent per 100 volts. The overlapping of the operating regions permits the counting of any sample up to 100 mm partial pressure of CO_2 at a constant voltage and gain. In first calibrating the system, it is advisable to select a counter with a low partial pressure of CO_2 and to operate at a point high on its characteristic for standard analysis. Figure 6 is a plot of counting rate against amplifier gain for several different voltage settings.

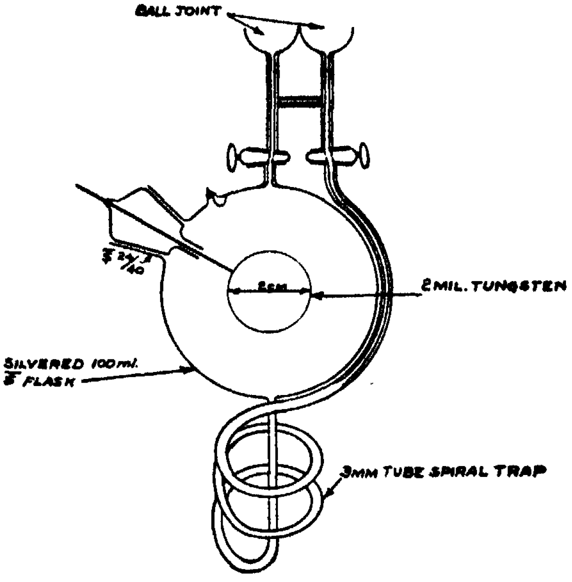

FIG. 2. Spherical proportional counter with spiral trap.

It is apparent from the design of the counter shown in Fig. 1 that some of the gaseous sample lies outside of the sensitive region of the counter. The correction for end effects is determined by one of the following procedures: 1. The ratio of the volume enclosed by the cathode to the total volume of the counter is determined by filling the counter with measured volumes of toluene to the appropriate levels; 2. A series of counters with similar ends but with different cathode lengths are filled with identical samples of $C^{14}O_2$. The counting rates are plotted against the reciprocal of the cathode length and the curve is extrapolated to infinite cathode length.

Two counters which have an effective geometry as determined by the first procedure of 78.7 percent and 90.4 percent gave corrected counting rates for identical samples of 37,400 counts/min. and 36,400 counts/min.

respectively. The extrapolated value (method 2) for the same sample of carbon dioxide was 37,300 counts/min. In a similar run six months earlier the same two counters, filled with the same carbon dioxide samples but using a different scaler, gave corrected counting rates of 36,700 counts/min. and 36,900 counts/min. respectively. This demonstrates that the volume correction is well within the over-all errors of handling samples, and that there is a high degree of reproducibility, not only in a given run but over long periods of time.

Figure 7 is a dilution curve in which the logarithm of the counting rate is plotted against the logarithm of the micromoles of Oak Ridge barium carbonate taken as a sample. The counts at each point done with the two counters, corrected for end effect, did not differ from the best straight line by more than a standard error of ±0.56 percent. The counting rates range from 1000 to 200,000 counts per minute. Failure to show any decrease from the expected counting rate at 200,000 counts per minute indicates that for all practical samples no coincidence correction need be applied. This gives an effective dead time of less than 3 μsec. in agreement with synchroscope observation. The absence of spurious counts from external sources is shown by a standard deviation of ±0.12 percent for ten repeated counts on the same counter, compared to a calculated standard deviation of ±0.11 percent.

Dilution experiments have also been carried out with tritium. The counting rate per cm³ of a tritium gas sample is constant and independent of the counter or the amount of gas taken for the count within sampling error over a range of 20,000 to 40,000 counts/min. Dilution experiments have not been run with H_2S^{35}.

The background count in the standard counter, which has a sensitive volume of 100 cm³, is 140 counts per minute unshielded. Shielding with 2 in. of lead lowers this background count to approximately 100 counts per minute.

Memory effects have been investigated for $C^{14}O_2$ and it was found that even for a sample giving as much as 500,000 counts per minute, pumping for a period of 5 minutes with a mechanical oil pump is sufficient to reduce the counting rate essentially to the background count. Carbon monoxide at a pressure of 70 millimeters and H_2S at a pressure of 85 millimeters were added to mixtures of carbon dioxide and methane, and the expected count was obtained with both of these additional gases present, although the operating region was shifted 100 to 150 volts higher. Sulfur dioxide at 41-millimeters partial pressure and dry anhydrous HCN gas at 65-millimeters pressure both attack the silver cathode and result in a complete loss of the operating region. Radioactive acetylene behaves similarly to carbon dioxide-methane mixtures when the CO_2 is at a low partial pressure.

The satisfactory behavior of H_2S-methane-$C^{14}O_2$ mixtures encouraged the use of radioactive H_2S as a counting gas for sulfur. It seemed probable that sulfide formation with silver cathodes would lead to very large memory effects, and evaporated chromium cathodes were used. A counter containing 21,000 counts of S^{35} at

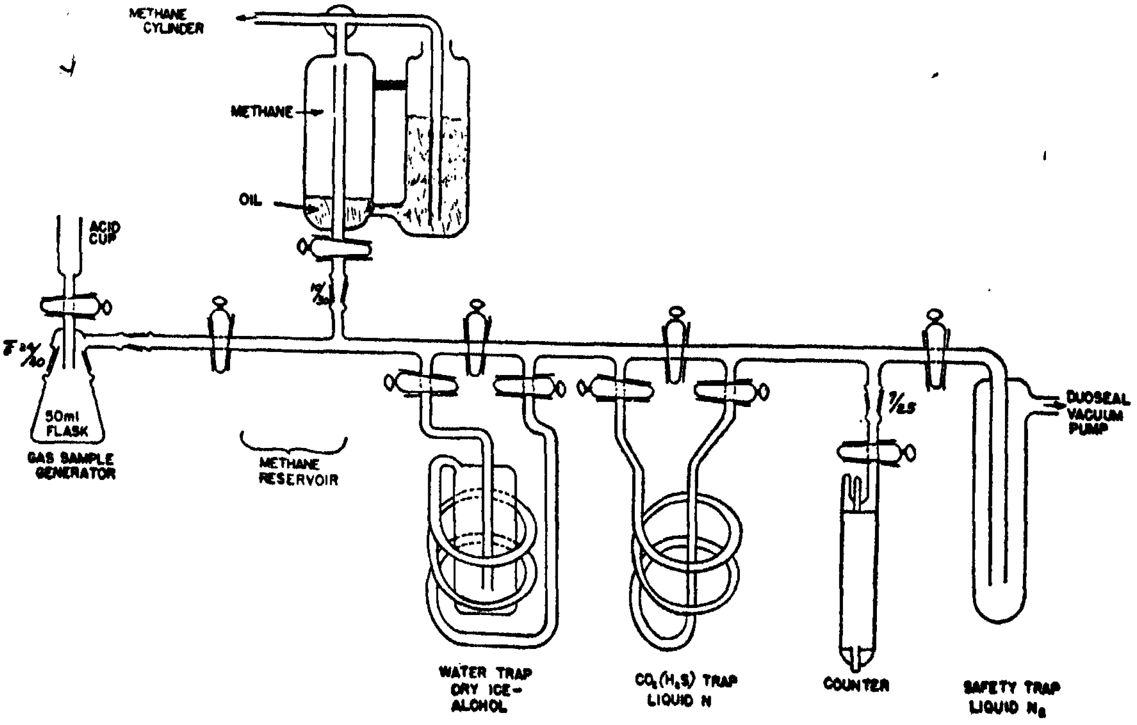

FIG. 3. Filling line for CO_2 and H_2S samples.

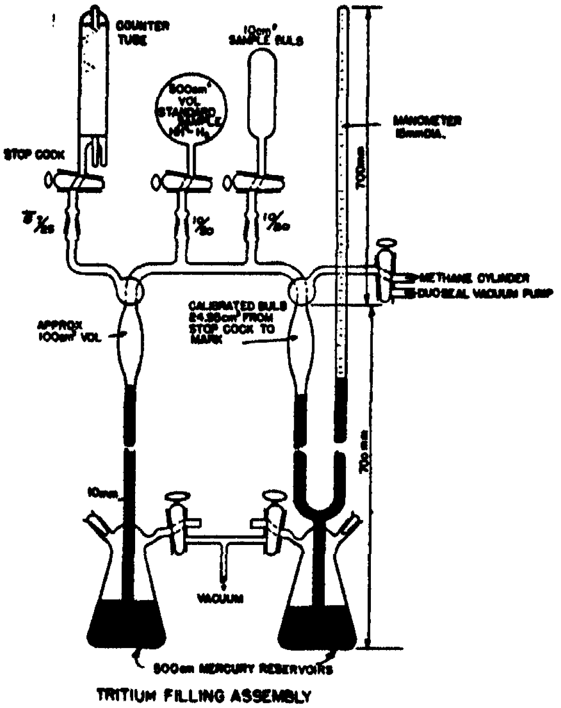

FIG. 4. Filling line for H^3 samples.

34-millimeters partial pressure of H_2S is reduced to background after a few minutes pumping with an oil pump.

Both silver plated cathodes and evaporated gold cathodes show a large memory effect with tritium. A silvered counter filled to 40 millimeters partial pressure of H^3, containing 136,000 counts per minute, gave 145 counts per minute above background, even after long, repeated pumping. Another silvered tube filled with H^3 at 4.5 millimeters pressure giving 409,000 counts per minute gave 50,000 counts per minute above background after having been pumped for an hour. This is a 12 percent memory effect. The same counter, after prolonged flaming and pumping, showed a decrease in the counting rate to 244 counts above background, but even this memory effect would be serious if low level counting were desired. The gold cathode, which was expected to show less absorption of hydrogen, was not better than the silver cathode, so apparently the difficulty lies more in the glass surfaces of the tube than in the cathode material itself. It is hoped that the conversion of tritium water to ethane (via ethyl Grignard) will be perfected shortly, which should permit counting tritium without memory difficulties.

One of the important properties of a counter is the ratio of the detected counting rate to the actual disintegration rate occurring within the sensitive volume of the counter. This ratio may be defined as the efficiency of the counter. An operating region of low slope in a proportional counter, as in Fig. 6, indicates that very few disintegrations are being missed. The length of the region of low slope is determined by the signal to noise ratio, and, if all disintegrations were detected, the slope of the characteristic would be zero.

Contributing factors to the slope in Fig. 6 are wall and end effects which cause an excess of small pulses in the distribution. The efficiency of counting these small pulses increases with voltage (or gain). To check this possibility we were kindly provided with a sample of $BaC^{14}O_3$ assayed by Dr. Warren Miller in his gas filled G-M tube. On this sample we obtained a 13.9 percent higher count than Miller did. It is doubtful that so large a discrepancy could be caused by spurious counts, since synchroscope observations show no appreciable number of multiple pulses or pulses due to electrical interference, and long delayed spurious pulses due to metastables or negative ions would be expected to have very small amplitudes. Another explanation to account for this discrepancy might be over-quenching of the G-M counter with a significant loss of counts in Miller's experiment. In this event the comparison is

TABLE I.

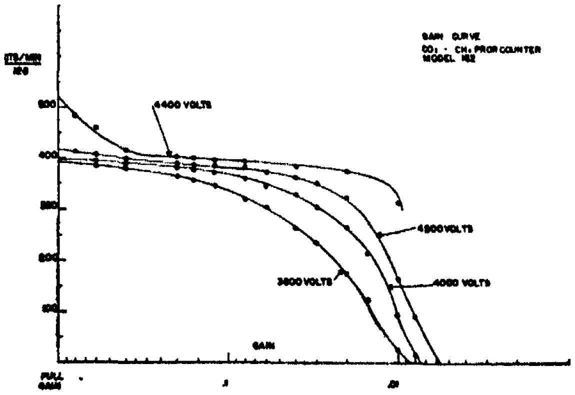

FIG. 6. Effect of high voltage on counting rate—amplifier gain curves.

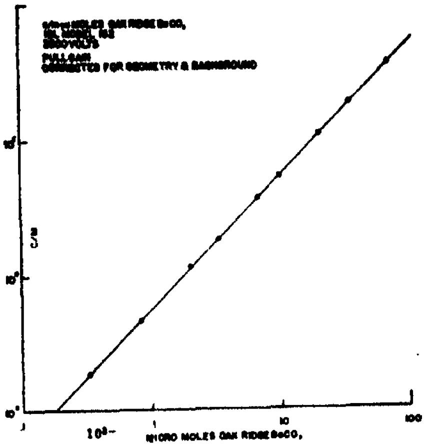

FIG. 7. Dilution curve for $C^{14}O_2$.

not significant. Therefore, the beta-spectra of both tritium and Carbon[14] have been investigated to provide an estimate of the counter efficiency. Figure 8 shows a plot of the spectrum of H^3 run with a counter 10 cm in diameter, the non-overloading amplifier and a single channel pulse height analyzer. If the value of 18.9 kv given by Hanna and Pontecorvo[6] for the maximum energy is assumed, the maximum intensity peak occurs at 3.5 to 4 kilovolts. It is apparent from the curve that the spectrum extends well below this energy. Conservatively, the minimum energy for counting is about 1 kilovolt.

A carbon spectrum has not been obtained to date because none of the counters constructed could encompass the beta-path length. The wall effects and pulse height distortion by the gas are sufficient to distort the spectrum to resemble a continuous distribution. However, if the counter is able to detect 1 kv as shown by the H^3 spectrum, then calculating from the Fermi theory[7] less than 1 percent of the C^{14} disintegrations are lost.

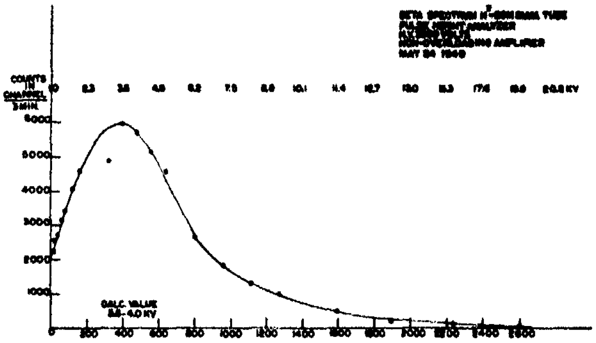

FIG. 8. Beta-spectrum of H^3.

The statistical behavior of the counter, both as far as background counts are concerned and for repeated counts on the same sample, provides strong evidence that the counting rate is not significantly disturbed by spurious counts caused by external disturbances. Since energies of about 1 kilovolt may be detected, we conclude that the efficiency of the counter is about 98 percent for C^{14}.

We have not been able to obtain the most precise energy distribution data on the tritium spectrum for several reasons. We are not equipped to carry out absolute energy calibrations of our counter tubes as was done by Hanna and Pontecorvo. Further investigations, both of the behavior of the counter with various gas mixtures and of the effect of the walls in distorting the beta-spectrum, would be required. Further work on the development of proportional counters for precise energy and absolute activity measurements is in progress. However, at present we feel that the described counter is entirely satisfactory for the routine assay of soft beta-emitters in the gaseous state.

The authors wish to express their appreciation to many members of the Brookhaven National Laboratory, especially to Dr. J. B. H. Kuper and W. A. Higinbotham, for their assistance and suggestions. The authors are indebted to the late H. G. Brewer, Jr. for the design of the amplifier and for his constant interest in this work.

Measurement of Fast Neutron Energies by Observation of $Li^6(n, \alpha)H^3$ in Photographic Emulsions

GEORGE R. KEEPIN, JR.*† AND JAMES H. ROBERTS
Department of Physics, Northwestern University, Evanston, Illinois

(Received October 10, 1949)

A new technique of neutron energy measurement not requiring neutron collimation is described. The method employs the nuclear reaction $Li^6(n, \alpha)H^3$ ($Q=4.64$ Mev) observed within photographic emulsions impregnated with enriched Li^6. Results on monoenergetic neutrons indicate a resolution of at least ±0.1 Mev in the region studied (from thermal energies up to 1.3 Mev). To extend the method to measurement of continuous neutron spectra, both the excitation function and the angular distribution of the Li^6 disintegration process should be known. However, for immediate practical application, the method may be calibrated with a well-known spectrum. The Li^6 technique is particularly well suited to energy measurements on neutrons within a material medium where perturbations introduced by the detector must be minimized and where collimation is clearly impossible.

I. INTRODUCTION

THIS research evolved from the need for a neutron spectrometer which does not require collimated neutrons and whose detector could be placed within a material medium without thereby introducing an appreciable perturbation of the distribution being studied. A photographic plate, due to its small size is well suited to these requirements except that the usual technique, the recoil proton method, requires collimation of the neutrons. This difficulty may be resolved if one can employ a neutron induced reaction disintegrating by a single mode into a small number of ionizing particles whose ranges and directions can be measured from which both neutron energy and direction can be determined. Almost the only possibility is the reaction $Li^6+n\rightarrow\alpha+H^3$ with an average cross section the order of 0.1 barn in the region of interest. Commercial (normal) lithium loaded plates are not satisfactory because the small percentage of Li^6 results in a prohibitively low ratio of disintegrations to recoil protons. To enhance this ratio the use of emulsions heavily loaded with Li^6 was suggested.[1] The Eastman Kodak Company impregnated 50μ NTA emulsions obtaining approximately 0.2 mg/cm² of Li^6. Results of preliminary studies with these plates have been previously reported.[2] Exposures have been made to thermal neutrons and to a Po−Be source at the Argonne National Laboratory and to monoenergetic neutrons produced by the $H^3(p, n)He^3$ reaction with the Van de Graaff generator at the Los Alamos Scientific Laboratory.

II. EXPERIMENTAL PROCEDURE

For an accurate analysis of the data it is necessary to obtain good discrimination between the alpha- and triton tracks as well as to distinguish between disintegrations and a background of proton tracks. A number of methods have been suggested to obtain such discrimination: (1) underdevelopment; (2) the use of a very fine-grained developer; (3) differential fading of the latent image resulting from delayed development; and (4) the use of reducers and desensitizing solutions. A combination of (1), (2), and (3) were used in this work. The plates were processed as follows:

1. Presoaked in H_2O for two minutes with slight agitation.
2. Developed in Microdol diluted one to four for 12 minutes at 68°F.
3. Fixed until clear, washed and dried slowly.

Plates were enclosed in a light tight cadmium box during exposure (except to thermal neutrons) and oriented at an angle of 5° to the direction of the neutron beam. Exposure times were calculated to give two or three disintegrations per field of view.

A Leitz ortholux microscope fitted with binocular body tube and a precision mechanical stage was used. Linear measurements were made with a calibrated Spencer micrometer disk No. 410. Compensating eyepieces of magnification 6× or 12.5× were used in conjunction with a 2 mm apochromat oil-immersion objective (90×, N.A. = 1.32). For this arrangement one division (R.U.) on the micrometer disk was equivalent

to 1.25 microns. Angles were measured to an estimated accuracy of ±0.7° with a Gaertner goniometer eyepiece. A depth of focus scale calibrated in microns gave vertical distances in the emulsion. Only those tracks which were entirely within the emulsion and in or near the focal plane were selected for measurement. Points were established on range-energy curves for alphas and tritons in these Li^6 impregnated emulsions and were found to agree within experimental error with Ilford's range-energy relations for protons** and alpha-particles in Ilford C.2 emulsions.[3]

III. KINETICS OF THE DISINTEGRATION PROCESS

Consider the disintegration of a Li^7 compound nucleus into an alpha-particle and triton of energies E_α and E_T, respectively. These are assumed entirely kinetic energies since there are certainly no excited states of tritium in the present energy range. If we let m be the neutron mass and M the mass of the Li^6 target nucleus there is in the center of mass system an energy $\mathcal{E}=E_n+Q-[m/(m+M)]E_n$ available to the disintegration products, the remaining energy $(m/m+M)E_n$ going into kinetic energy of the center of mass. The alpha-particle and triton divide $\mathcal{E}$ in their inverse mass ratio so that

$$P_\alpha^0=P_T^0=\left\{\frac{2m_\alpha m_T}{m_\alpha+m_T}\left(\frac{ME_n}{m+M}+Q\right)\right\}^{\frac{1}{2}}. \tag{1}$$

Motion of the center of mass as seen in the laboratory system adds, in effect, the components δP_α, δP_T and δP_n whose magnitudes are given by particle mass times velocity of center of mass.

From the geometry we have

$$\tan\phi=\frac{P_T^0\sin\phi_0}{P_T^0\cos\phi_0+\delta P_T};\quad \tan\gamma=\frac{P_T^0\sin\phi_0}{-P_T^0\cos\phi_0+\delta P_\alpha}. \tag{2}$$

Therefore

$$\tan\theta=\tan(\phi+\gamma)=\sin\phi_0/A+B\cos\phi_0, \tag{3a}$$

with

$$A=\frac{\delta P_\alpha\delta P_T-(P_T^0)^2}{P_T^0(\delta P_\alpha+\delta P_T)},\quad\text{and}\quad B=\frac{\delta P_\alpha-\delta P_T}{\delta P_\alpha+\delta P_T}, \tag{3b}$$

functions of the neutron energy alone.

Again from the geometry, Fig. 1, we have the vector relation

$$\mathbf{P}_T=\mathbf{P}_T^0+\boldsymbol{\delta}\mathbf{P}_T$$

or, squared,

$$E_T=\frac{1}{2m_T}[(P_T^0)^2+(\delta P_T)^2+2P_T^0\delta P_T\cos\phi_0]. \tag{4}$$

Eliminating ϕ_0 from Eqs. (3) and (4) we obtain a quadratic relation between neutron energy and triton energy for constant θ. Thus a plot of E_n *vs.* E_T with θ as a parameter shows that for each E_n and θ there are two possible values of E_T. We define the larger of these values as the f_T case (favoring the triton) and the

---

** For particles of the same velocity and atomic number but different mass, the ranges are proportional to their masses. This was used in relating range-energy curves for tritons and protons.

[3] G. Lattes, P. Fowler, and P. Cuer, Proc. Phys. Soc. 59, 883 (1947).

smaller as the f_α case (favoring the alpha). Using our established range-energy curves and this E_n *versus* E_t relation, a plot of E_n *versus* $R_\alpha+R_T$, the sum of alpha-particle and triton ranges, was developed (Fig. 2). The two cases f_α and f_t are similarly defined for this sum of ranges curve.

IV. SELECTION AND ANALYSIS OF DATA

Without the restriction of neutron collimation there are four quantities which may be observed for each disintegration: R_T, R_α, θ, and $R_\alpha+R_T$. At least two of these must be measured to determine the energy of the incident neutron. Consider the following combinations of measurements: I—R_α, R_T; II—R_T, θ; III—R_α, θ and IV—$R_\alpha+R_T$, θ. The first method determines E_n uniquely while the methods involving measurement of θ determine E_n as one of two values. If R_α and R_T are measured, E_n is determined directly from range-energy data and energy conservation: $E_n=E_\alpha+E_T-Q$. However, alpha-straggling and the steepness of the R_α *vs.* E_α curve at low energy renders a large error in the determination of E_α and hence E_n. Furthermore, the point of disintegration must be accurately located; this is often difficult especially for $E_n<2$ Mev where straight line disintegrations ($\theta\simeq 180°$) are highly probable. For higher E_n the above objections are no longer serious and we may expect method I to give an accurate determination of neutron energy provided no excited states are found in the triton. When either method II or III is used, many disadvantages are encountered. If $\theta\simeq 180°$, E_n is an insensitive function of θ and θ need not be determined accurately; however, in such cases the point of disintegration is difficult to determine with precision. On the other hand if $\theta\ll 180°$, E_n is a very sensitive function of θ and θ must be determined with a better precision than is experimentally possible.

The major difficulty common to methods I, II, and III is locating the point of disintegration precisely. However, if we measure the sum of alpha- and triton ranges and the angle θ (method IV), E_n will be uniquely determined by deciding between the f_α or f_t case which involves only a rough determination of the point of disintegration. From the sum of ranges curve, Fig. 2, it is clear that the best resolution in neutron energy is obtained by selecting disintegrations which (1) favor the triton and (2) have $\theta\approx 180°$, for under these conditions E_n is the least sensitive function of the two variables being measured. The experimental distributions for monoenergetic neutrons in this low energy region have confirmed this, indicating a resolution of at least ±0.1 Mev. Thus a complete analysis by this sum-of-ranges method of the spectrum (Fig. 3) of 1.3±0.025 Mev neutrons from the Los Alamos Van de Graaff shows that f_α disintegrations give the poorest energy definition, f_t disintegrations with $\theta<175°$ give a somewhat sharper peak and those f_t disintegrations with $175°\leq\theta\leq 180°$ give by far the best resolution in E_n. Note also in Fig. 3 that only method IV is capable of resolving the 0.27 Mev resonance in the Li^6 cross section for neutron capture; this peak is attributed to an unavoidable back-

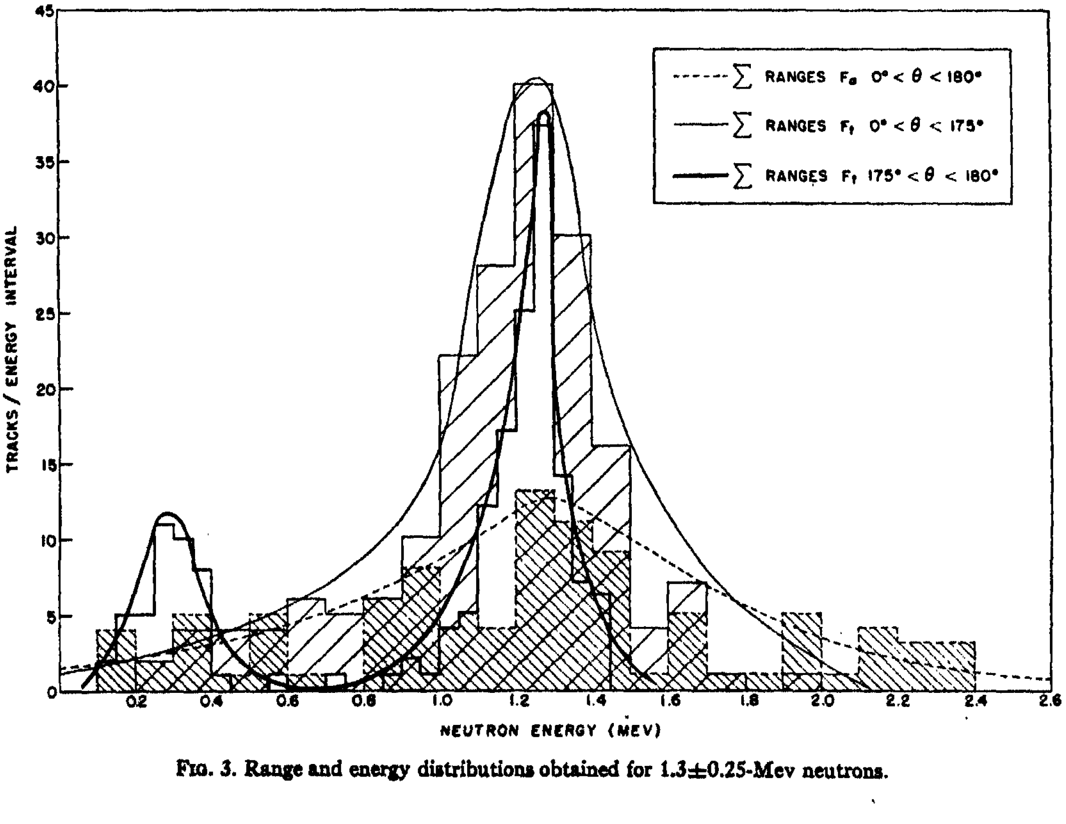

FIG. 3. Range and energy distributions obtained for 1.3±0.25-Mev neutrons.

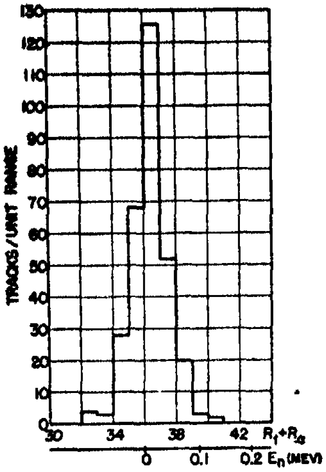

FIG. 4. Range and energy distributions obtained for thermal neutrons.

ground of scattered neutrons around the Van de Graaff. Exposures to neutrons of energy 0.6, 0.3, and ~0 Mev indicate that a resolution of better than ±0.1 Mev is possible all the way down to thermal energies (e.g., see Fig. 4). For $E_n < 3$ Mev there is no danger of confusing a disintegration with the shorter recoil proton tracks (cf. Figs. 5 and 6), whereas for higher E_n the average proton track length greatly exceeds the sum of alpha- and triton ranges, and the best possible discrimination between protons and alpha-triton pairs is required.

V. CONCLUSIONS

We have demonstrated the effectiveness of the Li^6 method for precise energy measurements on monoenergetic neutrons of a few Mev. It is planned to extend the method to measurements of continuous neutron spectra; for this either one may use an accurately known calibration spectrum or appropriate correction must be made for the energy dependence of:

(1) The Li^6 neutron capture cross section which at present is only roughly known up to 0.8 Mev.[4]

(2) The fraction of tracks measured according to geometrical selection criteria. *Viz.* tracks must be entirely within emulsion and approximately parallel to emulsion plane within a depth difference, $\delta = 10\mu$ between track extremities.

(3) The probability that $175° \leq \theta \leq 180°$.

An accurate measurement of the Li^6 cross section over the energy range of interest is being planned. Corrections for (2) have been developed for the case of isotropic and collimated incident neutrons.[5] For the

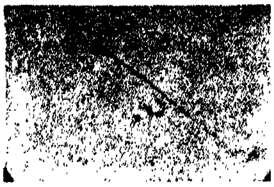

FIG. 5. Photomicrograph of a disintegration produced by a thermal neutron.

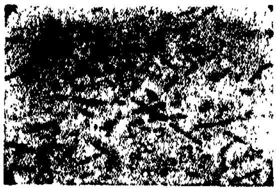

FIG. 6. Photomicrograph of a disintegration produced by a 1.3±0.025-Mev neutron.

angular selection criteria, (3), we ask what is the probability $W(\theta)d\theta$ of θ being in the interval θ, $\theta+d\theta$ for various E_n values. Referring to Fig. 1 we see that a disintegration is uniquely determined by the independent quantities E_n and ϕ_0 so that for each E_n we have:

$$W(\theta)\big]_{E_n}d\theta = \sum W(\phi_0)\big]_{\phi_0(\theta,\,E_n)}d\phi_0.$$

Or

$$W(\theta)\big]_{E_n}d\theta = \sum W(\phi_0)\frac{d\phi_0}{d\theta}\bigg]_{\phi_0(\theta,\,E_n)}d\theta,$$

the sum being taken over the two values of ϕ_0 at a given θ and E_n. $W(\phi_0)$ is of course the angular distribution of the disintegration process in the center of mass system. The quantity $(d\phi_0/d\theta)$ is immediately given by the geometry of Fig. 1, leaving only $W(\phi_0)$ to be determined. For *s*-capture of the incident neutron we have $W(\phi_0) = \frac{1}{2}\sin\phi_0$. However, since we have found definite indications of the presence of *p*-capture at energies considerably lower than would be expected, the angular distribution of the $Li^6(n,\alpha)H^3$ reaction should be measured. A method for doing this using Li^6 loaded plates has been proposed[6] and is now being applied. Pending the determination of these correction functions we should have then a fast neutron spectrometer which extends the photographic method beyond present limits set by recoil-proton techniques.

The authors are indebted to Professor A. J. F. Siegert of Northwestern University for many valuable suggestions, and to G. A. Linenberger and the Van de Graaff group of Los Alamos for the neutron irradiations. Finally, we thank Mr. R. S. Dike of Los Alamos for work on the illustrations.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

An Automatically Synchronized Electronic Switch

W. A. Budlong* and Bruce C. Lutz
Physics Department, University of Delaware, Newark, Delaware

(Received October 10, 1949)

An electronic switch has been developed which eliminates the difficulties with frequency adjustments usually encountered in existing electronic switches. This is done by developing a switching square wave synchronized by either input signal. Therefore this switch is very much easier to use as the control settings are not critical.

THE purpose of an electronic switch is to view simultaneously two different signals of equal or multiple frequencies on the screen of an oscilloscope. This is accomplished by using a pair of amplifiers which are permitted to function alternately. The square wave causing the switching must have a frequency which is a sub-multiple or multiple of that of the examined wave. For switching after each cycle it should have a frequency of one-half that of the examined wave. Therefore to view phenomena of any frequency it is necessary to have a continuously variable switching frequency, which is usually supplied from a free-running multivibrator. There are now two frequency adjustments to be made simultaneously, the multivibrator and the oscilloscope sweep, which is usually tedious and difficult. The chief feature of the automatically synchronized electronic switch is a scale-of-two circuit, synchronized by either of the two input signals. This entirely eliminates one frequency control and provides a switching frequency one-half that of the examined wave. In addition a positive pulse is produced at the start of each cycle of the examined wave which is fed to the synchronization terminal of the oscilloscope making operation possible over a wide range of settings of the oscilloscope sweep frequency control.

Another feature is the use of transformers isolating the two input circuits and making possible the examination of any two portions of a circuit without the danger of shorting part of it. A block diagram of the switch is shown in Fig. 1 and a complete circuit diagram in Fig. 3.

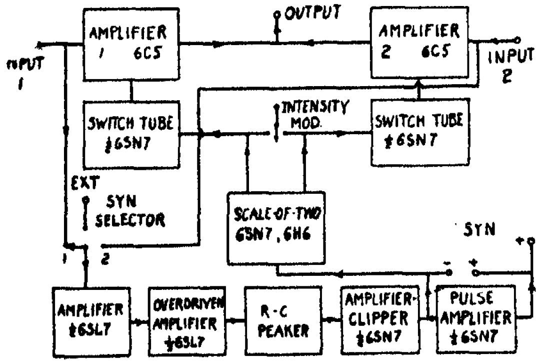

Fig. 1. Block diagram of automatically synchronized electronic switch.

AMPLIFIERS AND SWITCHING

The switching and amplifier circuits are based on those of Schultz and Anderson.[1] Symmetrical square waves 180° out of phase are put on the grids of the switch tubes thus causing them alternately to conduct and cut-off. This action through the common cathode resistors changes the bias on the two amplifier tubes making them function alternately as amplifiers. A potentiometer adjusts the balance of the bias and thus controls the vertical spacing of the two amplifier outputs on the screen. The output is taken over a common plate resistor and put on the vertical plates of the oscilloscope.

WAVE-SHAPING AND SCALER

The synchronization of the scale-of-two is provided from a wave-shaping circuit consisting of an amplifier, an overdriven amplifier, an R-C peaker, an amplifier-clipper, and a pulse amplifier-inverter.

The overdriven amplifier provides an essentially square wave output having the same frequency as that

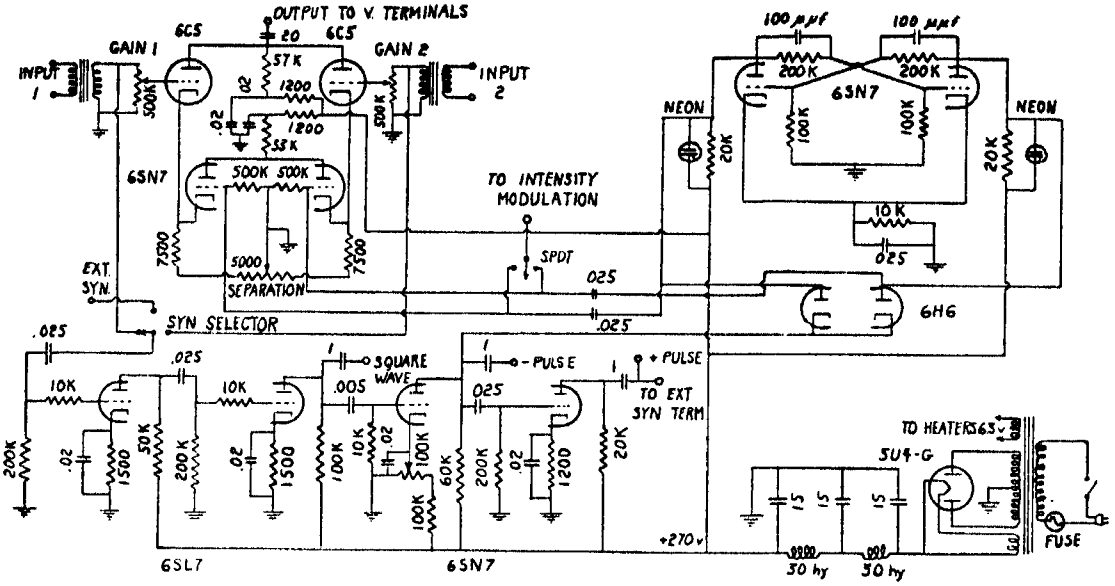

FIG. 3. Complete circuit diagram of the electronic switch. All resistance values are in ohms, all condenser values in microfarads. (K = 1000.)

of the observed signal which may be of almost any shape. This is transformed into a series of positive and negative pulses by the R-C peaker. The amplifier-clipper is biased to cut-off so that it is only sensitive to the positive pulses. The inversion action of the amplifier provides negative pulses superimposed on the plate potential. These operate a Higinbotham scale-of-two circuit,[2] which is simply a diode-triggered flip-flop.

The pulse amplifier-inverter provides positive pulses that are used to synchronize the oscilloscope sweep.

From the plates of the scale-of-two two symetrical square waves 180° out of phase are obtained and put onto the grids of the switch tubes. Thus a switch occurs at the beginning of each cycle of the examined wave. If desired the wave from either plate of the scale-of-two may be temporarily fed to the intensity modulation of the oscilloscope thereby blanking out either of the two waves as is often useful in demonstration work.

OPERATION

The electronic switch is shown at the right of Fig. 2. On the front left-to-right are input 1 terminals, gain 1 control, separation control, gain 2 control, input 2 terminals, synchronization selector switch, blanking control switch, neon lights, off-on switch. The neon lights indicate proper operation of the scaler circuit. On the left side are the outputs for the vertical input, external synchronization, and intensity modulation terminals of the oscilloscope. On the right side are outputs for square wave, negative, and positive pulses.

The switch operates satisfactorily from 25 to 15,000 cycles/sec. with any input over 1.5 volts. Although it operates most satisfactorily for viewing a single cycle, several cycles can be shown by appropriate adjustment of the sweep frequency and synchronization controls. This type of operation will cause small breaks in the pattern where the switch occurs, however this is kept to a minimum by the short switching time. Additional scalers could be used to avoid these breaks and to automatically show any even number of cycles.

This instrument is particularly well adapted for the demonstration and study of phase relations in alternating current circuits. In conjunction with a calibrated audio oscillator it provides a method of frequency measurement especially useful in those cases where the waveform is not readily adaptable to the Lissajou figure method, for example, pulses. Also it may be used as a square wave generator, or a pulse generator giving both positive and negative pulses.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

A Recording Microwave Refractometer*

George Birnbaum
National Bureau of Standards, Washington, D. C.

(Received October 12, 1949)

An instrument designed to measure and record a small difference in frequency between two cavity resonators is described. A sweep frequency technique is used to generate the resonance responses of the cavities. These responses are sharpened and made to control the operating time of a trigger circuit, whose average output is metered. A sensitivity equal to 200 c.p.s. is obtained in the measurement of the frequency difference between two high Q cavities, whose resonance frequencies are equal to 9000 Mc. Applications of this instrument are discussed, especially those relating to measuring changes in dielectric constant. A simple extension of the present instrument is suggested for simultaneously recording changes in dielectric constant and loss.

INTRODUCTION

IN the measurement of the dielectric constant of gases or changes in the dielectric constant of solids and liquids in the microwave region, the need arises for the accurate determination of small changes in the resonance frequency of a cavity resonator. An instrument, designed to measure and record such changes in frequency, is described in this paper. The use and adaptation of this instrument for measurements other than dielectric constant are also mentioned. In its present form, the recording microwave refractometer is especially suitable for investigating phenomena causing small changes in the dielectric constant of lossless gases and very low loss solids and liquids as a function of time.

Two basic methods present themselves for developing a recording microwave refractometer. One involves the use of a cavity as the frequency-controlling element of an oscillator; this is the well-known heterodyne-beat method.[1] The other approach is to employ a cavity as a circuit element to which either a cw or f-m signal is applied; this method is often employed for the determination of the dielectric constant of solids.[2] In this work, the second method was explored, and an instrument was developed which gives a sensitivity of 200 c.p.s. in the measurement of frequency difference between two high Q cavity resonators. In addition, the present instrument combines the following features: (1) relative simplicity of construction and adjustment; (2) flexibility with respect to operation over a wide band of frequencies in the microwave region; (3) availability of a wide range of sensitivities; and (4) ready adaptation to the simultaneous recording of changes in dielectric constant and loss.

DESCRIPTION OF CIRCUITS

Figures 1 and 2 illustrate the method by which a difference in the resonance frequencies of two cavities is measured by the microwave refractometer. A klystron oscillator is frequency-modulated by a saw-tooth voltage, applied to its reflector. The r-f power from the f-m oscillator is applied to two cavities, one functioning as a test cavity, the other as a frequency reference. When the outputs of the cavities, with slightly different resonance frequencies, are applied to the crystal detectors, resonance responses displaced in time are obtained. After amplification and sharpening, one of these pulses turns on a modified Eccles-Jordan trigger circuit, known in this application as a "flopover" circuit, and a short time later, the other pulse turns it off. The output of this circuit is a rectangular wave form with a constant amplitude, but variable width. The average value of this wave form is directly proportional to the frequency difference between the two cavities, provided that the "on-time" of the trigger circuit is directly proportional to frequency difference.

The circuit functions indicated in Fig. 1 may be developed in several different forms. Nevertheless, any satisfactory arrangement should provide for a linear relation between time and frequency. Not only is this desirable for metering purposes, but also for reasons of stability. The latter point is amplified in a separate section. Linearity between time and frequency is attained if the following holds: a linear modulation voltage is supplied by the sweep circuit; this is applied in the linear region of the klystron's electronic tuning characteristic; frequency pulling of the klystron due to high Q loading is avoided; and hum modulation of the klystron and the amplifiers is prevented.[3]

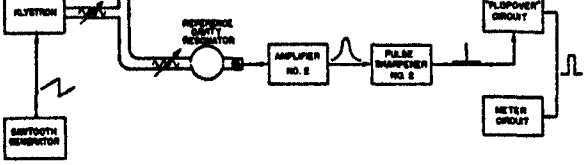

FIG. 1. Arrangement of components of the refractometer.

---

* A preliminary report of this work was presented at the Washington Meeting of the American Physical Society, Phys. Rev. 74, 1212(A) (1948).

[1] An example of this method for measuring the dielectric constant of gases at 3.2 cm has been given by C. M. Crain, Phys. Rev. 74, 691 (1948). Two stabilized oscillators [R. V. Pound, Rev. Sci. Inst. 17, 490 (1946)] were employed.

[2] See, for example, Works, Dakin, and Boggs, Trans. A.I.E.E. 63, 1092 (1944).

[3] *Since a recurrence frequency of 120 c.p.s. is employed, instability in the refractometer output due to hum is eliminated.*

The first of these conditions is realized by the circuit shown in Fig. 3. A cathode follower, with properly adjusted feedback, insures a constant charging current for the 0.01-μf capacitor; this arrangement therefore gives a linear sweep voltage. By firing the thyratron with a wave form obtained from the power supply, the repetition rate of this voltage is maintained at 120 c.p.s. The sensitivity of the refractometer is controlled by the amplitude of the sweep voltage. Although not included in the present equipment, it seems worth while to replace the variable potentiometer in the output cathode follower by a step potentiometer, in order to obtain a range of sensitivities which can be easily and accurately reproduced.

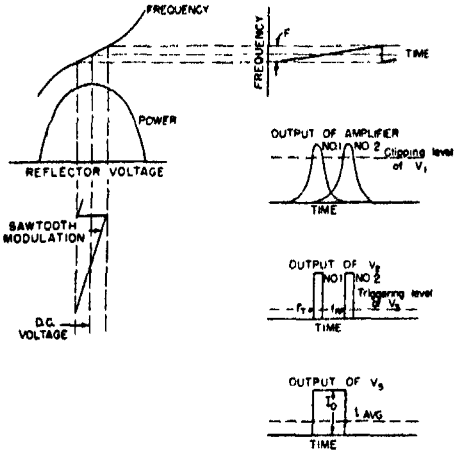

Fig. 2. Wave forms illustrating operation of equipment.

Among the factors contributing to hum modulation, attention was given, of course, to minimizing the amount of ripple in the klystron power supply. In addition, precaution was taken against cable pick-up. This was reduced by the use of a braided shield surrounding the cable to the klystron, with a ground connection at only one end. If this shield is to be effective, a high impedance should not be inserted in any lead at the power-supply end of the cable. Finally, hum modulation in the amplifiers was reduced by destroying the path for ground currents via the wave guide. This was accomplished by the use of insulated wave-guide joints between the klystron and the detectors.

In the wave-guide circuit, a "tee" junction divides the f-m signal between two similar circuits. Attenuators are included between the cavities and the klystron to prevent coupling between the cavities[4] and reaction back on the klystron. Some provision for controlling the matching of the klystron into the wave guide may be advantageous, since the klystron's electronic tuning rate and linearity depend upon its loading.[5] The present instrument, which operates in the 9000-Mc region, employs cylindrical cavities operating in the TE_{011} mode, whose Q-factors are approximately 10^4. The cavities are constructed of either Shelby steel or brass, and are plated with silver. Type 1N23A crystals, in tunable mounts, are employed as the detectors. A 6-db attenuator is included between each cavity and detector.

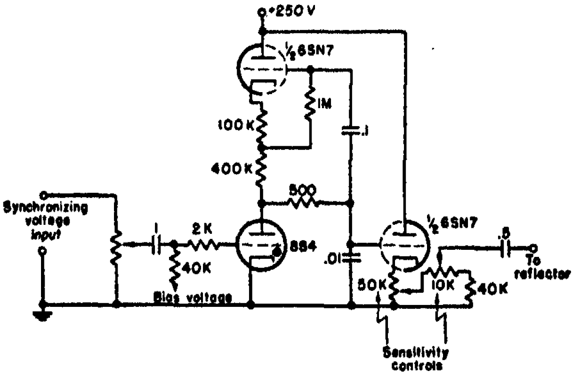

Fig. 3. Sweep circuit.

The broad, continuous form of the resonance pulse, as well as the fact that exact reproduction of this wave form is not essential, permits the use of amplifiers whose band-width requirements are not very critical. Conventional RC-coupled amplifiers with a gain of 10^4 and a pass band extending from 35 to 2000 c.p.s. were found to be adequate. After amplification, sharpening the resonance pulses is accomplished by the circuits shown in Fig. 4. The top of the resonance pulse is clipped at approximately 90 percent of its peak amplitude and amplified by V_1. For a given input into this stage, the clipping level is adjusted by varying the screen voltage. The grid leak arrangement of V_1 and the low screen grid voltage operate to maintain a constant plate circuit output over a limited range of input pulse amplitude. Further amplification of the peak of the resonance pulse is accomplished by V_2. When the output of V_2 triggers the blocking oscillator, V_3, a very sharp negative wave form is produced, which is suitable for firing the "flop-over" circuit, V_5. The diode, V_4, is used to decouple V_5 from the positive overshoot of V_3. The triggering level of V_3 is controlled by the cathode bias. The rectangular voltage output from the "flop-over" circuit is applied to V_7, a differential amplifier, which drives either an ammeter or a recorder. The grid of this circuit is clamped to ground by the d.c. restorer, V_6. In the present instrument it was found useful to provide the ammeter with the following ranges: 50 μa, 1 ma, and 10 ma. When the duration of the rectangular pulse is approximately one-tenth the duration of one sweep, the meter circuit supplies a current of 1 ma. For reasons which are given in the section on stability, pulse durations greater than this were not used. One ma is sufficient to operate directly an Esterline-Angus Recorder. A 20-μf condenser was placed in parallel with the ammeter or recorder to

---

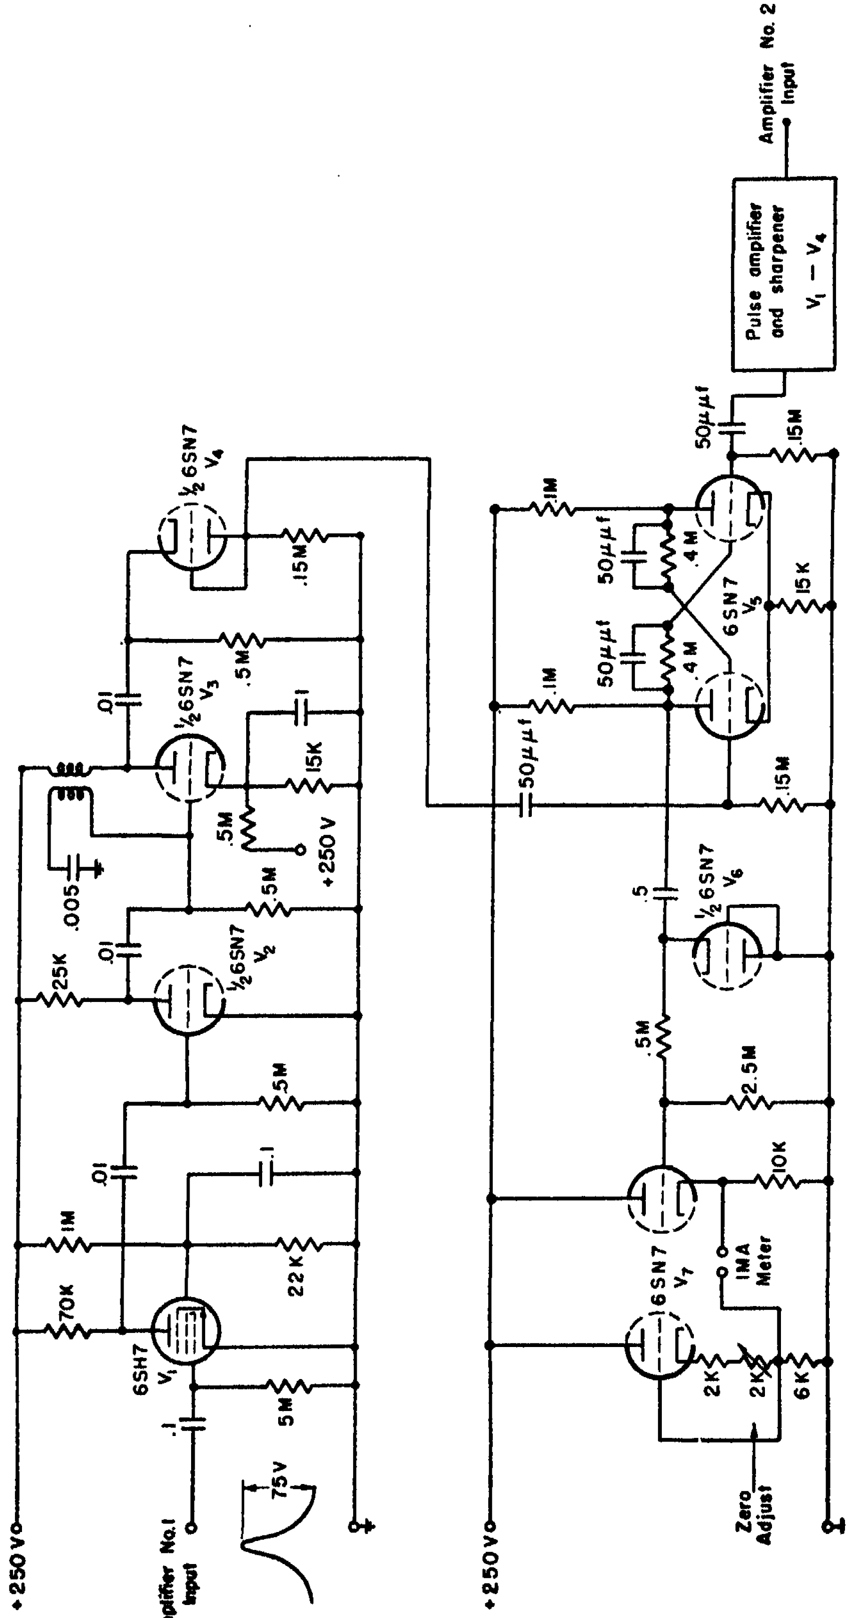

FIG. 4. Sharpening, "flop-over," and meter circuits.
]

shunt the a.c. components in the rectangular wave form. When using the recorder without this condenser, it was observed that the shape of the rectangular wave form across the 10 K resistor of V_7 was distorted; the addition of the condenser remedied this condition. The averaging of the rectangular wave form is performed by the ammeters.

Two electronically regulated power supplies are employed; one furnishes voltages for the Type 723A/B klystron[6] and the other for the electronic circuits. By making suitable changes in the microwave components, with the klystrons now available, the refractometer can be operated over a wide range of frequencies in the microwave region. The operation of the present instrument was checked at 3000 Mc by using a Type 707B klystron and a microwave circuit of the coaxial type, which included cavity resonators operating in the TM_{010} mode.

INITIAL ADJUSTMENT

Initial adjustment of the refractometer was accomplished with an oscilloscope for viewing the wave forms shown in Fig. 2. After a warming period, the cavity resonance pulses were made to appear on top of the klystron mode curve, by mechanically tuning the klystron. This adjustment insured that the modulation voltage was applied to the linear region of the electronic tuning characteristic. To observe this pattern, a directional coupler was inserted between the klystron and the "tee" junction, and the attenuation in front of the cavities was reduced. The d.c. reflector voltage was set for the klystron mode which gave the greatest power output and simultaneously the lowest electronic tuning rate (in Mc/v). Hence, a given amount of hum and instability in the reflector voltage had the smallest effect on the linearity (and ultimately the stability) of the refractometer. Next, the gain of the amplifiers, and the bias of the blocking oscillators, if necessary, were adjusted to trigger properly the blocking oscillators. Then the frequency of the reference cavity was varied with attention fixed on the output wave form of that blocking oscillator which was triggered by the resonance pulse of the test cavity. If the position of the pulse remained fixed, there was sufficient padding between the cavities and the klystron to prevent coupling among these components. The amount of attenuation necessary for operation in the manner just described was approximately 12 db preceding each cavity. For the purpose of checking the time-frequency relation, the position of the rectangular wave form on the oscilloscope trace was varied by adjusting the d.c. klystron reflector voltage. In this test, a constant current on the output meter of the refractometer indicates linearity. For this particular instrument, a constant current was obtained for a variation in the position of the rectangular wave form equal to one-fifth the distance occupied by one sweep. The width of the rectangular wave form was one-twentieth the distance occupied by one sweep. A very high sensitivity (5 ma/Mc) was employed with the idea of emphasizing any effect due to hum modulation.

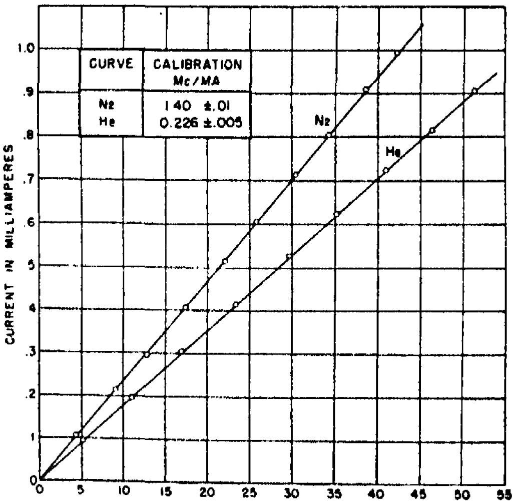

FIG. 5. Typical calibration curves. The calibration error was calculated from the uncertainty attached to the slope of the line, and the quantities in Eq. (1).

The sensitivity was adjusted by varying the amplitude of the sweep voltage applied to the klystron and/or varying the sensitivity of the ammeter. Small sweep amplitude corresponds to large expansion of the frequency scale and hence to high sensitivity in ma/Mc. In connection with adjusting the sensitivity of the instrument, it should be noted that the largest useful frequency change is governed by the extent of the linear region of the klystron's electronic tuning characteristic, while the greatest usable sensitivity depends upon the stability of the refractometer. Procedures for ascertaining the sensitivity are given in the following section.

CALIBRATION PROCEDURE

It is well known that $(\epsilon-1)/(\epsilon+2)$ is accurately proportional to density for non-polar gases. In the present application, the susceptibility $\epsilon-1$ is always less than 10^{-3}; consequently, with negligible error, $\epsilon-1$ is taken proportional to density.[7] Then assuming the ideal gas law,[8] it follows that

$$\epsilon-1=(\epsilon_0-1)(P/760)(273.2/T), \qquad (1)$$

where ϵ_0 is the dielectric constant for $P_0=760$ mm Hg and $T_0=273.2°K$. For a gas filling the entire cavity, the fractional change in resonance frequency, $\Delta f/f$, is given by[9]

---

[6] The klystron power supply is a slightly modified Browning Laboratories, Inc., Type TVN-7 BL. See reference 5, p. 205. A coarse and fine control for the reflector voltage was found to be useful. A d.c. voltage was used for the klystron filament.

[7] Of course, the frequency should be sufficiently far from any resonance absorption by the gas. This is certainly the case for non-polar gases in the microwave region. Unpublished experimental results by Birnbaum, Kryder, and Lyons, on N_2 at 9000 Mc verify that $\epsilon-1$ is directly proportional to density.

[8] If N_2, for example, were an ideal gas, its measured pressure at one atm would be too small by less than 0.1 percent.

$$\epsilon-1=2\Delta f/f. \tag{2}$$

Therefore, a measurement of the output current of the refractometer as a function of gas pressure for a gas whose ϵ_0 is known gives the calibration as well as the over-all linearity. Values of $(\epsilon_0-1)10^4$ equal to 5.87 ± 0.02 for N_2, and 0.710 ± 0.009 for He were taken from previous work at 9100 Mc.[10] Figure 5 shows the results of a typical calibration. The r.m.s. deviations of the measured values from the straight lines which best fit the data for N_2 and He are 0.002 ma and 0.004 ma, respectively. The curve for N_2 demonstrates a linearity over a range of 1.4 Mc, but this does not represent the maximum value, which is determined by the linearity of the klystron's electronic tuning characteristic. Each determination, conducted at room temperature, was completed in approximately 18 min. It is estimated that during these intervals, the temperature difference between the test and reference cavities varied by no more than 0.01°C. By using N_2 and He for the 1.40 Mc/ma and 0.226 Mc/ma calibrations, respectively, the changes in gas pressure were large enough to be read with sufficient accuracy on an ordinary mercury manometer. However, care was exercised to insure against distortion of the test cavity due to a difference in pressure between the atmosphere and the gas in the cavity. Such distortion was avoided by enclosing the test cavity in a metal chamber equipped with gas and wave-guide outlets, as shown in Fig. 6.

Since the accuracy of the calibration depends on the accuracy of the value of ϵ_0, it is desirable to use the rare gases whose dielectric constants have been measured at optical frequencies, where the precision is one or two orders of magnitude better than what is obtained by present radio frequency and microwave techniques. Careful work by Jelatis[11] shows impressive agreement between the dielectric constant of the rare gases as extrapolated from optical frequencies by the Sellemeier dispersion formula, $\epsilon-1=c/(f_0^2-f^2)$, and his own measurements at 1 Mc. Therefore, the rare gases may be used confidently as accurate calibration standards throughout the microwave region.

Greater convenience in the calibration procedure was obtained by using the refractometer as a null-indication instrument, where one cavity contained the gas and the other was equipped with a low tuning-rate plunger whose displacement was measured as a function of gas pressure. Once this measurement was done, the refractometer calibration was readily checked by noting the ammeter reading for a known displacement of the tuning plunger. This procedure may be used as an accurate check on cavity perturbation theory[9, 12] to aid in the design of such tuning plungers. A low tuning rate was obtained by displacing a small part of the cavity wall. Some of the TE_{011} reference cavities in the present equipment are tuned by a concentric cylindrical post, consisting of a micrometer tuning head ground to a small diameter, and protruding slightly into the cavity.

STABILITY CONSIDERATIONS

In discussing the problem of refractometer stability, in terms of output current or frequency difference, it is convenient to distinguish between a long-time stability which refers to the slow drifts occurring during one hour or more, and a short-time stability which refers to the rapid fluctuations occurring in less than a second. The long-time stability of the refractometer depends chiefly upon the variation of the center frequency of the klystron with temperature, the variation of the temperature difference between the two cavities, and the variation of the dielectric composition of the reference cavity. If the relation between frequency difference and the "on-time" of the "flop-over" circuit is linear, changes in the center frequency of the klystron merely shift the position in time when the resonance curves are traced out, without changing the frequency difference indication between them. However, the cavity responses cannot be permitted to wander over the entire length of the sweep, since this time-frequency relation is not everywhere linear. Also, for sensitive operation of the instrument, say at 5 ma/Mc, the entire sweep represents 3 Mc, a range insufficient to trace out completely the tails of the resonance pulse, even for a cavity with a O equal to 10^4. As the resonance pulses drift from the center of the trace, the amplitude (and eventually the shape) of the wave form nearest the end of the trace begins to change. Since the time of firing of the "flop-over" circuit depends upon the shape, and to a smaller extent upon the amplitude of the resonance

pulse, an error in output current is obtained. Nevertheless, this effect does not seriously limit the stability of the refractometer. Experience has shown that even for sensitive operation at 5 ma/Mc, the allowable drift in the unmodulated frequency of the klystron is as much as ±0.2 Mc. Long-time constancy in klystron frequency was improved by shielding the klystron from changes in ambient temperature. From the foregoing discussion, it is evident that the maximum separation in time (or frequency) between the resonance pulses should be limited to a small fraction of the duration of one sweep. In the present case this fraction was taken equal to one-tenth. Small and rapid changes in the unmodulated frequency of the klystron are caused by fluctuations in the voltages applied to it. In view of the foregoing discussion, this should cause no instability in refractometer output.

When a homogeneous cavity undergoes thermal expansion, the fractional change in frequency with temperature is given by $\Delta f/f = -\alpha$ per degree C, where α is the linear coefficient of expansion for the material.[13] For a temperature change between two steel cavities, which is equal to 10^{-2} °C, Δf is approximately 10^{-3} Mc for $f = 9\times 10^3$ Mc, if α is taken to be 10^{-5}, an average value for steel. Improvement in temperature stability may be obtained by constructing the cavities from invar, for which $\alpha \simeq 2\times 10^{-6}$ per °C, or by temperature compensating the cavities. However, a dual cavity unit, which is a single block of metal, hollowed out for two cavities, proved to be adequate in the stability tests. Such a unit, fabricated from brass, and silverplated, is shown in Fig. 7. A factor affecting the frequency stability of the reference cavity is the change in composition of dielectric in the cavity due to the changes in temperature, pressure, and especially moisture content of the atmosphere.[14] Therefore, the cavity should be isolated from the atmosphere by vacuum seals, and either evacuated or filled with a non-polar gas. Precaution against distorting the cavity due to changes in gas pressure may then be necessary.

FIG. 7. Dual TE_{011} cavity unit. The Q-values are 11,000. The upper cavity is tuned by the micrometer.

The relation between the short-time stability and the factors upon which it depends may be formulated as follows. Subject to the requirements that the detector operates as a square-law device, that the amplifiers pass undistorted the signals applied to them, that the transmission cavity has a high Q, and that the frequency modulation is linear, the shape of the cavity resonance curve is given by[15]

$$V/V_0 = [1 + 4Q^2(f_0 - f)^2/f_0^2]^{-1}, \tag{3}$$

where V and V_0 are the output voltages of the amplifier at frequency f and at the resonance frequency f_0, respectively. For $V/V_0 = \frac{1}{2}$, Eq. (3) gives

$$Q = f_0/\Delta f, \tag{4}$$

where Δf is the band width of the cavity between half-power points. Suppose that some r.m.s. noise voltage, e, is added to the resonance pulse. If V_1 is considered to be some fixed operating level for the trigger circuit (see Fig. 2), the resonance pulse plus the noise will operate this circuit at some new value of f, say f'. Then the fluctuations in firing, in units of frequency, $\delta f = f' - f$, due to some r.m.s. value of noise voltage is found to be

$$\delta f = (\alpha f_0/4Q)(e/V_1). \tag{5}$$

The factor $\alpha = [(V_1/V_0)(1 - V_1/V_0)]^{-\frac{1}{2}}$ shows essentially the dependence of the stability on the slope of the resonance curve at the firing point. Provided that operation does not occur too near the peak, the value of this factor varies slowly. It is readily shown that α/V_1 is minimum for $V_1 = (3/4)V_0$. Since each resonance curve operates the trigger circuit, the total frequency fluctuation, as manifested by jitter in both sides of the rectangular pulse is $(2)^{\frac{1}{2}}\delta f$.

The ratio e/V_1 represents the effective output noise-to-signal voltage ratio of the crystal detector and amplifier, and is expressed as[16]

$$e/V_1 = (4kTB)^{\frac{1}{2}}/MP. \tag{6}$$

In this equation, k is Boltzmann's constant, T is the absolute temperature, B is the effective noise band width of the amplifier, P is that r-f power absorbed by the crystal which corresponds to voltage V_1, and M is the figure of merit for the crystal. The substitution of

Eqs. (4) and (6) in Eq. (5) gives

$$\delta f=[\alpha\Delta f/4][(4kTB)^{\frac{1}{2}}/MP], \tag{7}$$

which shows the dependence of the frequency instability δf caused by noise on the resonance pulse as a function of the parameters of the instrument. If the band width, for a given value of Δf and frequency swept out per unit time, is reduced to the point where some minimum requirement for satisfactory reproduction of the resonance pulse is reached, then δf, calculated from Eq. (7) represents a minimum value. Assuming a recording system with a sufficiently small time constant, the value of the frequency swept out per unit time determines the fastest rate of change of frequency that the refractometer can resolve.

If P is increased beyond the microwatt range, or if d.c. bias is applied to a silicon crystal rectifier, M is no longer a constant. The rectified voltage of the crystal, for a given incident power, now has noise components whose fluctuations are proportional to $(f)^{-\frac{1}{2}}$, where f is in the audio frequency range.[17] A similar kind of fluctuation in grid to cathode voltage in the amplifier circuit occurs due to cathode emission changes.[18] Little benefit in suppressing noise is obtained in this case by the usual method of decreasing the sweep frequency so that the amplifier band width can be narrowed. The low frequency cut-off of the amplifier must be accordingly lowered, consequently, bringing in high amplitude noise due to the $(f)^{-\frac{1}{2}}$ law. Where the greatest sensitivity, and hence stability, is required, an alternative procedure consists in integrating the effect of as many sweeps as may be necessary. This was accomplished by adding a resistance-capacitance integrator to the grid circuit of V_7 (Fig. 4). Such an arrangement operated satisfactorily with the present meter circuit, which in this case supplied direct current to the ammeter. Of course, the time constant of the additional RC circuit now controlled the rapidity with which the refractometer was able to follow changes in frequency.

From the wave forms of Fig. 2, it can be seen that the average meter current is given by

$$i_M=(f_T-f_R)(I_0/F), \tag{8}$$

where I_0/F in ma/Mc is the sensitivity, and (f_T-f_R) is the frequency difference between the test and reference cavities. The effect of small variations in (f_T-f_R), F, and I_0 on i_M can be determined by examining the total differential of i_M, which is obtained from Eq. (8). It is then evident that di_M/i_M depends only on the instability in (f_T-f_R) for small values of (f_T-f_R), and when (f_T-f_R) becomes large enough di_M/i_M depends also on the instability in I_0 and F. The instability in (f_T-f_R), see Eq. (7), was discussed in the preceding paragraphs. The fluctuations in I_0 depend upon variations in the plate voltage applied to V_6 and V_7. The value of F, the frequency swept out in one period, is inversely proportional to the sweep rate, which in the present arrangement is controlled by the power line frequency. Where this frequency is not sufficiently stable, or when it is necessary to control the sweep rate, it is profitable to incorporate in the equipment a stable but variable frequency sweep generator.

While no special effort has been made to achieve ultimate stability in the present instrument, the results of some tests are indicative of what may be attained. In the calibration performed with He (Fig. 5) and in other tests, the short-time stability was 0.001 ma, or approximately 200 c.p.s. It is interesting to note that Eq. (7) gives $(2)^{\frac{1}{2}}\delta f\simeq 60$ c.p.s.[19] by taking $M=20$,[20] and using the following equipment parameters: $\Delta f=10^6$ c.p.s., $T=290$°K, $B=2000$ c.p.s., $\alpha=3$, and $P=5\times 10^{-6}$ w. The long-time stability was checked by using the dual cavity unit with each cavity sealed and evacuated. The klystron was shielded from changes in room temperature. With this arrangement, a recording of the refractometer output current revealed that the maximum current fluctuation over a period of 90 min. amounted to 0.004 Mc, and during several 15-min. intervals, the fluctuations were less than 0.001 Mc.

METHODS FOR MEASURING DIELECTRIC CONSTANT

Some methods for employing the refractometer in measuring the dielectric constant of gases were given in the section on "Calibration." In addition to the techniques discussed there, it is advantageous, in some investigations, to employ a flow technique. To effect this modification the end plates of the TE_{011} cylindrical cavity were perforated (the location and size of the holes were chosen for negligible effect on the Q of the cavity) so that a continuous stream of gas could be drawn through the cavity. In this form, the instrument was used in some preliminary experiments to record the variation in the dielectric constant of an artificially controlled atmosphere. The agreement was reasonably good between the measured changes in dielectric constant and the changes calculated from the temperature, pressure, and humidity of the atmosphere.[14] Further, the instrument in this form might be applied, for example, to measure the variations of the dielectric constant of the atmosphere as a function of time.[21]

In working with solids and liquids, great sensitivity to small changes in dielectric constant can be obtained by filling the entire cavity with the material. However, except for dielectrics possessing very small power factors, for example, 2×10^{-4} or less, the procedure would seriously decrease the Q of the cavity. But, the Q is hardly influenced by filling a small fraction of the cavity volume with a low loss dielectric while sufficient sensitivity to changes in dielectric constant is maintained. In this case, the fractional change in frequency is given by[9, 12]

[21] Such measurements are of interest in studies relating to radio propagation and meteorology. See, for example, "Meteorological factors in radio-wave propagation," Phys. Soc. London (1947); W. E. Gordon, Proc. I.R.E. 37, 41 (1949).

$$\Delta f/f = G(\epsilon - 1), \tag{9}$$

where G is a constant depending on the geometry of the sample and the electric field distribution in the cavity. If a cylindrical sample with a small diameter is inserted parallel to the electric field at the position of maximum intensity, in a rectangular cavity operating in its fundamental mode, $G = 2v/V$, where v and V are the volumes of the dielectric and cavity, respectively.[22] The dielectric constant of liquids can be measured by such a small-sample technique by containing the liquid in a thin-walled quartz tube. This and similar small-sample arrangements are recommended as being particularly suited to the refractometer. The advantages of such an arrangement are linearity in $\epsilon - 1$ of the refractometer output, and a rapid method for changing the sample.

The minimum detectable change in $\epsilon - 1$ for gases and for solids and liquids is calculated from Eqs. (2) and (9) by letting $f = 9\times10^3$ Mc, δf = short-time stability $= 2\times10^{-4}$ Mc, and $v/V = 10^{-4}$. The results are 4×10^{-8} for gases, and 1×10^{-4} for solids and liquids.

Because of the recording feature of the refractometer, as well as the convenience of reading frequency difference on a calibrated ammeter, the emphasis in this discussion has been, thus far, on the measurement of frequency changes which are no greater than the linear portion of the klystron's electronic tuning characteristic. Nevertheless, larger changes in the resonance frequency of the test cavity were measured by using the refractometer as a null-indication instrument, where the change in frequency was read from the calibrated tuning control of the reference cavity. Employing the refractometer in this manner, where the frequency change is substituted in Eq. (9), would make it convenient to measure the dielectric constant of low loss solids and liquids.

METHOD FOR MEASURING CHANGES IN Q

So far, the effect of changes in cavity-Q on the operation of the refractometer has been neglected; such changes are caused, for example, by dielectric loss. If the Q decreases, the amplitude of the resonance pulse decreases, and the width increases. Evidently, this can result in an error in the measurement of frequency difference, although the error can be decreased by triggering the blocking oscillator near the peak of the resonance pulse. This is the expedient which is used in the present instrument. A simple modification however, should enable one to reduce this error to a negligible value. Suppose that the amplified peak of the resonance pulse of the test cavity is differentiated to yield two very sharp pulses. Next, two rectangular wave forms can be generated, the width of each representing the time interval between the reference cavity pulse and each of the pulses resulting from the differentiation. Then the average value of the sum of these rectangular wave forms measures the frequency difference between the reference and test cavities, independent of changes in Q of the test cavity.[23]

Examination of Eq. (3) shows that the points of inflection are identical with the ¾-power points of the resonance curve. If the resonance pulse of the test cavity is differentiated, two pulses are obtained whose frequency separation, Δf, equals $1/\sqrt{3}$ times the band width of the cavity. Use of these pulses to generate a rectangular wave form which is then averaged gives a measure of $1/Q$. These pulses, in conjunction with the one obtained from the reference cavity, could be also used in the manner described in the previous paragraph to measure frequency difference. Therefore, both the frequency difference and $1/Q$ could be simultaneously measured and recorded by a slight extension of the present techniques. Since $1/Q$ is measurable, the loss tangent, $\tan\delta$, for dielectrics can be calculated from the equation

$$\tan\delta = (G/\epsilon)(1/Q_2 - 1/Q_1),$$

which holds for gases filling the entire volume of the cavity ($G = 1$), or for solids or liquids occupying a small fraction of the cavity volume ($G = \frac{1}{4}V/v$), for the arrangement of sample and cavity given in connection with Eq. (9).

Other applications, mentioned by *Pound*[1] for his heterodyne-beat method, can also be made with the refractometer. These are the use of the refractometer as an ultra-micrometer, or for the measurement of the thermal expansion of cavity materials. Both applications are possible because of the great sensitivity of the resonance frequency to cavity dimensions.

ACKNOWLEDGMENTS

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

Integrator for Small Beam Currents

T. A. Hall, S. D. Warshaw, and J. Dorsey
Institute for Nuclear Studies, University of Chicago, Chicago, Illinois

(Received October 17, 1949)

A simple circuit is described which integrates approximately beam currents of 10^{-14} amp. or larger. It consists of a d.c. amplifier, which converts the current into a voltage signal, and a voltage integrator circuit. Integration is approximate primarily because of slow circuit response to fluctuations; under usual conditions of high voltage accelerator work, one can expect integration accuracy of about one to five percent.

THE usual method of integrating a beam current—repeatedly charging a condenser connected to the beam target to some critical discharge voltage—is quite accurate for currents of 10^{-10} amp. or more, but for smaller currents this method demands impractically low capacitances. We describe here an integrator consisting of a simple d.c. amplifier, which converts the beam current into a change of voltage on the plate of an electrometer tube, and a standard circuit[1] which integrates this change in plate voltage. For most applications the range and accuracy of this integrator are determined by the d.c. amplifier's sensitivity, drift, and linearity. One can couple any appropriate d.c. amplifier to the circuit of the integrator proper. Essentially, any current that can be measured by the d.c. amplifier can be integrated.

The d.c. amplifier tube we have used is the Victoreen VX41-A, which is small and has a grid resistance of 10^{15} ohms. This tube plus a set of high resistances and a selector switch are housed in a steel can close to the beam target. A long shielded cable running between can and integrator circuit carries tube power and the d.c. signal. The circuit is arranged so that the target may be easily held near ground, −150 or −300 volts, in order to reduce secondary electron effects at the target if that is desired.

The VX41 plate connects to the grid of the integrator tube (5691, the more stable version of the 6SL7) through a battery and a potentiometer used to adjust the 5691 no-beam grid voltage. The operation of the regenerative, condenser-feedback integrator circuit is described in reference 1; its main advantage is that the amplifier must be linear over a plate swing of only a few volts, instead of the swing of about 50 volts required with the simplest integrator circuits, and that there is almost no voltage swing at the input grid. The output of the 5691 is the integral of the input signal; as it reaches a certain level the relay in the next stage closes, snapping the input grid back to the voltage of buss line C (Fig. 1) and restarting the cycle. Simultaneously, the normally closed contacts of the relay are used to pulse a register circuit (6SA7, 6V6).

The maximum counting rate could be raised, if desired, by pulsing into a scaler and by using a thyratron or Schmitt circuit instead of the General Electric mechanical relay (G.E. reference number K27J853).

A conventional vacuum tube voltmeter is installed to measure the plate voltage change of the VX41, which is proportional to the beam current. The ammeter itself may be switched from terminals 1 and 2 to a and b to measure the grid bias of the relay tube (6SN7).

In operation one makes three preliminary adjustments: First, with the count switch closed (5691 input grounded) and with the ammeter reading the bias of the relay tube, the regeneration potentiometer r_3 is adjusted so that the relay current is almost critical (6SN7 grid bias about −12 volts). Secondly, with count switch open and no beam, the 22½-volt battery potentiometer (r_1+r_2) is adjusted so that the relay current is again almost critical; the exact optimum for this setting is discussed below. Finally, the VTVM is set to zero with potentiometer r_4 if it is desired to read beam current during operation. The integrator is then ready to work. If absolute integration is desired, a 1½-volt cell is installed, attached to the selector switch in the d.c. amplifier can, so that the counting rate produced by a 1½-volt signal on the VX41 grid can be observed.

In the design of the integrator circuit, several factors limit the allowable sizes of the circuit elements. The counting rate is approximately

$$F = \frac{e_s}{e_f RC(1+A)}, \tag{1}$$

where A is the gain of the two-stage 5691 amplifier, e_s is the change in VX41 plate voltage due to the beam, and e_f is the voltage swing of the 5691 input grid during each cycle; $R \equiv r + r_1 r_2/(r_1+r_2)$ (see Fig. 1). Equation (1) is quite accurate if $e_s \gg e_f$. In order to satisfy this condition without excessive counting rates, A, R, and C should be large. This is not unconditionally possible. First, if C is too large, the voltage at the 5691 output will not be free to recycle quickly as the relay closes. Secondly, A is largest when the 5691 input grid has approximately zero grid bias, but in this bias region, grid current changes rapidly with voltage, acting as a false signal, especially if R is large. It is better to run the tube with slightly negative bias and reduced gain; then the grid current stays almost constant and produces no error. Thus for the circuit in Fig. 1 there is not much latitude in the choice of r, C, and amount of regenerative gain (r_3).

It is worth while to study the integrator in some detail, in order to obtain a condition for optimum inte-

---

[1] MIT Radiation Laboratory Series, Vol. 21, pp. 79–82.

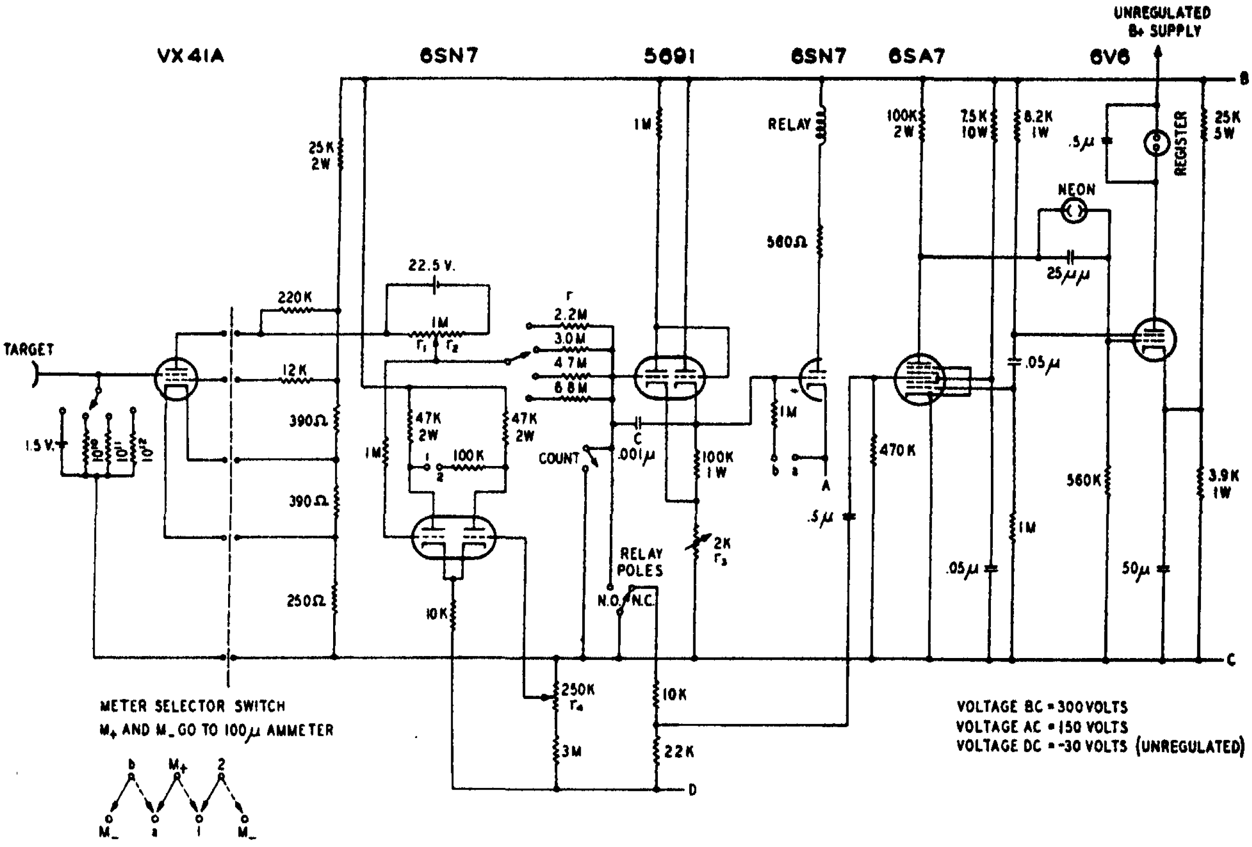

FIG. 1.

gration that applies to almost all voltage integrator circuits. Let e_g be the voltage at the 5691 input grid, and e_0 the value of that voltage when there is no beam; "ground" is defined presently as the value of e_g at the start of each counting cycle. During each cycle e_g obeys the equation

$$e_g=(e_s+e_0)(1-e^{-t/\tau}),\quad \tau\equiv RC(1+A) \tag{2}$$

in the case where e_s is constant. Then the time per cycle T is

$$T=-\tau\ln\left(1-\frac{e_f}{e_s+e_0}\right). \tag{3}$$

A power series expansion yields

$$T\approx\tau\left[\frac{e_f}{e_s}+\frac{1}{e_s^2}(-e_fe_0+\tfrac{1}{2}e_f^2)+\frac{1}{e_s^3}(e_fe_0^2-e_f^2e_0+\tfrac{1}{3}e_f^3)\right]. \tag{4}$$

It follows that the counting rate is most accurately proportional to e_s when $e_f=2e_0$. In other words, at the end of each counting cycle the grid should be returned *not* to its no-beam voltage but to a voltage twice as far from the firing point. This eliminates the quadratic term in Eq. (4) and, for a given counting rate (fixed e_f and varied e_0), reduces the cubic term by a factor of four. The condition $e_f=2e_0$ can be accurately satisfied in making the two preliminary relay tube adjustments described above since the values e_f and e_0 are accurately reflected in the bias of that tube. Its fulfillment considerably extends the range of accurate integration.

Aside from imperfect integration of a constant signal, as displayed in Eq. (4), there are these other inherent errors: Non-linear gain of the VX41, voltage drift in the d.c. amplifier circuit, slow response of the VX41 plate to a change in beam and imperfect integrator response to a non-constant signal e_s. The last two factors arise from the fact that neither d.c. amplifier nor integrator circuit can respond properly to fluctuations shorter than their own time constants. While all these factors prevent precision integration of the sort enjoyed with larger currents, the instrument is still a valuable beam monitor for most uses where great accuracy is not needed. If it is used to monitor a beam in high energy accelerator work, the integrator will function quite accurately, except for those isolated instants when the beam suddenly fluctuates; this means in practice an integration accuracy of about one to five percent in such work.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 2 FEBRUARY, 1950

An Electronic Circuit Which Extracts Antilogarithms Directly

F. CURTIS SNOWDEN AND HAROLD T. PAGE
General Aniline and Film Corporation, Central Research Laboratory, Easton, Pennsylvania

(Received October 27, 1949)

It has long been established that variable-μ tubes of types such as the 6SK7 were capable of outputs which were proportional to the logarithm of the input over a specified range of bias voltages. The use of inverted triodes, and related circuits, is also widely known. It was decided to combine these two older techniques in the hope of developing a new one. Accordingly, a 6SK7 was hooked up as an inverted triode, i.e., the plate was used as the controlling element, and the control grid was employed as the output element; the results obtained with this arrangement were then plotted and investigated. As reported herein, a circuit capable of extracting antilogarithms over a fairly extended range of input voltages was developed.

THE application of vacuum tubes in the direct extraction of the logarithms of the applied grid voltages has been recognized for some time.[1,2] Circuits developed for this purpose employ vacuum tubes of a variable-μ type, such as a 6D6, 6SG7 or 6SK7. The $i_p - e_g$ characteristic of such tubes is logarithmic over a certain range of grid potentials; that is, within the specified range of grid voltages, the plate current is proportional to the logarithms of the input grid voltages:

$$\log e_g = k i_p. \tag{1}$$

This property of these tube types has rendered them useful in applications such as photoelectric densitometer and colorimeter circuits,[2] where the desired output is to be proportional to the logarithm of the input.

Figure 1 shows a circuit which may be set up to confirm this property of the variable-μ tubes. Measurements were made on both the 6SG7 and the 6SK7 types. The critical range of grid voltages mentioned above differed, of course, for the two types, and the useful range also varied with different values for the cathode resistor, R_2.

Points on the $i_p - e_g$ curve for the tube may now be taken with this circuit. Note that the circuit of Fig. 1 provides for the initial bucking out of the plate current at the starting grid potential. This is done so that a more sensitive meter may be used in the plate circuit, and correspondingly greater accuracy achieved. Battery B_3 provides the bucking potential, and the necessary adjustments are made with the potentiometer R_3. Figures 2 and 3 represent families of $i_p - e_g$ curves for a 6SG7 and a 6SK7 respectively, with the various cathode resistors as indicated. The older 6D6 is not considered here, since its adaptability to circuits of this nature has been discussed elsewhere.[2] Each of the individual curves of Figs. 2 and 3 is the resultant average of five nonconsecutive check runs made under the conditions indicated. Similar families of curves were made on several tubes of each type. The range of grid potentials over which the $i_p - e_g$ characteristic was logarithmic varied somewhat from tube to tube. However, it was observed that *in all cases*, the 6SK7 characteristic was logarithmic between grid potentials of -10 to -20 when a cathode resistance of 10,000 ohms was used; the 6SG7 characteristic was similarly logarithmic between grid potentials of -4 to -10.

The curves of Figs. 2 and 3 also clearly demonstrate that the greater the cathode resistance, the greater the useful logarithmic range of the $i_p - e_g$ characteristic. However, the use of too large a cathode resistance causes the changes in plate current to be too small for useful purposes without additional amplification, which should be avoided whenever possible. Consequently cathode resistors of 10,000 to 12,500 ohms are generally chosen for optimum results in most applications.

The background of an old and tried application of vacuum tubes has now been presented briefly, along with some new data for more recently developed variable-μ tube types which can be used in conjunction with this application. Since these tubes have proven extremely valuable wherever the extraction of logarithms is desired, it can be easily imagined that an equally helpful circuit would be one which performed the reverse function, namely the extraction of antilogarithms. Inasmuch as the $i_p - e_g$ characteristic of the variable-μ tubes had been proven to be logarithmic over a specified range of input potentials, there was no valid reason to suspect that this same characteristic would not be antilogarithmic if these tubes were used in an inverted fashion.

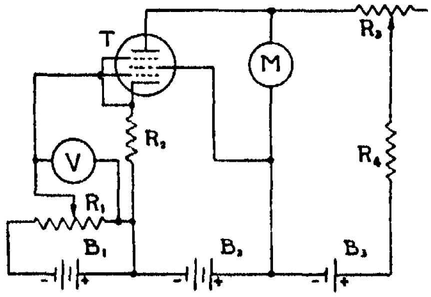

FIG. 1. A circuit which extracts logarithms directly.

B_1, 22½ volts
B_2, 90 volts
B_3, 1½ volts
M, 0–1 milliammeter
R_1, 50,000 ohms
R_2, 2500–15000 ohms
R_3, 50,000 ohm potentiometer
R_4, 1000 ohms
T, 6SG7 or 6SK7
V, 0–30 voltmeter.

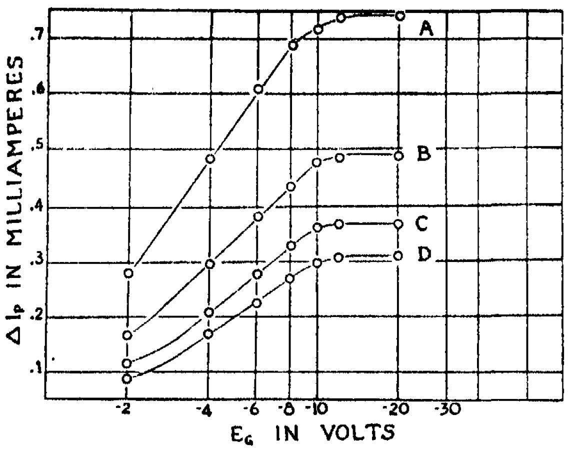

FIG. 2. I_p-e_g characteristic for 6SG7.

A, R_2 = 2500 ohms
B, R_2 = 5000 ohms
C, R_2 = 7500 ohms
D, R_2 = 10,000 ohms.

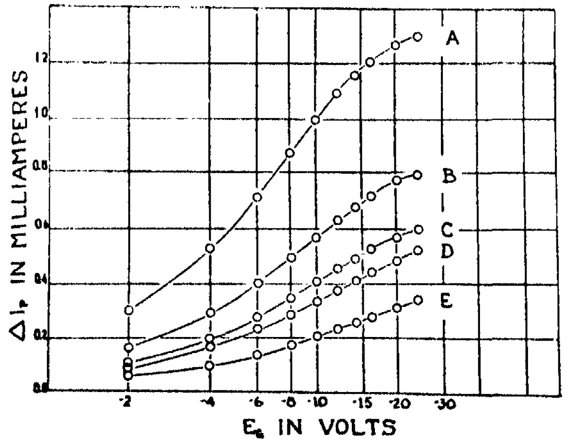

FIG. 3. I_p-e_g characteristic for 6SK7.

A, R_2 = 2500 ohms
B, R_2 = 5000 ohms
C, R_2 = 7500 ohms
D, R_2 = 10,000 ohms
E, R_2 = 15,000 ohms.

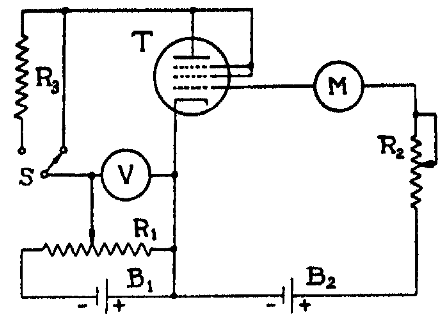

FIG. 4. A circuit which extracts antilogarithms.

B_1, 45 volts
B_2, $1\frac{1}{2}$ or 2 volts
M, 0–1 milliammeter
R_1, 50,000 ohm potentiometer
R_3, 300 megohms
S, SPDT switch
T, 6SK7
V, 0–50 voltmeter
R_2, 2500 ohm calibrated potentiometer.

The data plotted in Figs. 2 and 3 show that the 6SK7 is logarithmic over a more extended range than the 6SG7; as a result it was decided to investigate the properties of the former in an inverted circuit. Figure 4 is a diagram of the circuit used to determine the tube constants and characteristics of a 6SK7 connected up as an inverted triode; the screen and suppressor of the tube are connected directly to the plate. In an inverted tube circuit the signal is applied to the plate, which acts as the grid, and the output current is drawn from the grid element, which in this case acts as the plate; consequently to avoid unnecessary confusion we shall speak hereafter only of input voltage and current, denoted by e_s and i_s, and of output current, denoted by i_0.

The results desired from this circuit are the reverse of the conditions expressed by Eq. (1). We can express this desired result by:

$$\log k_0 i_0 = k_1 e_s \tag{2}$$

or, in terms of the antilogarithm of the input,

$$k_0 i_0 = \text{antilog} k_1 e_s, \tag{3}$$

where k_0 and k_1 are simply constants of proportionality.

B, B_2=2 v., R_2=1000 ohms
C, B_2=$1\frac{1}{2}$ v., R_2= 500 ohms
D, B_2=$1\frac{1}{2}$ v., R_2=1000 ohms.

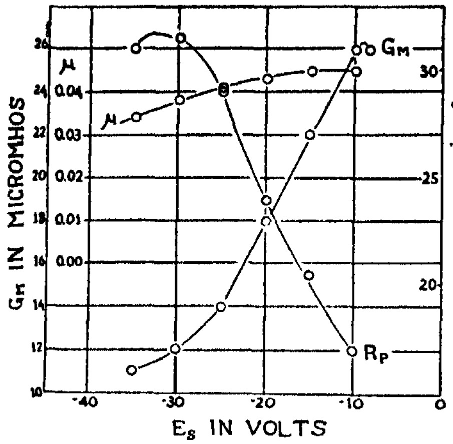

FIG. 6. $G_m-R_p-\mu$-characteristics of the inverted 6SK7.

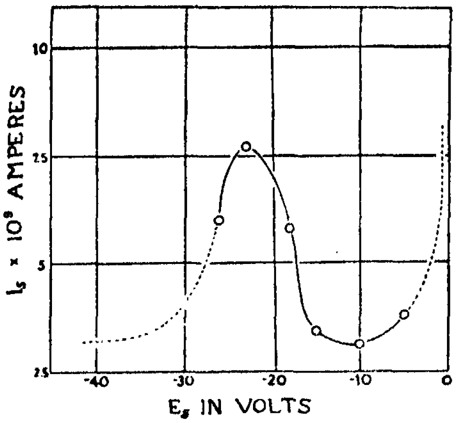

FIG. 7. Input current (L_s) curve for the inverted 6SK7.

The input voltage, e_s, was now varied by means of the potentiometer, R_1, its value being set with the aid of the voltmeter V. A 0-1 milliammeter was placed in the grid circuit for reading the output current. The output load was adjustable with the calibrated potentiometer R_2. Table I is a compilation of the output currents observed at the indicated grid supply voltages, input voltages and load resistances. Figure 5, the plot of these data, clearly shows that the logarithm of the output current is proportional to the input voltage, or conversely, that the output is proportional to the antilogarithm of the input. Thus the conditions of Eqs. (2) and (3) are satisfied, and the desired result achieved.

Similar results obtained with other 6SK7 tubes were equally satisfactory. The extent of the range of input voltages over which the i_0-e_s characteristic was antilogarithmic varied slightly; however, it was observed with all the tubes tested, that the plot of the data was antilogarithmic between input voltages of -18 to -30, when a load resistance of 1000 ohms was used. It was noted that tubes with metal envelopes were somewhat inferior to those with glass envelopes. If the data for the former type of envelope are rejected, the useful antilogarithmic range is extended to include all input voltages between -15 and -30, when a load resistor of 1000 ohms is used in the output circuit.

Figure 6 presents plots of the μ, g_m and r_p characteristics of the inverted 6SK7 as approximated from information available in the curves of Fig. 5. It is readily observed that μ and g_m are extremely low and that r_p is considerably less than the values obtained for a normal triode. However, these results are entirely normal for an inverted tube. It should also be kept in mind that these tube parameters are of secondary and rather irrelevant importance in this circuit since its primary function is to extract antilogarithms. The output of this circuit has been successfully amplified with a d.c. amplifier of conventional design. A useful output signal is then obtained. That amplification of the circuit output would be mandatory is obvious from the values for μ (*ca.* 0.04) and from the actual voltage amplification resulting in the circuit, which varied from about 0.011 to 0.027, depending upon the location on the input voltage axis. These values for voltage amplification correspond to an output load of 1000 ohms. It can also be seen from the results of Fig. 6 that the variable-μ characteristic of the 6SK7 is retained when the tube is inverted, μ changing by more than 25 percent over the range plotted.

The input currents are of more than usual interest in this circuit in view of the rather low output currents. Figure 7 is a plot of the input current *vs.* the input voltage when a load of 1000 ohms has been placed in the output circuit, and an output supply voltage of 1½ volts. These currents were measured in standard fashion by utilizing the drop across the 300 megohm resistor R_s of Fig. 4 when it was placed in the input circuit with the switch S. This voltage drop was derived from the curves of Fig. 5 by noting the output currents on the meter M, both with the 300 megohm resistor in the circuit, and again with this resistor bypassed. Knowing the resistance and the drop across the resistance, the input currents are then easily calculated.

A simple circuit for the extraction of antilogarithms has thus been presented along with a few of its more important characteristics. It is hoped that many applications will be found for this circuit, and that it will prove of definite benefit to the instrument designer.

ACKNOWLEDGMENT

The authors wish to acknowledge the helpful suggestions given them by Dr. R. H. Müller and the encouragement extended them by Dr. L. T. Hallett during the work leading to the results reported upon here.

Magnetic Suspension for Small Rotors*

J. W. Beams
University of Virginia, Charlottesville, Virginia

(Received November 15, 1949)

A magnetic suspension for small rotors has been developed which employs scattered light to regulate the vertical height of the rotor. Upon entering a horizontal beam of light the rotor scatters or reflects light into a photo-electron multiplier cell. This cell actuates an electronic circuit which in turn regulates the current through the supporting solenoid in such a way as to maintain the ferromagnetic rotor at the desired vertical position. Rotors with diameters down to 0.004″ have been stably supported. A $\frac{1}{64}$″ rotor was spun to an estimated speed of 800,000 r.p.s. which gave a centrifugal field in excess of one-half billion times gravity. Besides providing a support for rotors, the apparatus may be used as an analytical balance for weighing materials inside a vacuum chamber. It detects changes in mass of from 10^{-8} to 10^{-9} gram. Other uses also are indicated.

IN order to produce high centrifugal fields it is necessary to use as small rotors as possible. This results from the fact that for a homogeneous elastic rotor of a given shape the bursting speed depends upon the square of the peripheral speed and is independent of the radius. In other words, for a given shape of rotor made of an elastic material $v^2 = w^2r^2 = K$ where w is the angular velocity, r is the radius of the rotor, v is the maximum peripheral speed and K is a constant. Consequently, the maximum centrifugal field $w^2r = K/r$ and thus increases as r becomes smaller.

In previous reports methods of spinning rotors of various diameters to their bursting speeds have been described.[1] The rotors were suspended in a vacuum by an axial magnetic field and spun by a rotating magnetic field. In this method the vertical stability of the rotor is maintained by the effect of the rotor on the impedance of a small "pick-up" coil placed below or above the rotor and connected in the grid circuit of a high frequency oscillator which in turn regulates the current through the supporting solenoid. As the rotor moves upward or downward, the current through the supporting solenoid is automatically decreased or increased respectively by the proper amount to maintain the rotor at the desired vertical position. Such a magnetic suspension is extremely stable and in practice has a resistance to rotation much smaller than the air friction on the rotor even when the air surrounding the rotor is at a pressure the order of 10^{-6} mm of Hg. However, when the size of the rotor becomes very small (below 0.02″ in diameter) the effect of the rotor on the impedance of the pick-up coil is reduced and consequently the adjustments of the circuits required to maintain vertical stability of the rotor become increasingly difficult. In this paper a magnetic suspension is described in which the vertical height of the rotor is determined by the amount of light scattered by the rotor into a photoelectric "pick-up". With this arrangement much smaller rotors can be suspended and spun than with the previous method.

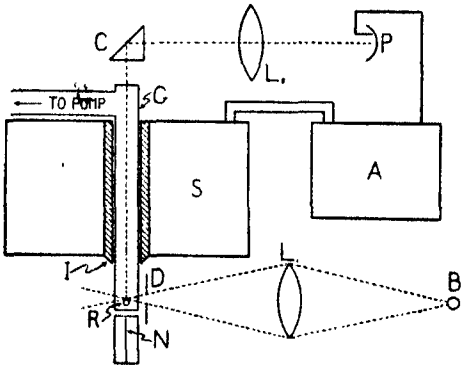

Fig. 1.

Figure 1 shows a schematic diagram (not to scale) of the method. The rotor R is surrounded by an evacuated glass tube G which is mounted coaxially with the supporting solenoid S. Light from a lamp B with a straight incandescent filament perpendicular to the page is brought to focus by a moderately long focus lens L_1 along a diameter of the glass tube in such a way that a thin horizontal beam or sheet of light crosses the glass tube. As the rotor R is pulled upward by the magnetic field of the solenoid S, it enters the light beam and scatters or diffusely reflects light upward through the glass tube, right angle prism C and lens L_2, which concentrates the light on the photo-electron multiplier cell P.

The current signal in P is amplified by the electronic circuit A and made to regulate the current through the solenoid S. When properly adjusted the current in S is automatically regulated so that the vertical position of the rotor remains constant. The horizontal stability is of course provided by the axial magnetic field of the supporting solenoid. A small iron wire N surrounded by a damping fluid and placed below and outside the vacuum chamber G served to damp out any horizontal motion of the rotor.

The solenoid S consisted of 23,000 turns of No. 28 copper wire wound on an insulated Bakelite frame. Its resistance is approximately 1300 ohms and its inductance with the iron core B is about 30 henrys. The iron

core is a cold rolled steel tube 4 inches long, 0.5 inch internal diameter, and 0.1 inch wall thickness. In the first experiments, it had a very narrow vertical slit to prevent eddy currents but this was later found unnecessary. In most of the experiments the current through the solenoid varied from 30 to 70 milliamperes depending upon the size and desired position of the rotor. It was found that the number of turns in the solenoid is not critical, as several different solenoids with varying numbers of turns, resistances and inductances were used successfully. In most of the experiments 500 to 1500 ohms resistance was placed in series with the solenoid described above.

In the majority of the experiments a 1P28 photo-electron multiplier tube was used at P to pick up the light signal although both 931A and 1P21 tubes were used successfully. With most of the circuits used it was an advantage to select photo-multiplier tubes with as low a dark current as possible. Also for the smallest rotors it was found desirable, although not necessary to keep the tube at dry ice temperature in order to maintain the "noise" or current fluctuations at a minimum.

Figure 2 is a diagram of an electronic circuit (A. Fig. 1) which has operated very satisfactorily for long periods of time without adjustment. Also it has been used for supporting rotors over a wide range of sizes and weights. It is composed of ordinary standard parts and is easy to adjust. The signal from the photo-electron multiplier cell P is first amplified by T_1 (6J5) and then applied to the grid of the cathode follower T_2 (6J5) which, in addition to reproducing the signal, generates a derivative of the signal. The signal which occurs across R_7 is applied to the grid of T_4 (6SJ7) while its derivative produced by the circuit R_8C_2 is applied to T_3 (6SJ7) in parallel with T_4. The two signals are mixed and applied to the grid of T_5 (6J5) which is a second cathode follower and then on to the grid of the power tube T_6 (6L6) which regulates the current through the solenoid. The resistance capacity combination $R_{11}C_5$ is not necessary although it makes possible somewhat easier adjustments. The resistances R_8, R_{11} and R_2 and the capacities C_2 and C_5 should be variable in order to facilitate adjustment. The filaments of T_2 and T_5 were each heated by separate insulated storage batteries.

It will be observed that as the rotor rises into the light beam the scattered light falling on P is increased and the current through the supporting solenoid consequently decreased. As a result the rotor falls and scatters less light into P which in turn increases the current through the supporting solenoid S and raises the rotor. Clearly this would give rise to oscillations were it not for the derivative signal generated by the C_2R_8 combination. The phase of this derivative signal is adjusted to be from 70° to 90° out of phase with that of the original signal and hence damps the oscillations. When this adjustment is made properly no vertical motion of the rotor is observable even through a microscope focused on scratches on the rotor. The values given in Fig. 2 were for supporting a 15-mil steel spherical rotor about 1.45 cm below the end of the tubular iron core, but they are not critical with rotor size.

The support circuit (Fig. 2) was found to operate just as satisfactorily with the first stage of amplification T_1 removed. This, of course changes the phase relations so that as the rotor moves out of the light beam the current through the supporting solenoid is decreased and *vice versa* so that the rotor is positioned on the top edge of the light beam rather than on the bottom edge as in the case of the first arrangement. With the first amplification stage out of the circuit it is necessary to increase the signal by increasing the resistance R_3 or the potential on P or both. In practice it is usually found more convenient to use the whole circuit as shown in Fig. 2.

The rotor was spun by a rotating magnetic field produced by an alternating current in two pairs of coils (not shown in Fig. 1) surrounding the rotor but outside the glass vacuum chamber. The frequency of the rotating magnetic field or the a.c. current in the coils is set equal to the desired running speed of the rotor and is controlled piezoelectrically. The rotor is accelerated in a way similar to that of an armature of an induction motor. It should be noted that although the "slip" is large, the comparatively high electrical resistance of the steel rotor gives a satisfactory starting and accelerating torque. It has been shown previously[1] that the frictional drag on a spinning rotor supported magnetically in a high vacuum is so small that the rotor accelerates to speed as an induction motor and then "locks in" and spins in synchronism with the rotating magnetic field without hunting. Except for the piezoelectric control, the driving circuit is similar to that used previously. The power supplied to the coils is about 10 watts and it is necessary to cool them with air circulated by an electrically driven blower. The acceleration of the rotor varied with the size of the rotor but it usually took several hours to bring the rotors up to full speed. The temperature of the rotors was a few degrees above room temperature.

The rotor speed was measured by a photoelectric pick-up for rotor diameters of 20 mils and above. For rotors below 20 mils in diameter no satisfactory direct method has been found for measuring the highest rotor speeds so they must be estimated by indirect methods. However, in all of the experiments if the rotors are accelerated for a long enough period they will "lock in" and spin in synchronism with the rotating magnetic field so that the maximum speeds of the smaller rotors are determined by the respective frequencies of the driving circuits which of course are determined quite accurately by a frequency meter calibrated against W.W.V. With a 1/64-inch diameter steel spherical rotor kindly furnished by Mr. W. S. Pierce, Jr., Miniature Precision Bearing Company, estimated rotor speeds of 800,000 r.p.s. were obtained without exploding the rotor. This gives a centrifugal field on the periphery of over a half-billion time gravity.

As the diameter of the rotor is reduced below about 20 mils, it becomes more difficult to adjust the damping needle *N* (Fig. 1). The diameter of the steel or alloy needle *N* is made smaller than the rotor and usually is surrounded by water. So far, the requisite damping has been obtained by a tedious process of trial and error. It should be noted that any sudden vertical motion of a rapidly spinning rotor may set it into horizontal oscillation especially if the axis of the magnetic field is not exactly vertical so the power supplies to the electronic circuits must be well stabilized and the spinning rotor should be kept free of vertical motion.

The distance of the rotor below the core of the solenoid varies with the size of the rotor and shape of the core. For rotors below $\frac{1}{8}$ inch in diameter, a satisfactory working distance with the solenoid described above is about 1.5 cm. It will be observed that for rotors with dimensions small in comparison to their distances below the solenoid core, the force F on the rotor is approximately $M(dH/dX)$ where H is the magnetic field, X the distance along the axis of the field, and M the magnetic moment induced in the rotor by the field H. For soft iron (but not necessarily for hard steel) M is roughly proportional to μH so the lifting force $F\propto \mu H(dH/dX)$ where μ is the permeability of the rotor material. Consequently the proper rotor distance below the solenoid is determined by the shape and intensity of the magnetic field and may be varied over considerable ranges.

RESULTS

As mentioned previously the apparatus described in this paper was developed primarily for obtaining high centrifugal fields for use in a number of different studies. So far a series of experiments have been carried out on the bursting speeds of steel spherical rotors of different diameters. These results show that for the particular steel used, the maximum peripheral velocity obtained was approximately the same (10^5 cm/sec.) for all sizes of rotors tried. However, the probability that a given rotor would reach maximum peripheral speed increased markedly as the diameter of the rotor decreased. The explanation of this seems to be that as the rotor diameter is decreased the amount of material around the center of the rotor which is under maximum stress is decreased and consequently the probability of finding a flaw or crack in the stressed part of the smaller rotor is decreased.

Observations also have been made on the centrifugal fields necessary to pull films off of the periphery of the rotor. Since the thickness and density of the films are known the forces on the films can be calculated. In the highest centrifugal fields some of the "trash" laid down on the surface during the polishing process apparently was thrown off although further observations must be made before this can definitely be established. Attempts to use the apparatus for the study of possible molecular orientations by centrifugal fields also are in progress.

In one of the experiments a very narrow slit was placed at *D* in Fig. 1 in order to cut down as much light background as possible. However, in addition to cutting down the background it gave rise to a diffraction pattern the result of which was to give in effect a slow increase of light intensity as the beam was approached from the bottom or top. A 1/64-inch rotor was carefully supported in the lower region of the light beam. The pumps were then started and the system quickly evacuated to less than 10^{-6} mm of Hg. During this evacuation, the rotor was observed through a 30-power microscope and found that its height was considerably decreased. This was repeated several times and traced to the buoyancy of the air. The volume of the rotor was 3.36×10^{-5} cm^3 and its weight 2.6×10^{-4} gram. Further experiments were then carried out to determine the sensitivity of this balance and it was found that between 10^{-8} and 10^{-9} gram change in weight could be observed. Clearly this observation indicates that with the proper design the apparatus may be used as a most sensitive balance. Magnetic suspension balances have been used previously[2] but the present method affords much greater sensitivity and stability and the weighing can be carried out in vacuum, i.e., during a chemical reaction on surfaces, for osmotic pressure measurements, etc. A more detailed description of this application will be described later.

The lower limit to the diameter of rotor that can be supported by the above apparatus has not as yet been reached. The smallest rotor so far used was about 4 mils in diameter.

The writer wishes to express his appreciation and indebtedness to Mr. J. Dillon and Mr. W. Lucke for help with the electronic circuit.

On Adapting a Powder X-Ray Diffraction Camera for Reflection Patterns

Jonathan Parsons
Edsel B. Ford Institute for Medical Research, Detroit, Michigan

(Received October 12, 1949)

A method is described by which a commercial x-ray diffraction powder camera, designed to take rod or tubular mounts, may be easily adapted to accommodate small, flat mounts. Provision is made to change the customary continuous rotation to that of 10° rotary oscillation. A diffraction pattern of the core of a large renal calculus is shown as being illustrative of the patterns obtained from this modified camera.

SOME powder x-ray diffraction cameras are available commercially which will take reflection patterns from fairly large slabs of material as well as the usual powder diagrams. Others like the North American Philips 114.59-mm camera are designed solely for use with powdered specimens. It has been found possible to adapt the Philips camera[1] fairly easily for use with flat samples without interfering in any way with its accurate and efficient use in powder studies. The parts required can be made without recourse to an expensive machine shop. Flat sections of bone, renal calculi, teeth, and other substances may be studied by the method and their surfaces "mapped" analytically with the adapted camera which may be returned in several minutes to its original state for powder studies.

To adapt this camera for use with flat samples, four modifications in design are required: (1) A sample platform to support flat samples with their surfaces on the axis of rotation, (2) rotary-sample oscillator to replace continuous rotation, (3) a smaller pinhole insert to fit the sample end of the collimating tube snugly, and (4) a lead-lined cap to replace the regular beam-receiving tube.

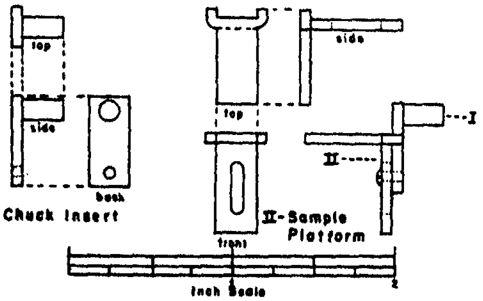

FIG. 1. Specimen mount.

A flat specimen mount has been constructed according to the details shown in Fig. 1. This mount consists of a chuck insert and a sample platform which are clamped together by a screw. The rod end of this unit fits into the camera chuck in place of the standard brass specimen rod. In use a flat sample is attached to the platform, which is then adjusted by means of the screw so that the axis of oscillatory motion is tangent to the surface of the sample. The assembly detailed in Fig. 1 will accommodate samples up to $\frac{1}{4}$ inch in thickness. Thicker samples could be mounted if the arm of the chuck insert were lengthened and one or more threaded holes added.

The rotation axis of the powder camera is given an oscillatory motion of 10° by means of a heart-shaped cam and follower-arm, constructed to fit over the regular motor and camera axis pulleys, respectively.

FIG. 2.

---

[1] W. Parrish and E. Cisney, "An improved x-ray diffraction camera," Philips Tech. Rev. 10, 157–167 (1948).

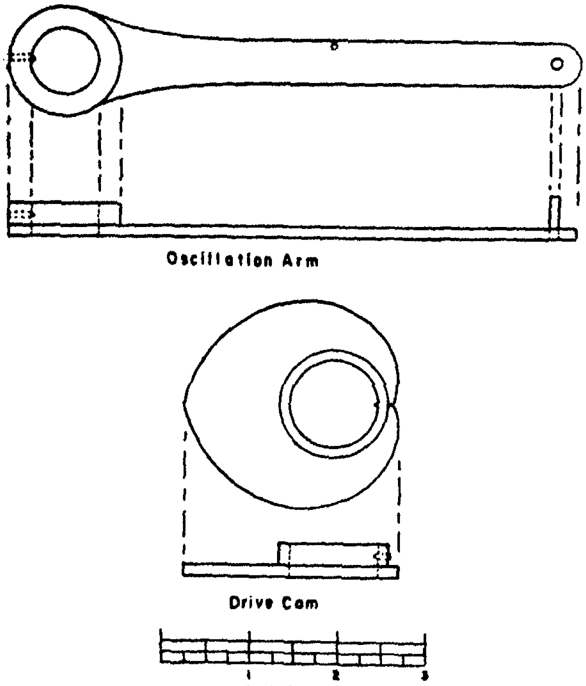

FIG. 3. Oscillation attachment.

Figure 2 is a photograph of the completed assembly and Fig. 3 is a scale drawing of the oscillation arm and drive cam. The cam and arm are secured to these pulleys by Allen head screws. A tension spring holds the arm against the cam as the latter rotates. The shape of the cam was determined empirically to give a uniform oscillatory motion of 10° to the specimen mount.

Since the x-ray beam strikes the sample at an oblique incident angle, the area irradiated is considerably larger than the beam cross section. To reduce the size of this area and increase line resolution, a brass insert has been made for the small end of the collimating tube. This insert is 4 mm long, has a bore of 0.013 in. on the inner end and a guard bore of about 0.016 in. at the sample end. A flange prevents this insert from being pushed too far into the end of the collimating tube.

The oscillation range of a flat sample must be as low as possible in order to keep the blocking of low Bragg angle lines to a minimum. However, this oscillation range should not be set so low that the area upon the sample becomes elongated more than twice the beam diameter. Oscillation ranges of from 15° to 25° without this insert have been used. In order to register low Bragg angle lines a tube with a long K_α wave-length target material should be used.

A diffraction pattern obtained by reflection is single. This necessitates mounting the sample so as to reflect downward, since the film must be loaded into this type of camera with its continuous surface at the bottom.

A further consequence of the one-sided diffraction of flat samples is that a different method must be used to obtain the position at which the direct beam strikes the film. A lead-lined cap has been substituted for the regular beam-receiving tube. By using such a cap it is not necessary to punch the film on the receiving tube side. At the end of each exposure the camera is opened, with only safe light illumination, and the specimen mount removed. The x-ray beam is turned on at low voltage and tube current for a fraction of a second, in order to register the direct beam position.

A pattern shown in Fig. 4, which was obtained with the camera adapted as described, was taken from the core of a large renal calculus. The flat surface was obtained by bisecting the stone with a fine jewelers' saw. Upon analysis of this pattern calcium oxalate proved to be the principal constituent.

FIG. 4. Pattern of renal calculus core.

By using this special sample mount with its oscillatory axis motion it is possible to analyze selectively small inclusions or narrow layers in sample surfaces without altering their crystalline arrangements. Information about possible orientations in the structure may also be obtained. This method is not as easy to use as the straight powder analysis but when used in conjunction with the latter, additional information about the crystalline nature of the sample, particularly about the variations in composition through the volume of the substance, is often found.

Laboratory and Shop Notes

An Experimental KVAH-Meter

G. M. Petropoulos
National Technical University, Athens, Greece

November 28, 1949

PRINCIPLE.—Figure 1 shows the principle of the KVAH-meter. The voltage of the a.c. circuit is rectified[1] by a suitable metal rectifier and then smoothed by an electrolytic condenser. The current flowing through the pressure circuit of the d.c. KWH-meter is thus quite proportional to the a.c. circuit voltage. The primary of a transformer is installed in series to the a.c. circuit. Its core has an air-gap in order to secure an approximately constant inductance. The voltage induced in the secondary, which contains a considerable number of turns, is rectified and smoothed as in the case of the voltage circuit. The d.c. thus obtained is passed through suitable windings installed in the place of the current coils of the d.c. KWH-meter.

The ripple of the unidirectional currents passing through the meter elements can easily be smoothed to a value of the order of 5 percent. Thus, the torque produced by the alternative components of these currents will not exceed 0.25 percent of the torque due to the product of the d.c. components. Consequently, the dependence of the meter constant (rev./KVAH) from the a.c. circuit power factor will be practically negligible.

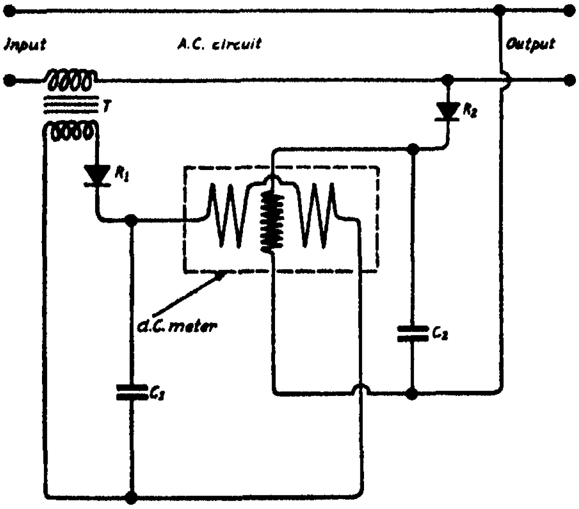

FIG. 1. Principle diagram of the KVAH-meter.

Application.—A single-phase KVAH-meter has been arranged in accordance to the above principle with the following data. The current coils of a motot type, 10A, 110-v d.c. meter have been replaced by two coils with 8500 turns each, of 0.15-mm enameled copper wire. The resistance of both coils in series was 3750 ohms and the total resistance of the potential circuit of the meter, 5800 ohms. The original d.c. meter constant was 2850 rev./KWH.

Each of the rectifiers of Fig. 1 consisted of 30 elements of the selenium type, 18 mm in diameter. Non-conductive and conductive resistances were, as measured under working conditions through a C.R.O., about 0.5 megohm and 1300 ohms respectively. Each smoothing capacitor consisted of three 40-μF, 150-v electrolytic condensers in parallel.

The core and the arrangement of the windings of the transformer (T) are shown in Fig. 2. The primary, wound over the secondary, consisted of 16 turns, 1.5 mm in diameter cotton insulated copper wire. The secondary had 4000 turns of 0.25-mm enameled copper wire. A 0.51-μF condenser was connected across the secondary, causing an increase of the secondary voltage, due to the leakage reactance of the windings.

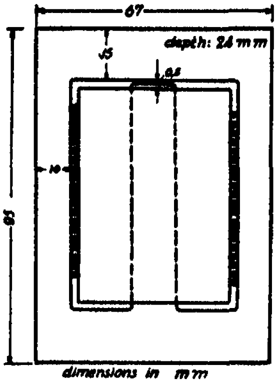

FIG. 2. Core and windings of the transformer.

Figure 3 shows the results finally obtained in trying to secure linearity[2] between the current of the a.c. circuit and the d.c. voltage across the final current coils of the meter. The ripple of the d.c. voltages across the coils in question and the voltage circuit of the meter was, as measured through a C.R.O. under full load, less than 2.5 percent of the d.c. components.

Results.—The KVAH-meter described above has been tested with a rotary meter testing set at 220 v. The results obtained are given in Fig. 4 and seem to be quite satisfactory. The values of the meter constant at 0.1, 0.5, and unity power factor are very closely together so that the performance under these conditions is represented by the common curve. The meter constant is roughly 1000 rev./KVAH at full load, i.e., about one-third of the original constant of the d.c. meter (2850 rev./KWH). It may be concluded that if the adaptation of the d.c. meter was carried out so as to bring the number of revolutions per KVAH closer to its original constant, the faults under small loads would be comparable to the normal d.c. meter faults.

Practical considerations.—In the case of a symmetrical three-phase load, an adequately adapted single-phase meter would be able to measure the number of KVAH consumed. For an unbalanced three-phase load, the meter should have a special design: as the voltages are about the same in all three phases, the potential circuit of the meter could be connected, after rectification and

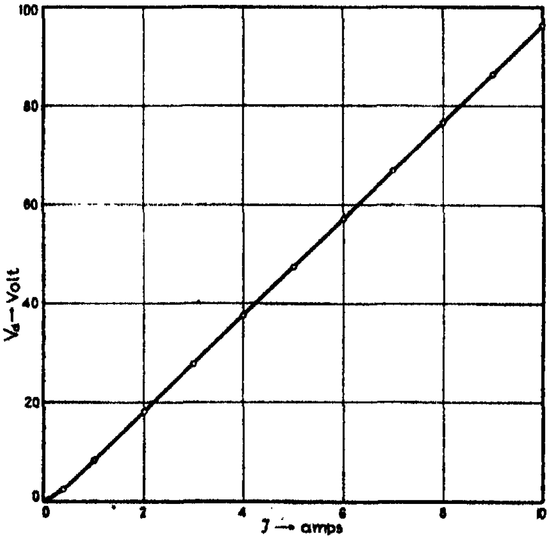

FIG. 3. Current circuit characteristics.

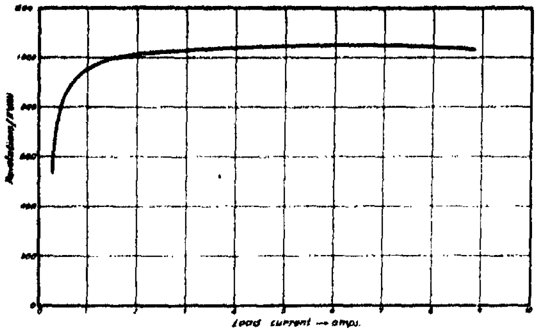

FIG. 4. Meter characteristics at 220 volts a.c.

smoothing, across any one pair of line conductors. Due to the differences in the line currents, three separate current circuits had to be used, each supplying one-third of a triple winding occupying symmetrically the space provided for the two current coils of the d.c. meter.

Regarding the stability of the KVAH-meter described, one can object to the use of metal rectifiers. They suffer, as it is well known, from a resistance variation due to aging. This would result in a slow variation of the meter constant with time. However, modern metal rectifiers seem to maintain their characteristics over long periods without any appreciable variation. Another question arises in connection with the considerable temperature coefficient of the rectifiers. As this coefficient is negative, a temperature compensation of the total circuit seems practicable.

In presenting the above results, the author is not suggesting a device ready for practical use. However, a further investigation as regards the stability of its performance, which seems to be a question of metal rectifiers construction, may lead to a possibly cheap solution of the KVAH-meter problem.

Acknowledgment.—The author expresses his best thanks to Messrs. Ferranti Ltd., Hollinwood, England, for valuable information.

[1] A KVAH-meter using rectification is described in the British Patent Specification 357,347. Its principle is substantially different, due to the lack of a smoothing device and of an air-gap in the transformer core. In order to reduce power factor influence, the single-phase meter described in the patent should have at least two potential circuits, out of phase.

[2] The design of a device transforming an a.c. into a proportional d.c. has been the subject for the Mech. and Elec. Engineering degree thesis, of Miss. D. Kokkinou.

Simple Low Power Electronic Relay

WILLIAM P. RATCHFORD AND M. L. FEIN
*Eastern Regional Research Laboratory, Philadelphia, Pennsylvania**
November 28, 1949

THE recent note of Linnel and Haendler[1] describing a simple thermostat relay in which an *FG* 57 thyratron controlled several hundred watts prompts us to describe a similar inexpensive low power circuit (Fig. 1), which we have used for about a year with a precision manostat.[2] This relay used a 2050 thyratron.

In order that the signal grid shall remain in control when the anode is positive, terminal (2) of the secondary must be 180° out of phase with terminal (1) of the primary. This is conveniently determined by trial after the relay has been assembled. If the tube fires continuously, the leads from the secondary should be reversed.

The relay has satisfactorily operated the air inlet valve of the manostat; L is the 750-ohm solenoid of the valve. When an increase in pressure closes the regulator contacts, the filament voltage is applied across R_1 and is thus impressed on the signal grid out of phase with the anode voltage. The tube does not fire, and the air inlet closes. When the pressure falls and opens the contacts, the signal grid is no longer biased to cut-off and loses control. The tube fires and energizes the solenoid, thus opening the air inlet, and the cycle repeats. R_2 limits grid current.

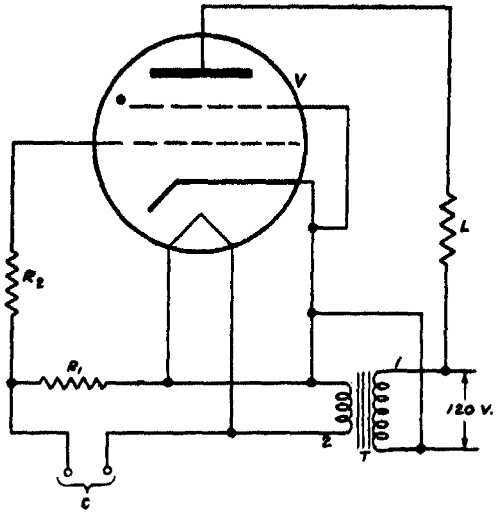

FIG. 1. Low power relay. $T=6.3$ volt a.c. 1 amp. $R_1-R_2=1$ megohm, 1 watt. $V=2050$ thyratron. $L=750$–800 ohm solenoid. C = connection to regulator.

Although suitable for controlling only low power (10 watts or less), the relay has replaced a commercial unit costing five times as much.

We wish to thank Dr. C. R. Eddy of this Laboratory for helpful suggestions.

Point-Focus X-Ray Monochromators for Low Angle Diffraction

JESSE W. M. DUMOND
California Institute of Technology, Pasadena, California
November 21, 1949

GUINIER[1] has applied the principle of the reflection type curved crystal focusing *x*-ray monochromator[2] to improve both intensity and angular resolution in low angle *x*-ray diffraction studies. In Guinier's method, a thin sample is placed in the convergent monochromatic *x*-ray beam and the low angle diffrac-

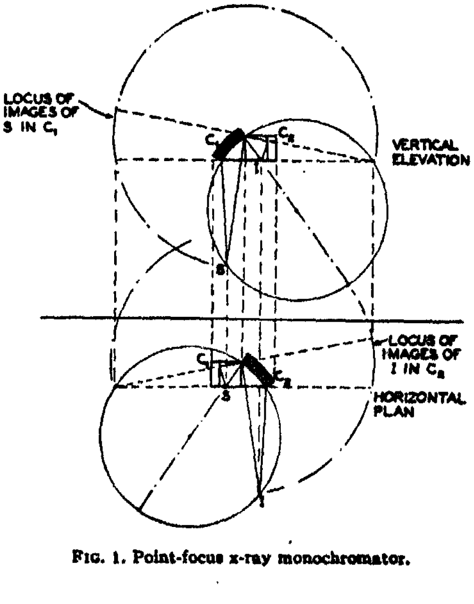

FIG. 1. Point-focus x-ray monochromator.

tion pattern is formed as a diffuse distribution symmetrically disposed on either side of the central primary line focused by the crystal.

An x-ray monochromator capable of forming a beam converging to a *point* focus would have the following important advantages. (1) The scattered intensity incident in the focal plane would be increased (relative to the line focus monochromator) in the ratio of the feasible line height to the line width, perhaps several hundred fold. (2) The awkward and complicated analytical procedure[3] for transforming the line focus diffraction pattern distribution into the point focus distribution would be completely avoided. (3) In the case of the two crystal monochromator described below, the residual factor limiting the sensitivity of the method, namely the background fog from incoherent scattering of the continuous x-ray spectrum incident on the first crystal, would be greatly reduced because practically only monochromatic radiation reaches the second crystal.

The type illustrated in Fig. 1 can be made of two monocrystalline quartz lamina cut to a cylindrical shape in the unstressed state, the concave surface being of radius R. The lamina should be cut so that the (310) planes ($d \cong 1A$) are parallel to the plane tangent to the cylinder *at one end of the cylindrical arc*. The lamina must then be elastically bent in a precisely profiled holder so that the surface which had radius R now has a radius $R/2$. This will fulfill the condition for monochromatization and exact focusing for all points on the cylindrical crystal arc. The full line circles are the loci of real focal points (both source and image) for each crystal. The foci shown are approximately those for Cu-K radiation. The dot-and-dash circles are the loci on which lie *the images of each focal point mirrored in the different (310) planes along the bent crystal arc*. The generators of the two cylindrical crystal surfaces *are mutually at right angles*. Thus, each crystal causes the final beam to converge in one of the two dimensions normal to its direction of propagation. Figure 1 shows the disposition of the components in both horizontal and vertical projection. The crystals are disposed so that the pertinent short arc of the dot-and-dash circle, on which the image of S (or I) lies, is in each case projected upon the plane of the other view approximately *as a point coincident with I (or S)*. The (thin) scattering sample is to be placed near the second crystal in the final doubly converging beam, and for best focusing, it should coincide nearly with the polar region of the surface of a sphere whose opposite pole is at the final focus of the beam.

In the second type of point-focusing monochromator illustrated in Fig. 2, use is made of a mica crystal which is bent by cementing it (under pressure with a rubber cushion) to the carefully figured concave surface of a metal block having two different principal radii of curvature, R_1 and R_2. The dot-and-dash line CC is the axis of rotation of the lathe in which such a concave surface is generated. It is easy to show that $R_2/R_1 = \sin^2\theta$ where θ is the Bragg angle. The figure shows the approximate geometry for monochromatizing fluorine K radiation from a fluoride target. The permissible crystal arc of radius R_1 is limited by a well-known aberration[4] but *for the production of a point focus*, there is no limit whatever to the extent of the arc of radius R_2 (about the axis CC). The arc may be a complete circle if convenient. To insure good homogeneity of scattering angle, however, it would be preferable to use the complete circle design only for a much shorter wave-length and smaller Bragg angle.

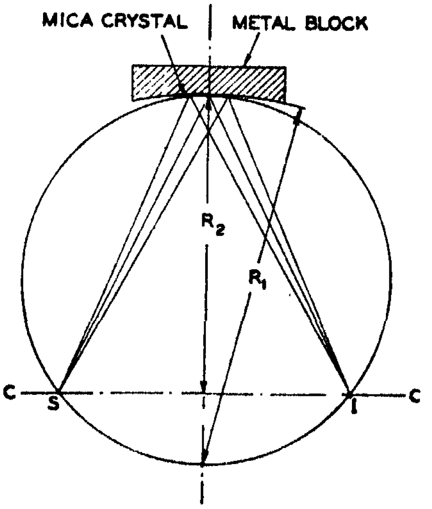

FIG. 2. Point-focusing x-ray monochromator.

The circularly symmetrical low angle diffraction patterns thus obtained could be studied very conveniently by direct G-M counter methods. To do this, an opaque concentric circular stop of *variable* radius r would be inserted in the pattern and the counter would measure the intensity associated with that part of the pattern *outside* the radius r.

Ultrasonic Tissue Disintegrator

F. F. BIRD AND K. S. LION
Laboratory of Applied Biophysics, Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts

December 8, 1949

THE ultrasonic disintegration of organic matter for electron microscopic and other investigations requires a high concentration of energy in the treated substance. This energy is frequently conveyed from a crystal transducer through an oil bath

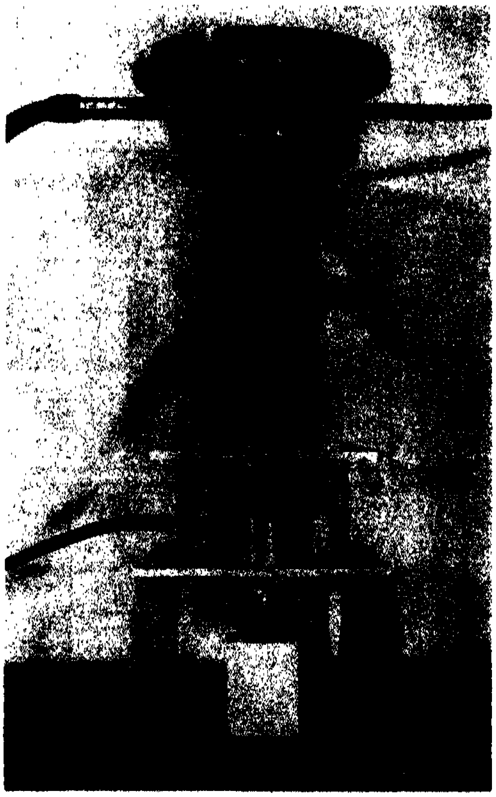

FIG. 1.

to the substance which is usually a suspension in a glass beaker. This often causes reflections and standing waves in the walls of the beaker so that the efficiency of the treatment is much reduced. Direct contact of the treated substance with the oscillating crystal surface is seldom possible because of the difficulty of cleaning and sterilizing these surfaces. Electrode surfaces on crystals, or bending membranes from magnetostrictive generators also tend to disintegrate so that metal particles are likely to get into the suspension.

These disadvantages are considerably reduced by using a method whereby an oscillating rod dips from above into the glass beaker filled with the suspension to be treated. Figures 1 and 2 show a Raytheon 10-kc magnetostrictive transducer adapted for this purpose. This transducer has a laminated nickel rod which drives a diaphragm acting as an impedance transformer. In normal use the diaphragm serves as the oscillating bottom of a container for the substance to be treated. For the above described purpose an aluminum rod is fastened in the center of the diaphragm, and the unit is mounted upside down. This requires a change of the water cooling duct as indicated in Fig. 2. The aluminum rod has never caused any trouble through disintegration, although for some special purposes it may be covered with glass.

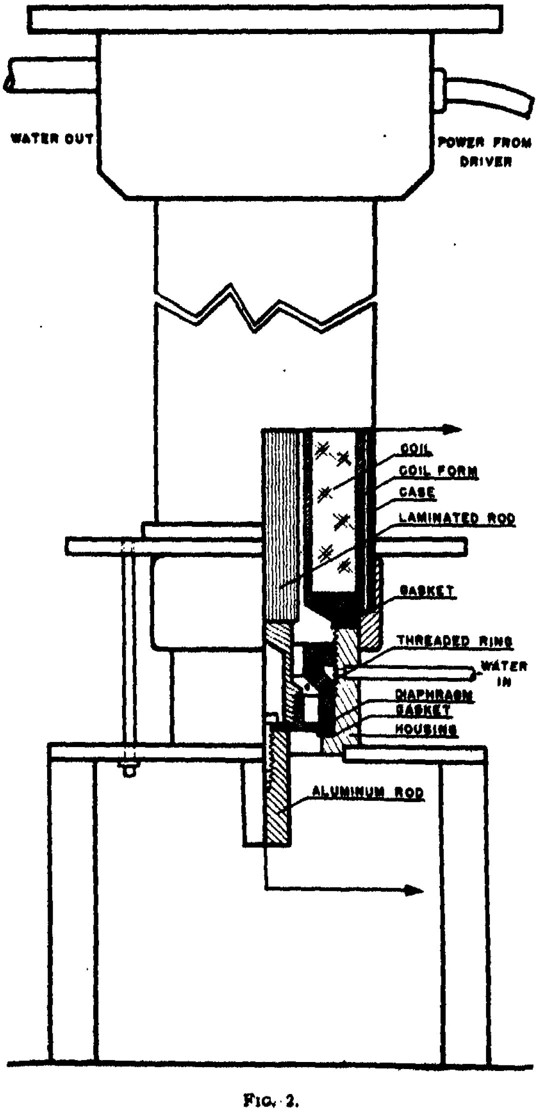

FIG. 2.

The instrument is mounted in the following way: First a quarter-inch hole is drilled through the center of the diaphragm. This is best done by grinding since the Stellite surface resists conventional drills. The aluminum rod is fastened to the diaphragm by a machine screw, and the laminated rod is screwed into place. The diaphragm and the rod are held in position in the brass housing by the threaded ring. Cooling water enters through the holes in the threaded ring, flows through the space between the laminated rod and the coil form and out the tube at the top of the coil. To bring pressure upon the gaskets the whole assembly is held between two aluminum plates which are connected by brass rods. An appropriate stand constructed of wood elevates the instrument so that a small sample in a beaker can be placed under the rod for treatment.

A Reprojection Method for Studying Cloud-Chamber Photographs

D. A. BROMLEY* AND R. D. BRADFIELD
Department of Physics, Queen's University, Kingston, Ontario, Canada

August 3, 1949

A SIMPLE reprojection system for use in studying stereoscopic cloud-chamber photographs has been assembled and used in this laboratory. Much more elaborate apparatus of this general type has been described elsewhere[1,2] but it is hoped that the relatively simple design described here will be of service to others.

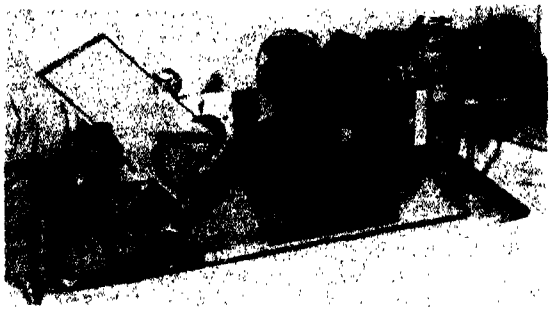

FIG. 1. The reprojection unit using the ground glass screen.

The stereoscopic photographs are obtained in the usual way, using two 35-mm cameras rigidly mounted on an aluminum casting. The films are automatically advanced for each exposure by small electric motors. A cam arrangement, driven from the film itself, opens the motor circuit and locks the film accurately in position.

Spring mounted Plexiglas windows were set into alternate backs for the cameras coincident with the position of the 35-mm frame during exposure in order to hold the film accurately in the focal plane of the lenses and permit reprojection.

The camera unit is removed from above the cloud chamber and is mounted with the optical axes horizontal as shown in Fig. 1.

Magnetic screen clamping devices have been used throughout for ease and speed of operation. A 15×12-inch section of boiler plate was machined and attached to the plywood base on which the entire unit is mounted. One side of the magnetic circuit of a 10-henry choke coil was removed, the resultant poles were machined to rest on the boiler plate, and to increase the stability of lead-weighted plate was fitted flush with the base of the magnet.

The screen shown in Fig. 1 consists of a 10×12-inch ground glass plate, free to rotate about a horizontal axis which in turn is fastened to, and moves with, the base. A second choke coil unit mounted over the screen axis and an iron disk armature fixed to the axis permit clamping at any angle. A graduated circle on the disk and a grid system ruled on the boiler plate are used to assign coordinates.

The screen assembly shown in Fig. 2 is considerably more flexible in use and consists of a 12-inch circular aluminum plate finished with white enamel on the working surface. A 3-inch mild steel hemisphere was attached rigidly to the screen with its center of curvature coincident with the center of the front surface of the screen and an iron-clad magnet was assembled to hold this screen in any position while permitting rotation in all directions. In order that the residual magnetism should be sufficient in itself to hole the screen in position the core was turned from mild steel. The 1¼-inch iron pipe which formed the external section of the magnetic circuit and the core face were turned to a spherical profile to match the screen hemisphere closely. The dimensions used are such that the screen can take any position outside of an approximately 30 cone about the support magnet. This magnet is mounted as shown, using a heavy aluminum frame. A selenium rectifier with a 0–130-volt d.c. continuously variable output is used to energize the holding coil.

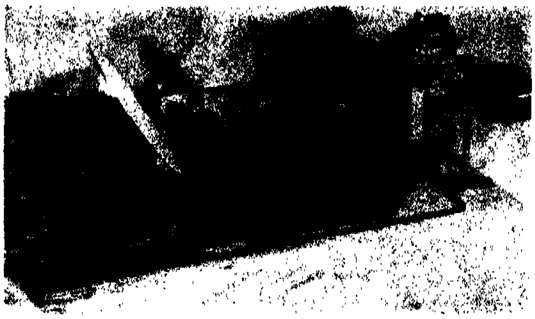

FIG. 2. The reprojection system using the disk screen. The selenium rectifier is shown in the background.

The films are rewound after processing in the cassettes and replaced in their respective cameras. For each frame the screen is moved to bring the images of the top and bottom of the chamber into coincidence and the distances from the film planes to the screen are checked against the original distances. This serves as a check on the film positioning. Angle and range measurements are made directly on the screen surface; when permanent records are desired, photographic paper is clipped to the screen and exposed.

To avoid distortion caused by the plate glass chamber roof a similar plate was inserted in the proper position between the screen and cameras during reprojection.

The writers wish to express their appreciation of Dr. J. A. Gray's helpful interest in this project.

A Nomogram for G-M Counter Resolving-Time Corrections

HOWARD L. ANDREWS
Laboratory of Physical Biology, Experimental Biology and Medicine Institute, National Institutes of Health, Bethesda, Maryland

November 21, 1949

IT is well known that a G-M counter tube fails to respond to all primary ionizing events within it because of the finite time required to recover sensitivity after each discharge. Because of this recovery time an observed counting rate *n* will be lower than

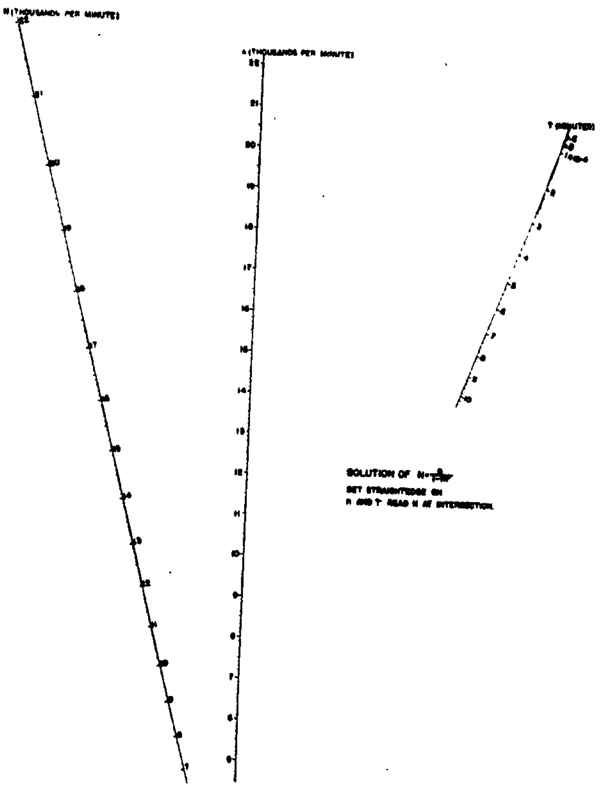

FIG. 1. Nomogram for determining resolving-time corrections.

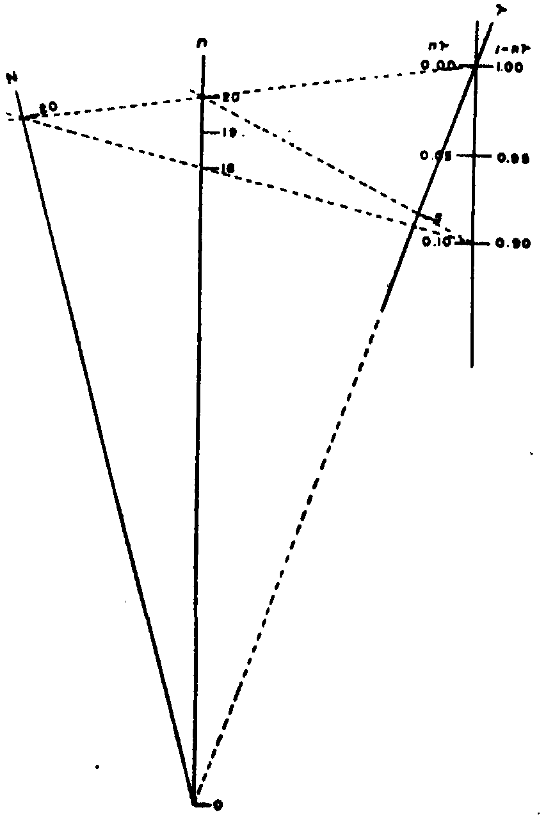

FIG. 2. Constructional details of nomogram.

the true counting rate N by an amount which increases with n. It can be shown[1] that

$$N = n/(1-n\tau), \tag{1}$$

where τ is the resolving time of the counter tube. τ is most usually determined by using two radioactive sources and determining the counting loss.[2]

When large numbers of observations must be corrected the time involved becomes appreciable and the possibility of computational errors is not negligible. The nomogram shown in Fig. 1 was devised to provide a solution of Eq. (1) which can be carried out rapidly and accurately by relatively untrained personnel.

To construct this nomogram the linear n scale is first laid off. The τ-scale is then drawn from the zero of the n scale at a convenient angle. At a convenient point on the τ-scale the auxiliary ($n\tau$) and ($1-n\tau$) scale is drawn parallel to the n scale and appropriate values are laid off linearly. Reasonable values of n and τ are chosen and $n\tau$ is computed. The non-linear τ-scale is now constructed by laying a straight edge across the chosen values of n and $n\tau$ and plotting values of τ at the intersection, Fig. 2. To determine the slope of the N scale two values of n and τ are so chosen as to yield the same value of N from (1). Then

$$\frac{n}{n'} = \frac{1-n\tau}{1-n'\tau'}. \tag{2}$$

Since the linear $n\tau$-scale is also a ($1-n\tau$) scale two lines can readily be drawn through the two chosen values of n and ($1-n\tau$). The intersection of these lines determines the N scale which must pass through the zero of the n scale. With the slope of the N scale determined the graduations are obtained by projecting the n scale using $n=0$ as a center.

The nomogram is based on two successive applications of the basic product-nomogram with non-logarithmic scales.[3] Reference to Fig. 2 shows that the n, τ, and $n\tau$-scales form the first product nomogram which will also give values of ($1-n\tau$). Equation (1) can obviously be solved by a simple product-nomogram formed with n, N, and ($1-n\tau$). If the ($1-n\tau$) scale is continued to zero the N scale extended will be found to intersect at this point and thus the basic requirement for the construction is fulfilled. Since given values of n and τ serve to determine both $n\tau$ and ($1-n\tau$) the ($1-n\tau$) scale is not required explicitly and a single straight edge application is sufficient to obtain N.

To determine the accuracy obtainable a series of 50 problems were computed by (1) and compared with the solutions obtained with the nomogram by a variety of personnel. The average error of 0.2 percent obtained with an 8 in.×10 in. reproduction includes both the errors of drawing and reading. This is quite adequate for correcting most counting data.

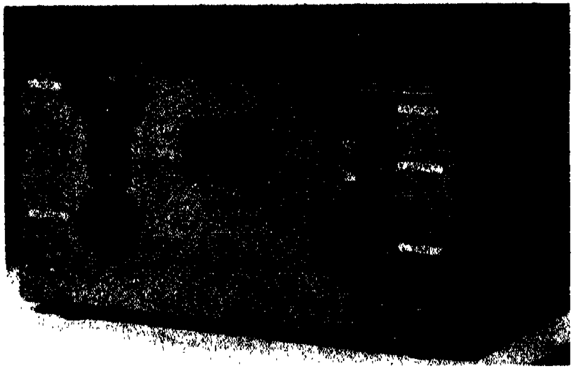
New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

D.C. Magnetic Amplifier

This amplifier, developed in London by Electro Methods Ltd., is designed for the amplification of small d.c. voltages in measurements work. The gain is constant to ±½ percent with a ±10 percent change in line voltage, and the zero drift over a period of several weeks is less than ±50 μv referred to the input terminals. Max. power gain—14,000; max. voltage gain—27; max. transconductance—5×10^6 micro-mhos; load resistance = 3 ohms; power line—117 v, 60 cycles; max. output current—300 ma.

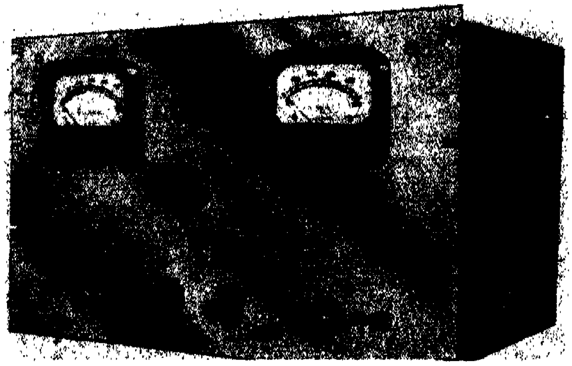


The amplifier is intended for use in measurements and control and, when used with thermocouples or strain gauge pick-ups, makes possible the recording of temperatures, pressure, accelerations, etc., on standard recording milliammeters. The excellent reliability of magnetic amplifiers makes the unit suitable for standby application when the reliability of vacuum tube amplifiers would not be adequate.—TRANS-SONICS, INC., *Bedford, Massachusetts.*

D.C. Power Supply

This regulated power supply is a laboratory source of stable, ripple-free d.c. power. It is continually variable in output voltages from 0–500 v. The ripple is less than 10 mv.

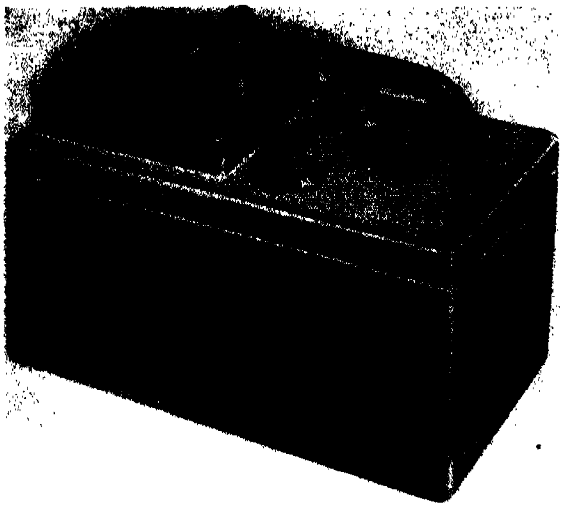
Power input is 105–125 v, 60 cycle. A.c. output is 6.3 v at 10 amp. (non-regulated). Regulation between 10 and 30 v is two percent, between 30 and 500 v it is one percent. The unit is mounted in relay rack or cabinet, and is compact in size.—CHATHAM ELECTRONICS CORPORATION, *475 Washington Street, Newark 2, New Jersey.*



Gamma-Survey Meter

A five-range ionization chamber-type gamma-survey meter covering the unusually wide range from 0–5 mr/hr. to 0–50,000 mr/hr. is the only instrument of its type offering a scale changing meter with only one range visible at a time. The instrument is unusually rugged for field work, yet highly accurate for laboratory use. The large 4-in. scale changing meter is shockproof for added protection. There are separate scales for the five ranges: 0–5, 0–50, 0–500, 0–5000, and 0–50,000 mr/hr.

The instrument has a hermetically sealed ion chamber and the entire instrument is immersion proof. The instrument can be set



to zero in a radiation field of any strength; this setting is maintained . . ., there is no zero drift.

Built to strict military specifications, the K-350 has a ±10 percent accuracy over an operating range from −10°F to 125°F. Warm-up time is negligible. This instrument is non-microphonic. The K-350 has a sturdy steel case and convenient shoulder strap. One thousand-hour batteries furnish power for the instrument.

Further details including complete description of this unit and other Kekeket electronic instruments for the detection and measurement of radioactivity are available on request.—The Instrument Division, The Kelley-Koett Manufacturing Company, *12 East 6 Street, Covington, Kentucky.*

Alpha-Counter

The Model 501 alpha-counter is a nuclear instrument for the detection of alpha-particles from any source. All uranium and thorium ores may be quickly, qualitatively, and quantitatively analyzed, when the radioactive content is as low as a fraction of one percent. The device is stable in operation so that it may be calibrated against known sources and samples.

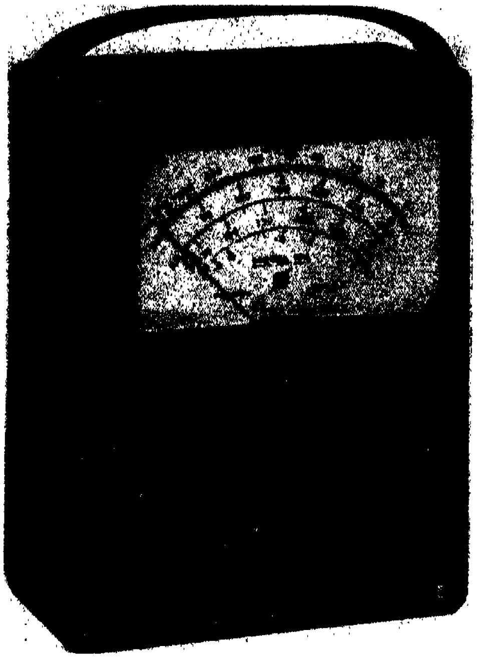
The Clarkstan alpha-counter utilizes a highly efficient optical system and a newly developed phosphor screen. From these it provides a statistical count of alpha-particle scintillations. Unlike the spintharascope, which must be used in the dark, the Model 501 alpha-counter may be used under subdued white light or red light illumination.

The Clarkstan alpha-counter has wide use and applications for the prospector, assayer, nuclear physicist, teacher, and mineralogist. It comes complete with luminescence-quenching filter, radioactive samples, aluminum carrying case, and complete instructions. The net price is $5.00.—The Nuclear Division, Clarkstan Corporation, *11927 West Pico Boulevard, Los Angeles 34, California.*

Volometer

Some of the special features of this rugged and flexible 20,000-ohm/v meter include a 4⅜ in. square meter—50 μa—Alnico magnet—three a.c. current ranges to 3 amp.—three resistance ranges to 20 meg. Weighing only 2 lb. and 5 oz., and housed in a high impact round-cornered Bakelite case with carrying strap, it measures $5\frac{1}{4}\times6\frac{3}{4}\times2\frac{7}{8}$ in.

Specifications: five d.c. voltage ranges at 20,000 ohm/v to 3000 v; five a.c. voltage ranges to 3000 v; three resistance ranges to 20 meg. Also three a.c. and d.c. current ranges to five db ranges.



The new Model 104 volometer is a product of precision standards, but is priced at only $24.95.—Electronic Measurements Corporation, *423 Broome Street, New York 13, New York.*

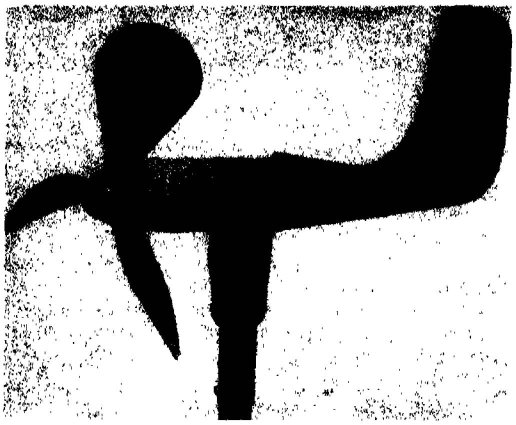
Aerolog Wind Recording System

A new method of recording the wind movement and its direction is based on pneumatic impulses rather than electrical impulses. This method enjoys entire freedom from an external source of power which fails so often during those critical times when the record is most important, or is entirely absent in remote locations.

The system comprises a transmitter, support, recorder, and connecting hose. The transmitter contains a propeller-driven bellows-type air pump housed in a streamlined wind vane identical in size and shape to the Aerovane transmitter. This transmitter includes a distribution valve to direct the pressure impulse into one (or two) channels of a four-channel tube, according to the direction of the wind vane. The propeller is geared to the pump in such a ratio that each unit (mile, knot, or kilometer) of wind passing the propeller causes a single pressure impulse.

The support of this transmitter is of the conventional steel tube type with a tripod base.

The recorder is of the continuous strip chart type, with spring-driven clock drive. The receiving mechanism is composed of four diaphragms, each connected to one of the four channels in the



connecting hose. To each diaphragm is connected a pen which normally draws a straight line on the chart but upon receiving an impulse is deflected momentarily about ¼ in. sidewise. Thus a record of the four cardinal directions can be made. When the impulse is channeled through two of the tubes simultaneously, an intercardinal direction is indicated.

The mechanism also contains a slide bar which is actuated by any one of the above pen motions. This slide bar in turn actuates a fifth pen whose mechanism is so arranged that each tenth stroke is longer than the preceding nine, thus making possible counting wind movement by decades.

This system will operate with as much as 60 ft. of connecting hose.—Friez Instrument Division, Bendix Aviation Corporation, *Baltimore 4, Maryland.*

Air-Cooled High Vacuum Pump

A self-cooled high vacuum pump for laboratory use has been developed to form a simple, handy, reliable, and economical evacuation tool for applications both where large or small receptacles have to be kept under constant vacuum for long periods and where small systems shall be repeatedly evacuated.

The air-cooling principle offers a considerable simplification in installation and service, as no special cooling medium supply and no protection devices in connection therewith are necessary.

The three-stage mercury diffusion pump produces a high vacuum pressure of 10^{-4} mm Hg against as high a forepressure as 20 mm Hg. This feature simplifies and reduces the cost of the necessary pump equipment on the forepressure side, and even a water jet pump may be used as a forepump.

The great compression capacity of the pump has also made it possible to equip the unit with a mercury trap on the forepressure side. This trap prevents a backflow of gas from the forepressure to the high vacuum side if the pump should stop for some reason, such as failure in the power supply.

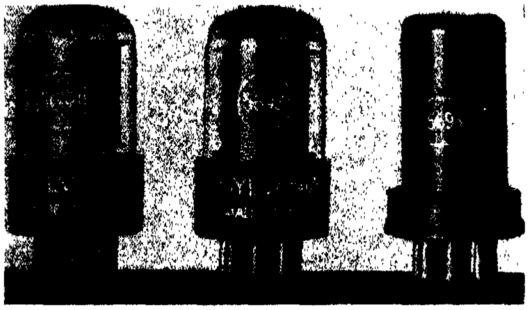
The patented design of the pump also offers easy dismantling for cleaning purposes and ensures correct assembly.—Aros Electric, Inc., *16 East 71st Street, New York, New York.*

Industrial Electron Tubes

Three new electron tubes suitable for a wide range of industrial services where dependable operation and a service life up to 10,000 hr. is required, feature of exceptional uniformity, stability of characteristics during 10,000-hr. rated life and specially designed mounts to withstand shock and vibration.

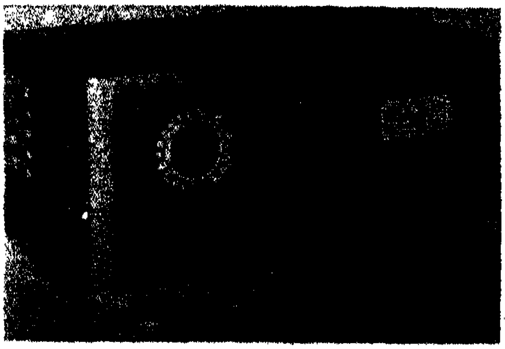
Structural specifications include ability to resist impact shocks of 100 G for prolonged periods, 500 G for short periods, and 2½ G during continuous vibration at 20 cycles per second, while being operated at maximum rated voltages.

The three new types include 5691, a high mu twin triode recommended for voltage amplifier use and supplied with series-unit heater; 5692, a medium mu twin triode with series-unit heaters suitable for balanced d.c. amplifier, multivibrator, blocking oscillator and resistance coupled amplifier applications; and 5693, a sharp cut-off pentode designed particularly for high gain resistance coupler amplifier service. The 5693 may be operated with No. 1 grid resistance values up to 40 meg.—Sylvania Electric Products, Inc., *Emporium, Pennsylvania.*



Proportional Counters

The phenomenally low alpha-background of less than one count per hour makes the PC-2A an outstanding instrument in the nuclear field. It is no longer necessary to struggle with background when counting low activity samples. With the wide range



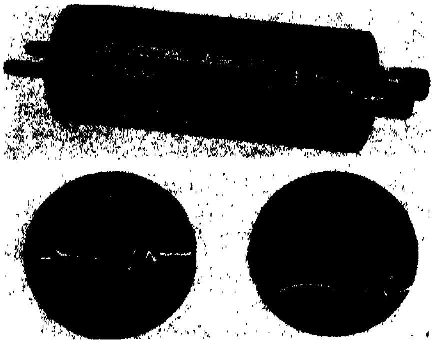
of sample types and sizes which the PC-2 accommodates, sampling time is greatly reduced. Excellent reproducibility and stability is obtained and complete automatic operation reduces operation time to an absolute minimum.

The types of samples counted are evaporated salts, precipitates, compressed pellets, loose soils, and ashed samples. The maximum sample size that the chamber accepts is 2¼ in. diameter by ¼ in. thick.

The PC-2 takes the fullest advantage of automatic operation, thus reducing the operating cycle to recording the data, exchanging the sample, and pressing a lever. A scaling factor of 8, 16, and 32 is provided and the maximum counting rate is 15,000 c/min. Gas flow control is automatic and timing is automatic up to 20 hr. A flush panel mounting, a register with lever-type reset, and illuminated leakproof bubbler are provided. All that is needed to put the PC-2A in operation is a cylinder of commercial argon, available in most any city.—NUCLEAR MEASUREMENTS CORPORATION, *3339 Central Avenue, Indianapolis 5, Indiana.*

Labmarkers

The Berkshire Labmarker is essentially a wave-shaping device used to produce time marks in cathode-ray oscillography. A sinusoidal input voltage (maximum amplitude 30 v r.m.s.) is converted by the Labmarker into a series of sharp unidirectional pulses. These pulses may be displayed directly on the face of a cathode-ray tube by connecting the output of the Labmarker to the vertical input. Timing marks consisting of short breaks in the oscillograph trace are obtained by connecting the output of the Labmarker to the "*Z*" input terminals of the oscilloscope. Both of these timing methods are shown in the photographs. The records shown are unretouched actual photographs showing spike potentials in giant internuncial fibers of the cockroach, with 1000-cycle time marks.



The Labmarker is a compact self-contained unit which may be plugged into the terminals of an audiofrequency oscillator. No other power source is required. The output binding posts of the Labmarker may be used with leads having single or double banana plugs, spade tips, phone tips, or plain wire ends.

Two types of Labmarker are available, the Model 1N, giving negative pips; and the Model 1P, giving positive pips. The price is $10.00 f.o.b. Concord, Massachusetts, for either model.—BERKSHIRE LABORATORIES, *P. O. Box 70R, Concord, Massachusetts.*

Vacuum Gauge

A new recording vacuum gauge for recording total pressure in the extremely useful range from one micron to 10 mm of mercury has been made possible by circuit modifications in the standard Alphatron cold-emission ionization gauge permitting connection to a Brown ElectroniK recorder, and it possesses the same continuous linear response to total pressure as does the Alphatron itself. Ionization is provided by means of alpha-particles emanating from an enclosed radium source.

Incorporating either strip or circular chart recorders, and full-scale sweeps of 24, 12, or 4½ sec., the recording Alphatron provides versatility to meet a demand for continuous recording of either slowly changing pressures or rapidly fluctuating pressures.

The total pressure range of 1 micron to 10 mm is covered in three separate ranges provided by the Alphatron, 0–0.1 mm, 0–1 mm, 0–10 mm. Normally, recording occurs on whichever of these three ranges the Alphatron is set. Optionally, a two-position switch can be provided to record normally in one position and in the other position to record only a single specified range. In this position the Alphatron indicates but does not record in the other two ranges.

Control of an external circuit can be provided at option also, by a mercury switch on the recorder which can be set to open or close as the pressure rises above or falls below a given value, with an accuracy of ±2 percent of the full-scale value.

The recording Alphatron is calibrated at the factory and arrives as a complete unit comprising a complete Alphatron gauge, a Brown ElectroniK recorder and a ten-foot connecting cable.

The upper scale is usually set for 0–10 mm, but can be factory-set for 0–20 mm at option without loss of linearity.—NATIONAL RESEARCH CORPORATION, *70 Memorial Drive, Cambridge, Massachusetts.*

Ultrasonic Soldering Iron

The soldering of aluminum and other light metals and alloys is made easy by means of an ultrasonic soldering iron, Type E7587, which consists essentially of a removable copper soldering bit and a magnetostriction transducer. The soldering bit, which is heated by means of a conventional resistance winding, is secured to a brass block held in firm contact with the nickel core of the transducer. The ultrasonic power necessary to drive the transducer is supplied by an electronic amplifier comprising the power supply unit.

In this new soldering iron the problem of temporarily destroying the refractory oxide film, which forms on most light metal and alloys, is solved by ultrasonic stimulation. This provides a clean surface and greatly facilitates the soldering of aluminium and other metals which form refractory oxides.

The soldering iron is simple to use, and has the advantage that no flux is required, and that standard soft solders may be employed. To avoid electrolytic action, however, it is advisable to use a solder with a tin-zinc base instead of the usual tin-lead alloy.

In application, the soldering bit is allowed to heat to the usual operating temperature. The transducer is then energized, and the bit is tinned by applying a soft solder. After this, soldering is carried out in the normal way, care being taken to maintain a good liquid contact between the bit and the work. This ensures the maximum acoustic efficiency and enables positive and uniform joints to be obtained.

The ultrasonic frequency chosen to operate the bit is well above the normal audible range, so that no discomfort is experienced by the operator.

This new ultrasonic soldering iron, which is the first commercial model of its kind in the world, should prove of particular value in the aircraft, civil engineering, shipbuilding, and hardware industries, and in fact in all manufacturing industries where the successful soldering of aluminum and its alloys has for so long been a pressing production problem.—Mullard Electronic Products Ltd., *Century House, Shaftesbury Avenue, London, W.C. 2, England.*

Variable Electronic Filter

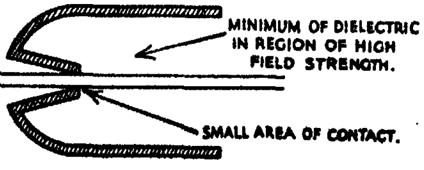
The Model 300 single-section and the Model 302 dual-section variable electronic filters have a continuously variable cut-off from 20 c.p.s. to 200 kc. Each section has an attenuation rate of 18 db per octave, and sections can be cascaded to provide 36, 54, etc. db attenuation. A range switch selects the type of section desired—high pass or low pass—as well as four decade frequency ranges. In addition, the Model 302 dual-section filter can be switched to a band pass position so that any band width between 20 c.p.s. and 200 kc can be selected.

Compact in construction and reliable in operation, the—SKL—Series 300 filters fulfill a long-felt need in sound analysis in conjunction with sound level meters, psycho-physical and physiological measurements. To the communications, radio broadcasting, recording, and moving picture industry, these new filters bring a convenience and flexibility not hereto available.—Spencer-Kennedy Laboratories, Inc., *186 Massachusetts Avenue, Cambridge 39, Massachusetts.*

"CO-AX" Very Low Capacitance Cables and Flexible Feeders

CO-AX articulated-air-insulated coaxials by Transradio Ltd. are extensively used on account of their exceptionally low capacitance and/or attenuation values and their great flexibility.

The following new types have now been added to this range of highly specialized cables: 1. *Type C34 low capacitance cable:* O.D. 0.85 in.; capacitance 4.8 mmf/ft.; impedance 231 ohms. 2. *Type C344 very low capacitance cable:* O.D. 0.85 in.; capacitance 4.3 mmf/ft.; impedance 259 ohms. 3. *Type A34 highly flexible medium power transmission line:* O.D. 0.85 in.; impedance 73 ohms. At 100-Mc attenuation is 0.65 db/100 ft. and loading 1.5 kw. Bending radius 3 in. 4. *Type A344 flexible 51.5-ohm medium power transmission line:* O.D. 0.85 in.; nominal impedance 51.5 ohms; bending radius 4 in. Loading 2.3 kw and attenuation 0.78 db at 100 Mc/sec.—Transradio Ltd., *138a Cromwell Road, London, S.W. 7, England.*



BASIC PRINCIPLE OF CO-AX AIR-SPACED CABLES

Diffusion Pump

A new fractionating oil diffusion pump, superior to previous pumps of the same size, has been developed by Distillation Products, Inc. Known as the MCF-300 pump, the new model provides a speed of approximately 300 liters per second in the range 10^{-5} to 10^{-4} mm Hg, the highest ever achieved with a 4-in. I.D. pump casing. An ultimate vacuum of 5×10^{-7} mm Hg at 25°C is attainable without cold traps.

The MCF-300 embodies three-stage concentric-cylinder type of fractionating jet assembly fitted into an enlarged boiler. The larger boiler area not only provides sufficient vaporizing surface to insure adequate fractionation and jet power, but also permits the use of external electrical heating units without danger of burn-out. The unusually powerful vapor jets are capable of pumping hydrogen one and one-half times faster than air and, with Octoil as the pump fluid, will operate against a forepressure of 0.150 mm Hg or more, depending on the heater input.

Important features are the compact size of the water-cooled casing and the ease of removal of the jet assembly for cleaning. A new, improved method of centering the jet assembly in the casing is employed. Backstreaming is low and thermal efficiency high because of the streamlined double-wall jet design.

The MCF-300 pump is recommended to the experimental physicist and research engineer for evacuation of continuously pumped electronic devices, such as, electron diffraction cameras, electron microscopes, mass spectrometers, small cyclotrons and synchrotrons, Van de Graaff machines, linear accelerators, and UHF power tubes. The new pump may also be used on vacuum coaters and other kinetic systems when unusually low pressures are required.—Distillation Products, Inc., *755 Ridge Road West, Rochester 13, New York.*

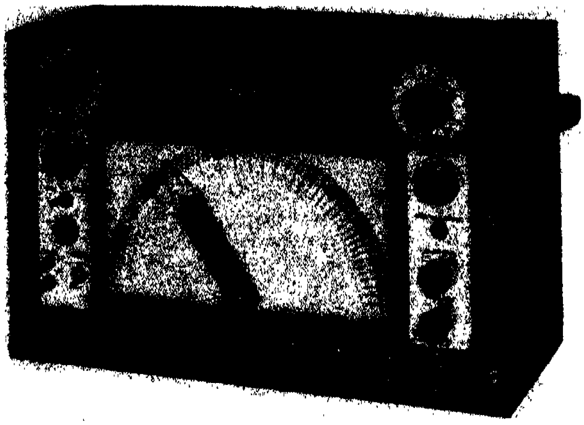
"Infinite Life" Counters

Research at Radiation Counter Laboratories, Inc. has discovered that a combination of the gas argon admixed with a small amount of xenon, oxygen, and nitrogen, yields a self-quenching Geiger counter of essentially infinite life. Data on counters with this admixture was presented recently at the symposium on Geiger counters held at the Naval Research Laboratory. These counters, like ordinary counters, operate with any standard scaler whose high voltage can go up to 1800 volts or more. No perceptible change in counter characteristics has been found up to 4×10^{9} counts. The useful counting life appears to be at least 100 times longer than for conventional Geiger counters filled with chemically decomposable organic quenching gases. Since these thin window counters have a near atmospheric pressure filling they should not be used or shipped to higher altitudes.

The counters are available with a mica window thickness of 3–4 mg/cm². For those experimenters using less energetic emitters such as C^{14} and S^{35}, mica window thicknesses of less than 2 mg/cm² are available.

Each counter tube is checked twice before it leaves the laboratory and complete threshold and plateau curves are provided with each unit tube.—RADIATION COUNTER LABORATORIES, INC., *1844 West 21 Street, Chicago 8, Illinois.*

Audiomatic Generator Model 282-A audiomatic generator is an audio sweep generator. This instrument has a low distortion beat-frequency oscillator with a manually adjustable range of 0–32 kc. Automatic frequency variation is applied to the normally fixed r-f oscillator of the BFO, and this variation is continuously adjustable by means of a dial calibrated in 500-cycle increments from 500 cycles to 10 kc.



An internal saw-tooth generator drives the frequency variation circuit at a linear time rate, and the same saw-tooth wave is made available for use as an oscilloscope deflection voltage, for the x axis amplifiers. By this means, the time base of the oscilloscope starts at the setting of the "start frequency" dial and portrays the frequency range to which the "swept band" dial is set. The time rate of the sweep circuit is adjustable from 2 to 10 sweeps per second. By adjustment of the "start frequency" dial, discontinuities in a response curve may be spread out and examined in great detail.

The purity of output waveform has been kept to rigid standards to eliminate the portrayal of spurious responses in testing band pass and high pass filters. In addition to its function as an audio sweeper, this instrument is a high quality beat-frequency type of oscillator, with less than one-half percent distortion at frequencies above 100 cycles.

The output impedances are 4000 ohms single-ended, or 600 ohms balanced to ground. Separate jacks are provided for these impedances; the center of the 600-ohm output transformer may be grounded but is also accessible for connection to the circuit under test.

Dimensions are 19 in. wide, 12¼ in. high, and 8¼ in. deep. Power consumption is 50 watts, from a 115-volt, 50–60-cycle power line.—THE CLOUGH BRENGLE COMPANY, *6014 Broadway, Chicago, Illinois.*

Manufacturers' Literature

Cenco News Chats—No. 66, winter 1949–1950 issue, contains portrait and comments on the life of Sir Isaac Newton, description of the American Petroleum Institute, performance data on laboratory gas burners, and description of an automatic vacuum and pressure controller.—CENTRAL SCIENTIFIC COMPANY, *1700 Irving Park Road, Chicago 13, Illinois.*

Metal Powders—Bulletin 567 illustrates and describes some of the more important applications for the iron, steel, nickel, manganese and silicon powders produced by the company, such as in the making of gears, bearings, bushings, magnets and magnetic cores, and also as reagents and catalysts in the chemical and process industries.—THE NATIONAL RADIATOR COMPANY, PLASTIC METALS DIVISION, *Johnstown, Pennsylvania.*

Special Films and Plates—A new 8-page booklet describes special sensitized plates and films for the scientific and industrial laboratory, and includes a description of emulsions available for spectrographic work, photomicrography, and nuclear track studies, with complete information regarding the sensitivity of these emulsions.—INDUSTRIAL PHOTOGRAPHIC DIVISION, EASTMAN KODAK COMPANY, *Rochester 4, New York.*

The Laboratory—Volume 19, No. 2, contains an article on chemical accomplishments in respect to food flavor and descriptions of a direct-reading viscometer, improved Fisher burner for natural gas, instruments for recording temperature and pressure, and an improved dropping mercury electrode instrument.—FISHER SCIENTIFIC COMPANY, *717 Forbes Street, Pittsburgh 19, Pennsylvania.*

Precision Spectrometer—Bulletin 165–50, 4 pp., describes Model L124 Precision Spectrometer, reading to one second of arc. The instrument is used principally for precise determinations of refractive indices and dispersion and for measurement of prism and wedge angles.—THE GAERTNER SCIENTIFIC CORPORATION, *1201 Wrightwood Avenue, Chicago 14, Illinois.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Copying Film

Autopositive is a sensitized film designed to produce a positive copy directly from a positive drawing without an intermediate negative step. It can be handled in normal room light and may be exposed on blueprint equipment employing a high intensity light source. The emulsion, on a translucent base, is silver-sensitized and will retain fine lines and minute detail. Material printed on opaque stock or on both sides of a page can be copied, and a right-reading print obtained by reading through the back of the film. A matte surface on both sides of the film permits making ink or pencil corrections or additions. A standard 2-solution eradicator is employed for erasing. The film can be used as an overlay in combination with cloth or paper for drawing revisions. Thirty- and 100-ft. rolls are available in widths ranging from 24 to 44 in.—EASTMAN KODAK COMPANY, *Rochester 4, New York.*

Printed Circuits

A process has been developed for supplying specified circuit layouts on ceramic, plastic, paper, and wood-base surfaces. The deposited material is normally conductive but non-conducting outlines can also be deposited. The bond is permanent, the outline is dimensionally accurate, and the deposit does not appreciably raise the surface. Soldered connections can be made as required by the user.—ELECTRO PATTERNS, INC., *68-39 79 Street, Middle Village, New York.*

Woven Glass Fabric

Soft-Flex is a processed glass fabric with crepe or herringbone weave in a 51-in. width and 6-oz. weight. It is stated to have an excellent "hand," and to be flexible without wrinkling. It is available in colors or white, plain or in patterned finishes. The material is odorless, translucent, and flameproof, and can be washed. Applications include draperies, filtering, dust collecting, and laminates.—WATERWAY PROJECTS, INC., *1008 North Highland Avenue, Los Angeles 38, California.*

Surface-Active Chemical

Rada, rosin-amine-D-acetate, is a surface-active amine salt in water-soluble form which is being used by the petroleum industry. In some oil fields the extraction of crude petroleum depends largely on secondary recovery methods, one of which is water injection. The new chemical provides control of bacterial action and affords protection against corrosion in water-flooding systems. It also acts to reduce turbidity in the flood-water, preventing plugging of oil-bearing sands.—HERCULES POWDER COMPANY, *Wilmington, Delaware.*

Rust Inhibitor

Santolene C, a hydrocarbon-soluble, water-insoluble nonmetallic organic material, is designed as a rust inhibitor for gasoline, fuel oil, kerosene, and similar light oil products in pipe lines and static storage. A dosage of 0.002 percent is effective when tested against distilled water, while 0.01 percent is required for protection against sea water. In these concentrations there is no effect on the usual specification items for gasoline, kerosene, and No. 2 fuel oil, except that the ASTM test on gasoline shows a moderate increase in gum at the higher concentrations, not more than 1 mg per 100 cc per 0.002 percent of inhibitor.—MONSANTO CHEMICAL COMPANY, *St. Louis 4, Missouri.*

Cellulose Acetate Cement

Acetate cement for bonding cellulose acetate assemblies is a solvent mixture designed to replace acetone which is highly flammable and which is considered to be a dangerous fire hazard even when stored in very small quantities. The new solvent is less volatile than acetone, and can be safely stored in unlimited quantities. In contrast with acetone, which often evaporates before it has an opportunity to soften, penetrate, and weld a cellulose acetate assembly, the new cement evaporates slowly enough to prevent blushing, has good penetration, and provides an excellent bond, according to the manufacturer. It is water-white, free-flowing, and is stated to be nontoxic.—SCHWARTZ CHEMICAL COMPANY, *326 West 70 Street, New York 23, New York.*

Pipe Insulation

K-Shield, made of foamed polystyrene, is a light-weight, rigid insulation for segmental application on vessels, pipes, and pipe fittings. It is made in three thicknesses in sizes for pipe from ¾ to 36 in., and in specified shapes for curved surfaces. It weighs from 1¼ to 1¾ lb. per cu. ft. and has a thermal conducting factor of 0.27 Btu/sq. ft./min./deg. F/in. at 70°F. it has high moisture vapor resistance and is not subject to mold growth, rot, or decay. It is nonirritating to the skin, and has no food value for insects and rodents. It is rigid, has a compression strength of 20 lb. per sq. ft., and can be cut and fitted with ordinary tools. It is designed for applications in the temperature range −250°F to 170°F.—ROBINSON INDUSTRIES, *3049 Curtice Road, Coleman, Michigan.*

Core Material

Ferroxcube, ferromagnetic ferrite, has been announced as a new transformer core material suitable for components of r-f electronic circuits. The material has a permeability more than 10 times that of powdered iron and a high electrical resistivity 10^7 times as great as that of iron. Eddy current losses are reduced as a consequence of this high resistivity.—NORTH AMERICAN PHILIPS COMPANY, *100 East 42 Street, New York 17, New York.*

Conducting Rubber Vee-Belts

Rubber, leather, canvas, and other types of belting generate static charges and, under low humidity conditions, can build up very high voltages. While the charge can be bled off by point or brush contacts on the belt surface, this device is not completely satisfactory. The accumulation of charge can be prevented by "loading" the belt with conducting material. While excessive loading will act adversely on the mechanical characteristics of the material, it has been found that normal belt life is retained when sufficient conducting material is incorporated in the belting to make it static-proof. The resistance of this belt is approximately 10 meg. when measured between disk electrodes at a spacing of 8¼ in., as determined with a 500-v megger. It may be noted in this connection that a resistance of 75 meg. for a 4-in. spacing, determined under the same conditions, is stated by one of the industrial fire insurance companies to eliminate static when operated between grounded metal pulleys.—B. F. GOODRICH COMPANY, *Akron, Ohio.*

High Resolution Recording with Soot

K. R. Eldredge*
Research Laboratory on the Physics and Chemistry of Rubbing Solids, Department of Physical Chemistry, University of Cambridge, England

(Received November 15, 1949)

The treatment of a soot coating with a hydrocarbon solvent compacts the coat so that fine lines may be drawn in it with little force. The line resolution available is somewhat better than that of ordinary photographic films. Enlargements up to fifty times the size of the original record may be usefully employed.

I. INTRODUCTION

During the course of an investigation of the mechanism of the friction of rolling it was desirable to have a simple method for recording the frictional data. It was also necessary that the method use very little force for operation since any recording force would be added to the coefficient of friction for the rolling system, which might be of the order of 0.0001.

The method using an ordinary soot film on glass or other backing was tried for recording. It was found that the coefficient of friction was high and that the lines drawn were quite jagged and wide. For soot coats that were thick enough to make good photographic reproductions, the line widths drawn were seldom less than 0.1 mm wide and were generally more. A fluffy soot coat is rather sticky and tends to pile up irregularly on the writing point.

It was found that treating the soot coat with a solvent markedly altered and improved its character for recording purposes. Sooted plates were easily made in which the necessary recording force was about one milligram, the coefficient of friction less than one, and which had a line resolution exceeding 500 lines per centimeter.

II. PREPARATION OF THE SOOT COATS

Microscope slide glass, measuring three inches by one inch, was chosen for the record material because of the ready availability and ease of storage. From five to twenty complicated records have been made on each plate. After recording the plates were lacquered and served as negatives for the production of final enlarged photographic prints.

Ground edge microscope slides which are flat and fairly free from scratches are used. Small scratches do not seem to interfere with the writing point although the soot is not cleaned from the scratch and a black speck is left on the record. The plates are cleaned so that they are fairly free from dirt but small amounts of residual grease and dust are of little importance.

The simplest source of smoke is a wax candle. The cheap, smoky varieties with a wick size large enough to support a flame of a height of two or three centimeters are the best. The soot deposited is slightly uneven but sufficiently uniform. Liquid fuels burned from a wick were also tried but with much less satisfactory results. It was found that the soot usually deposited with a string or rope-like appearance which was completely unsatisfactory for recording purposes. Burners may be devised which will produce proper soot coats but they are unnecessarily complicated for the present purpose.

During the sooting process the glass slide is gripped along the edges, near one end, with a pair of laboratory tongs with grooved jaws. The glass is held flat or nearly flat in the upper one-third of the candle flame. As the soot deposits the glass is moved back and forth until the candle flame just ceases to be visible through the soot coat. After treatment the optical density of this thickness of soot allows the easy production of black and white prints on photographic paper of any grade of contrast. Thinner soot coats will produce better line resolution but will be more difficult to print.

After the glass is sooted it is put aside for cooling. It may be cooled very quickly if it is laid flat on a metal plate. At this stage the soot is fragile and a strong puff of air or a drop of liquid on the soot surface will ruin its uniformity. The solvent may be introduced by condensation or by capillary action and, after wetting, the surface becomes much stronger. Any of a large number of ordinarily water-free hydrocarbon solvents may be used. The presence of any appreciable amount of water weakens the bond between the soot and the glass so that patches of the soot may float away.

---

* At present with the London Office of the ONR.

The condensation treatment was done by immersing the cool glass slide in the vapor phase over a solvent boiling in a large beaker. The process is finished as soon as the surface is wet with the condensed liquid. Carbon tetrachloride may be used but care should be observed to prevent the production of poisonous gases with open flames.

The three methods which have been used to introduce the solvent into the soot by capillary action are as follows:

1. The slide is tipped up at a small slope of about 1:100 and 6 or 8 drops of kerosene are put on the slide at the high end.
2. The slide is placed vertically in a closed box with the lower end in the solvent. The solvent will creep up for a considerable distance at the rate of a centimeter in 5 to 10 minutes.
3. The slide is dipped vertically and progressively into the solvent at such a rate that the capillary line in the soot is always one or two mm above the liquid surface.

The third method produces the most uniform result. The first method was generally used, but the first centimeter of the coating is spoiled where the liquid first touches the slide.

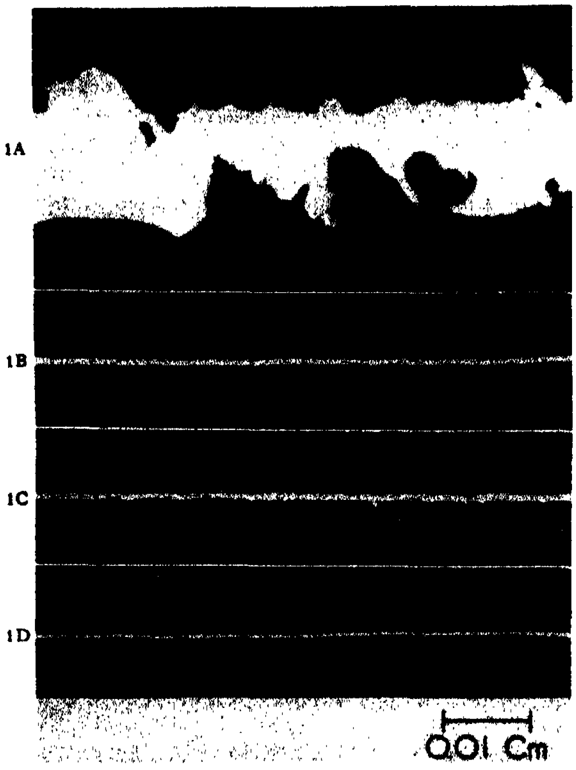

FIG. 1. Lines produced in a soot layer on a glass plate. All lines drawn with the same stylus in the same soot layer. 1A. Fresh candle soot. 1B. Soot layer treated with kerosene and line drawn while plate was still wet with kerosene. 1C. Kerosene removed with carbon tetrachloride and line drawn in dry soot layer. 1D. Soot layer re-wet with kerosene and line drawn while wet.

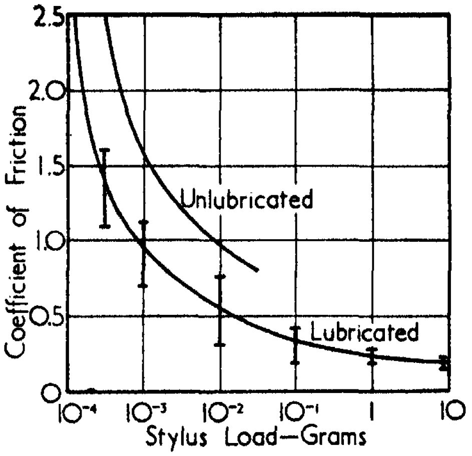

FIG. 2. Friction curves for a metal stylus moving through a soot layer deposited on glass.

The character of the soot changes markedly during the solvent treatment. The initial deep brown color of the coat changes to a neutral gray. Tar-like materials are washed out. The most striking change is the decrease of optical density. The final density obtained can be gauged by the distance of capillary wetting ahead of the liquid. If the distance is three or four mm the layer will be optically thin. If it is one-half mm or less the layer will be nearly as dense as before treatment. This applies for low viscosity liquids such as acetone as well as for higher viscosity materials such as an SAE 20 lubricating oil.

During the wetting a particle re-orientation seems to take place in the form of a vertical structure growing up from the glass surface. The granularity of the coating increases as the optical density decreases. The probability of the vertical growth arrangement in the optically thin coatings is shown by the fact that very lightly loaded writing points, which do not cut through the soot layer, produce black lines. This is apparently the result of crushing the carbon into a more compact layer.

After the initial wetting, liquid can be poured over the slide quite freely without disturbing the soot record. The slides are cleaned after recording with carbon tetrachloride in order to remove oils and particles of soot detached by the stylus. If the room humidity is high the slide should be warmed to remove any water condensed by the evaporation cooling of the carbon tetrachloride.

In order to make the slides permanent, they are lacquered after the record is made. A satisfactory cellulose lacquer may be made as follows:

Thick cellulose cement	2 parts
Amyl acetate	1 part
Acetone	4 parts.

This is poured on the sooted surface and allowed to run around by tilting the slide. It will dry in a few minutes. Sufficient lacquer should be used to produce a shiny coat since a thinner mat finish is much less resistant to handling.

III. FRICTION AND LINE CHARACTER

The force required to record in the soot or the fineness of line obtained can be favorably influenced by the treatment given to the coating, either before use or during use. Results obtained at various stages of treatment are outlined.

A. Fresh, Untreated Candle Soot

The coefficient of friction may be over two. The vertical force required to produce a line is very small but the lateral force may be many milligrams because of the stickiness of the particles. In Fig. 1 the white line shows the erratic character of the soot removal in the untreated layer compared with the lines obtained with treated soot.

B. Soot Treated with Kerosene and Used While Still Wet

The coefficient of friction of this lubricated layer, as shown in Fig. 2, varies between 0.2 and 1.0 but 0.7 is a reasonable average at light loads. The force required is very small, and stylus loads down to one milligram have given good records. The line of Fig. 1B is typical of the results achieved. The debris removed by the writing is rather fluffy in appearance.

C. Soot Coat Treated with Kerosene, Washed with Carbon Tetrachloride and Used Dry

With this treatment the coefficient of friction again reverts to the high value and writing loads of the order of ten milligrams or more are necessary to break through the soot layer. The line width, such as is shown in Fig. 1C, is, however, almost as good as that obtained in lubricated layers.

D. Soot Treated with Kerosene, Washed with Carbon Tetrachloride, Allowed to Dry and Then Re-Wet with Kerosene

This soot coat is harder and more brittle than that from method IIIB. The coefficient of friction drops to that of the lubricated value, but the minimum writing force is nearer to ten milligrams. Figure 1D is a typical result. The debris removed is quite flaky in appearance. This method produces the finest lines.

A reproduction of a small portion of a grating made in one of these coatings is shown in Fig. 3. The left side of the grating is 400 and the right side is 200 lines per centimeter in the original. The width of the individual lines is approximately 10 microns.

The frictional data shown for the lubricated soot layers in Fig. 2 are the results from over a hundred measurements made during the course of an investigation. The vertical limit lines on the lubricated soot curve include over 95 percent of the results from diverse methods of preparation and thickness of soot coats. The dry friction is exceedingly variable but the curve shown is a reasonable average of the results.

The lubricated soot curve of Fig. 2 is shown as extending to loads lighter than one milligram. This part of the curve is not ordinarily practical for use because the capillary force holding a fine writing point to the oiled soot coat is of the order of one milligram. The data were obtained by applying a negative mechanical force to the stylus.

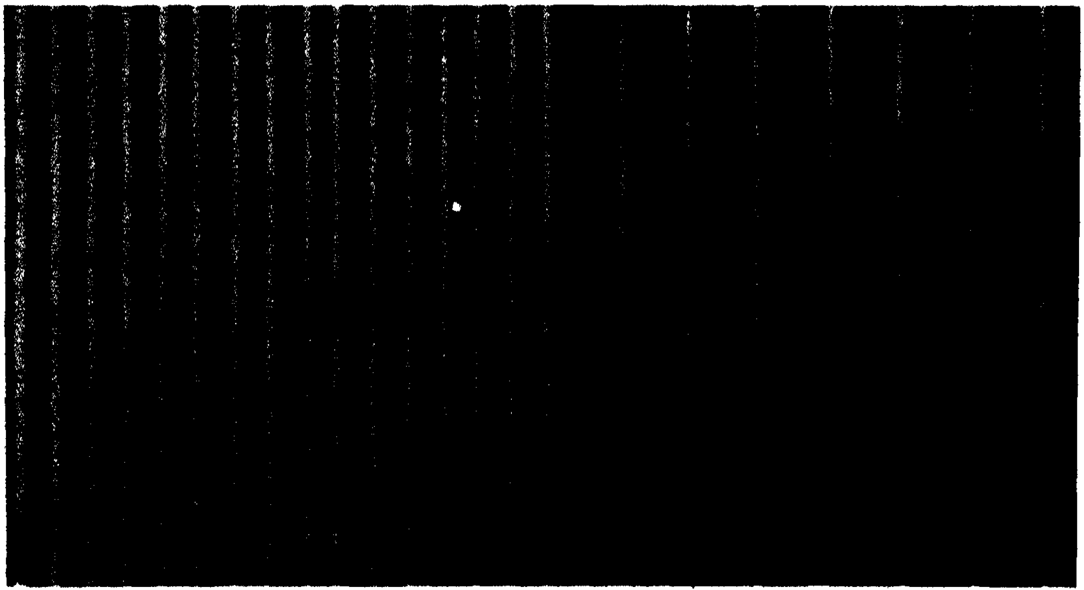

FIG. 3. Enlarged portion of a grating ruled in a treated soot layer.

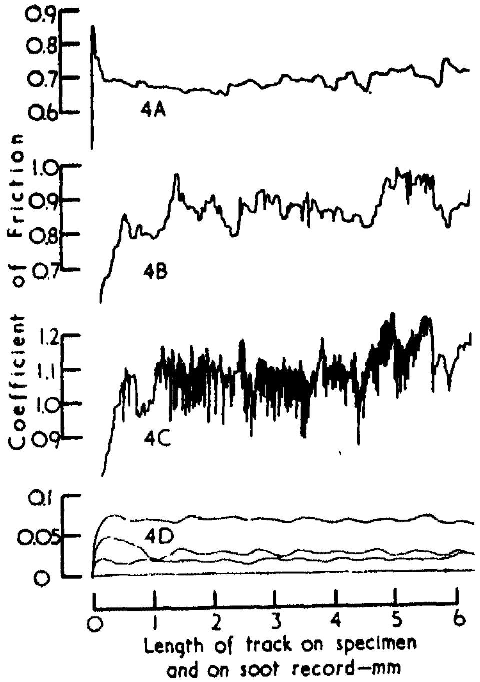

FIG. 4. Typical coefficient of friction records obtained with the soot recording method. 4A. Sliding, steel on copper, first passage. 4B. Sliding, steel on copper, second passage. 4C. Sliding, steel on copper, third passage. 4D. Rolling, steel on copper. A decrease of rolling resistance occurs after each passage over the same track.

The lubricants referred to in the above sections have been kerosene or other oils of higher viscosity. In any event it has been found that better results are obtained if the surface is actually wet and not just damp. If the record can be made within a period of a half an hour, kerosene is highly satisfactory. If longer times are necessary light lubricating oils may be used to obtain equally good records.

IV. THE STYLUS AND ITS SUPPORT

For many purposes the use of too fine a writing point may be a disadvantage. For any purpose where the record is enlarged less than about twenty times, a line width such as that of Fig. 1D may produce poor results. It will be found that such lines are so narrow that ordinary photographic enlargers will not resolve them satisfactorily.

Since the load on the writing point is very small, even copper is hard enough to serve as a durable material. Steel wire, however, of 20 B.S. gauge or smaller has generally been used. The wire is clipped off diagonally with a pair of pliers and then ground by hand to a point which is suitably fine for the purpose. The writing points used to make the records for the illustrations were prepared with little effort in a few minutes.

The complexity of the mounting for the stylus will depend upon the application. The side force required to move the stylus will be about three-fourths of the load on the stylus, if inertia forces are not considered. In general, a considerable amount of motion in the direction normal to the sooted surface will have to be allowed in order to be able to lift the stylus to change the records. If the stylus is spring mounted and not hinge mounted the lateral rigidity should be 10 to 100 times greater than the rigidity in the direction normal to the surface to prevent the tip of the stylus from lagging too far behind the writing arm. The small size of the records and the small forces required make it possible to design quite high frequency systems.

V. RESULTS

A number of typical friction records are shown in Fig. 4. These records are direct enlargements from the soot records and the lines obtained are black. The stylus used was somewhat coarser than that used for the previous illustrations in order to permit satisfactory results with 10× enlargements. The full length of the original records was 1.5 to 2 cm. After enlargement a convenient record length of 15 to 20 cm was obtained.

The records in Fig. 4 show a comparison of sliding and rolling friction under similar conditions. Both sets of records were made with a load of 600 grams on a 1.58-mm diameter steel ball sliding or rolling on an unlubricated annealed copper surface. During sliding there is an increase of friction and the development of the "stick-slip" phenomenon with successive passages over the same track. During rolling, each passage of the ball over the same track showed a decrease of friction. The friction continued to decrease measurably after twenty or more passages.

VI. ACKNOWLEDGMENT

Grateful appreciation is extended to members of the staff of the Laboratory of Physics and Chemistry of Rubbing Solids who contributed suggestions and much help in the construction of apparatus. The continued encouragement by Dr. F. P. Bowden was of great assistance.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

A Ratio-Recording Double Beam Infra-Red Spectrophotometer Using Phase Discrimination and a Single Detector[*, **]

ABRAHAM SAVITZKY[***] AND RALPH S. HALFORD
Department of Chemistry, Columbia University, New York, New York

(Received June 30, 1949)

A simple modification is described for converting a Perkin-Elmer Infra-Red Spectrophotometer to double beam operation for direct recording of percent transmission *versus* wave-length. A phase discrimination system is used, requiring no changes in the optical system, and no sacrifice of versatility or ease of prism interchange. A complete spectrum over the rocksalt region may be obtained in 25 minutes with good resolution, and with no attention from an operator. Samples as small as 1×6 mm can be studied. The system is readily adaptable to other spectrophotometers, including those in the visual and ultraviolet range, the only limitation being sufficiently rapid response by the detector.

INTRODUCTION

THE desirability of using direct ratio instruments for the recording of infra-red spectra is immediately obvious when one considers the labor involved in taking energy curves with sample in and sample out, and then carrying out the point by point division to obtain a spectrum of percent transmission *vs.* wave-length. There is also the attendant difficulty that there may be variations in source intensity or in atmospheric absorption between the two runs. An instrument which performs this function automatically must be capable of viewing the radiant energy passing through both sample and standard simultaneously.

As recently described by Williams,[1] present double-beam automatic percent recording spectrophotometers may be generally divided into two types: (a) The beams which have passed through sample and reference cells are passed through the entrance slit of the spectrometer alternately. Any difference in intensities of the two beams is seen by the detector as an a.c. signal, the phase of which determines the direction of movement of a "comb," or diaphragm to produce an optical null.[2–4] The position of the diaphragm is recorded as percent transmission. (b) The two beams pass separately through the spectrometer, and fall on separate detectors. The ratio of the two signals can be obtained by placing the reference signal across the slidewire of a recording potentiometer and balancing against the sample signal.[5–7]

In the latter system, it is necessary to contend with problems of drift, and differences in sensitivities and spectral response of the two detectors. These difficulties are not present in the former case; since it is an a.c. system, there are no drift problems and the null method eliminates errors which might arise in the detecting and amplifying system. It does, however, use a rotating mirror at one point in the optical system, with the possibility of undesirable motions amplified over the long optical path of the monochromator, and of spurious a.c. signals arising from inhomogeneities in the moving reflector. Commercial instruments based on the above systems are available but expensive.

In planning the construction of the percent recording instrument described in this paper, the authors wished to take account of the following requirements, in addition to the utmost economy:

1. Conversion of the Perkin-Elmer Model 12B Monochromator[8] in our laboratories with the minimum of changes in the optical system.
2. There should be no moving parts with critical functions in the optical system; especially no moving mirrors.
3. There should be no interference with the use of the spectrophotometer as a direct deflection instrument when desired.
4. The two beams should be as close together as possible, for ease in thermostating reference and sample cells at very low or high temperatures.
5. The high speed of response and the sensitivity of the Golay detector[9] employed in the instrument should be used to best advantage.

The instrument to be described below makes use of the phase discrimination characteristics of the breaker or commutator rectifying system. It requires no change in the basic spectrometer other than the addition of a removable superstructure containing a rotating sector, motor, and breakers. Since the sector acts merely as an on-off device, its positioning is not critical, and its

construction requires no more than ordinary care. Figure 1 is a photograph of the complete instrument.

PRINCIPLE OF OPERATION

The great selectivity, in many respects similar to that of sharply tuned amplifiers, afforded by the use of the breaker-type rectifying system has been adequately recognized and reported.[10–12] Of particular interest in the present instance is the fact that this system also acts as a phase discriminator, such that signals 90° out of phase with the breaker operation do not contribute to the d.c. component of the output signal.

The operation of the breaker system is shown in Fig. 2. The signal (a frequency of 10 c.p.s. is used in this instrument) passes from the amplifier through a phase inverter and impedance matching system, appearing at points *A* and *B* as a pair of signals (2*a* and 2*b*) 180° out of phase. The switching motion of the center point of the breaker is synchronized to be either exactly in phase, or exactly 90° out of phase, with the signal. When in phase, as shown by curve 2*c*, the output is a d.c. signal whose magnitude is proportional to that of signal entering the amplifier. When the breaker is set 90° out of phase with the square wave, as shown in curve 2*d*, the output is a square wave having twice the frequency of the input signal, and having no d.c. component to appear at the output of the filter.

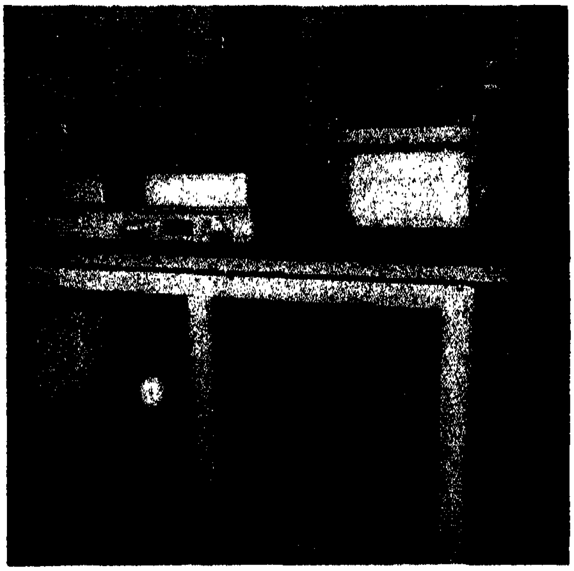

FIG. 1. The complete spectrophotometer. The amplifier is mounted behind the upper panel of the rack beneath the table, the second panel contains a standby amplifier, the third is a dummy. The control panel, providing for the functions enumerated in the text, is mounted above the Brown recorder. Test points on the front panel of the amplifier are used for monitoring the signal with the oscilloscope.

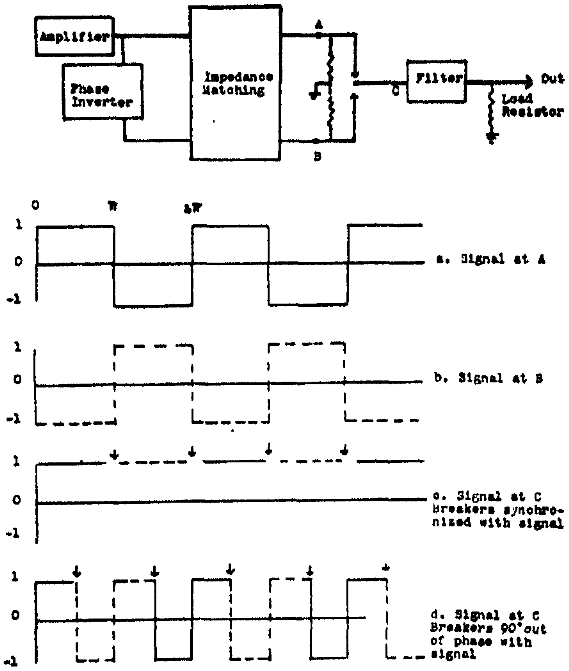

FIG. 2. Operation of breaker system.

If the signal entering the amplifier is a composite of two waves differing in phase by 90°, a pair of breakers can be used, set so that upon rectification each produces a d.c. component proportional to one of the signals, while the a.c. component due to the other signal is removed by filters.

Although the above analysis of breaker operation makes use of square waves these may be resolved by Fourier methods into a sum of sine waves consisting of the fundamental and its odd harmonics:

$$F(x)=4/\pi[\sin x-\tfrac{1}{3}\sin 3x+\tfrac{1}{5}\sin 5x-\cdots].$$

The breakers may be considered to be acting on each of these components individually. Thus, the method is applicable when one has only the fundamental frequency present, or any combination of fundamental and odd harmonics. The breaker operation is such that even harmonics of the breaker frequency do not contribute to the d.c. output in either the in phase or the 90° out of phase case. In our application of the principle we have, however, used a sharply tuned amplifier, which eliminates all harmonics but the fundamental.

The operation of the complete ratio system can be illustrated by the block diagram of Fig. 3. Radiation from the source housing passes the rotating sector which can be seen in Fig. 4, through the absorption cells, and falls on the entrance slit. The sector is shaped so that it divides the radiation beam into upper and lower halves each interrupted at 10 cycles per second, with a 90° phase difference. The beam then passes through the monochromator and falls on the detector which converts the radiant energy into a composite electrical signal of the type discussed immediately

above. After amplification, the signals are separated by a pair of breakers, 90° out of phase, and filtered. The reference signal is placed across a slidewire in a Brown recorder, and finally, the sample signal balanced against it. The position at balance is the ratio of the two signals, and is continuously recorded by a pen mechanically connected to the variable arm of the slidewire. The optical portion of the system is illustrated in Fig. 4.

THE MECHANICAL SYSTEM

The "superstructure," above the source housing in Fig. 4, contains the sector disk, synchronous motor, and breakers. In order to achieve good mechanical balance one revolution of the sector corresponds to two electrical cycles and so it is driven at only 300 r.p.m. Connection is made to the breakers by a 2 to 1 bevel gear. The breakers themselves are a war surplus item† and, since they are designed to be run at 1800 r.p.m. in both the input and output ends of a 30-megacycle receiver, are remarkably sturdy, free of noise, and provided with all necessary phasing adjustments. The entire superstructure can be raised or lowered, varying the proportion of energy in the sample and reference beams as desired. It can be raised till the entire beam passes through only the outer portion of the sector, for direct deflection records requiring the maximum energy. Moreover, the assembly can be moved parallel to the optic axis in the space between housings, permitting the use of large or small cells at will. The cell must, of course, be placed close to the rotating sector.

If desired, when recording directly, the superstructure can be removed entirely. An auxiliary on-off disk run by a 600-r.p.m. synchronous motor is placed directly in front of the globar. The motor is rotated until the sector interrupts the light in phase with one of the two breakers on the superstructure.

THE DETECTOR

Since the successful operation of this instrument depends in no small part upon the fast response and high sensitivity of the Golay cell, a description of its operation is given here. The position of the detector is shown in Fig. 4. The energy from the exit slit is focused on the detector by a silver chloride lens. The detector itself[9] consists of the pneumatic cell, in which radiant energy falling on an absorbing membrane heats the gas in the cell. The pressure change due to this heating is transmitted through a small constriction to a second chamber where it distends a flexible mirror. The motion of this mirror is amplified by an optical lever system of line grids. Changes in light intensity are observed by a thalofide (thallous sulfide) photo-conductive cell.[13]

Extensive studies have been made on the sensitivity of our detector which has an air filled cell. At present the equivalent noise input (ENI) of the detector-am-

FIG. 5. Amplifier circuit diagram.

plifier system is believed to be $\pm 1\times 10^{-10}$ watt R.M.S. for an amplifier time constant of 2.3 seconds.[††, 14]

At least a $\sqrt{5}$-fold improvement would be expected if the air were displaced by xenon.[15] However, replacement of the Golay cell and optical grid by a plane mirror causes no more than 25 percent reduction in the noise level, if any, indicating that at least the major part of the noise originates in the optical amplifier, either in fluctuation of lamp intensity or movement of the lamp filament, since extinguishing the lamp removes practically all noise from the system. This leads us to conclude, subject to the reservation concerning the energy standard employed, that the intrinsic ENI of the Golay detector is less than $\pm 5\times 10^{-11}$ watt R.M.S. in our arrangement. In this circumstance an even greater improvement is to be expected from the substitution of xenon, which causes five-fold increase of response at the expense of $\sqrt{5}$-fold increase in that part of the noise only which originates in the Golay cell. We have not sought this improvement since we have already attained the operating condition wherein the prism itself usually constitutes the major limit of resolving power and since, for ratio measurement, we preferred the more rapid response of the air cell.

The noise level is not altered perceptibly by removal of the superstructure, although the mechanism is audible when operating.

THE AMPLIFIER

The output of the thalofide cell is transmitted to the amplifier (Fig. 5) through a coupling network[16] which acts as a filter having a pass band approximately 30 cycles wide. The amplifier proper consists of three resistance-coupled triode stages. Further narrowing of the amplifier passband is achieved by use of a twin-*T*

[††] The sensitivity of this detector was not measured directly. Dr. Van Zandt Williams of the Perkin-Elmer Corporation has kindly supplied the information that, measured with a thermocouple of known sensitivity, the energy at the exit slit of a Perkin-Elmer spectrophotometer, with Globar at 250 watts, at 955 cm^{-1} and slit of 0.085 mm, is about 2.7×10^{-8} watt. The above result for our Golay cell is obtained from the observation that, for a deflection of 80 percent of full scale, the noise level is 1 percent to 1.5 percent, peak to peak, measured over an interval of at least 15 minutes. A factor of 4.6 is used for conversion of peak to peak values to R.M.S. (see reference 14). The above sensitivity measurement is offered primarily for comparison with other detectors installed in Perkin-Elmer instruments.

FIG. 6. Schematic diagram of control panel and recorder modifications.

negative feed-back network[17–22] in the second stage. Gain is controlled in the conventional manner at the input to the third stage. Unbypassed cathode resistors provide grid bias. Cathode followers are used for impedance matching between the amplifier-phase inverter plate circuits, and the low impedance filters. Since the signals from the two cathode followers must have the same amplitude, a balance control is provided at the phase inverter input.

Most of the amplification of the detector signal occurs in the optical amplifier preceding the thalofide cell, reducing the gain requirements for the electronic amplifier so that Johnson noise and other random effects in it are completely negligible. This greatly decreases the restrictions on the first triode stage, so that no more than ordinary precautions[23] must be observed in construction. However, because of the unusually high capacities of the cathode coupling condensers, C_8, C_9 C_{10}, and C_{11}, leakage resistance becomes of great concern, requiring the use of 600-v oil filled paper capacitors. The resistance-capacitance filter system (Fig. 6) has been furnished with variable capacities to provide a wide range of response times.

Filament power is obtained from 6-v storage batteries. For greater stability, the exciter lamp used in the Golay optical amplifier is supplied from a set of No. 6 dry cells. To avoid undesirable feedback across the *B*-battery plate supply, it was found necessary to provide a separate supply for the cathode followers. While this might have been avoided by the use of decoupling filters in the early amplifier stages, these are quite difficult to construct for this low frequency.

To allow for the use of an oscilloscope in locating troubles in the amplifier, and for monitoring purposes, test points, marked by ⊗ in the circuit diagram, have been connected to banana jacks on the front panel.

CONTROL PANEL AND RECORDER

The circuit of the control panel, located above the recorder in Fig. 1, is shown in Fig. 6. The signals from the pair of breakers and the filter system are now completely independent, and can be called signal *A* and signal *B*. These, together with a constant signal, *C*, obtained from potentiometer R_{37}, appear at the selector

switch, S_3, which allows one to take the ratio of B/A, A/B, A/C, or B/C.

Switch S_4 permits "expansion" of the ratio scale so that the full range of the ratio potentiometer can be used to record ratios from 0–50 percent, or 50–100 percent, as well as the normal 0–100 percent. The position of the "100 percent" mark is completely arbitrary, since it is determined by the relative amounts of energy in the reference and sample beams. A rough setting can be made by raising or lowering the sector. Potentiometer R_{39}, acting in the same manner as a gain control, is used for a fine setting of the ratio maximum.

The ratio slidewire R_{47} is mounted at the rear of the recorder chassis, Fig. 7, and is coupled mechanically to the cable drum which drives the pen and variable arm of the recorder slidewire. The ratio slidewire acts as the load resistor for the reference circuit, except when recording the ratio of A/C or B/C. The ratio fine control, R_{39}, is the load resistor for the sample circuit. The potentiometer used for R_{47} should have the same useful angle of rotation as the recorder cable drum; the General Radio type 214-A can be made to match closely by filing the end stop.

Rapid change of the recorder functions is provided by the use of push buttons. The shift from normal recording to ratio recording is made by a relay actuated by Button 1. The relay is mounted underneath the Brown amplifier. Pressing any other button releases the relay, allowing the recorder to function normally. Thus signals A, B, or C may be recorded directly at any time. In addition, positions have been provided for recording signals from any other equipment which might be used with the spectrometer, such as heater thermocouples.

FIG. 7. Ratio slidewire at rear of recorder chassis.

The characteristics of the rectifier system are such that the output signals are referred to a ground or zero potential, which always places the signal zero at the zero of the recorder. When desired, such as when observing detector performance by signal to noise ratios, the signal zero for direct deflection from either channel can be placed at any other point on the paper by means of switch S_5 and potentiometer R_{38}.

The Brown recorder is modified electrically only by the addition of the relay and slidewire mentioned above. The automatic standardization has been mechanically disconnected.

SLIT CONTROL

Although the ratio recording system will compensate for most variations in the energy entering the spectrometer, such as the water vapor and carbon dioxide absorptions, the response of the Brown amplifier tends to fall off when the reference signal falls below 4–5 millivolts. Because of the enormous variations of globar energy with wave-length[24] some method of slit adjustment must be provided.

At present, continuous slit control is achieved by use of the Perkin-Elmer slit cam. This device is unfortunately quite inflexible, allowing for only one set of operating conditions, such that it can be used only with the NaCl prism and even then it affords only one slit schedule, suitable for use with liquids and gases. Solids and slurries that scatter appreciably, as well as single crystals whose apertures are likely to be small, require larger slits, especially when examined with polarized light, than are obtainable with the device. Some helpful variations can be attained by using drums of various diameters on the slit micrometer in addition to the one provided. Table I shows slit widths obtained with the standard drum. The peak noise to signal ratio with these slits amounts to about 1 percent on the ratio scale for a filter time constant of 2.5 seconds.

Ideally, of course, slit control should be based on the amplitude of the signal in the reference channel. Two methods are suggested, one manual, the other automatic:

1. The amplifier signal may be monitored by means of an oscilloscope plugged into one of the breaker test points. The slits are reset manually when the signal falls below a specified level on the oscilloscope screen.

2. Figure 8 shows a suggested‡ automatic slit control

---

[24] See reference 1, p. 146.

‡ We have been informed by Professor D. F. Hornig that he has been using a mechanism of this kind with success.

system, which has not yet been tested. The breaker shown is operated by an auxiliary synchronous motor, which is adequate to keep the breaker phased properly once it is set to select the reference signal. A filter of very long time constant should be selected to prevent rapid changes in slit width when passing through the water vapor region. The desired reference signal level is selected by adjustment of the potentiometers R_L and R_B.

ABSORPTION CELLS

A typical cell for non-volatile liquids consists of a round rocksalt plate, on which is placed a semicircular plate. The sample is placed between the semicircular and circular plates and the assembly clamped in a brass cell holder. The single thickness of NaCl acts as the reference cell.

To make a cell for volatile liquids, the half-plate may be heated, Saran thread[25] allowed to flow around the edges, and a heated round plate pressed on. The Saran acts as a cement, so that no holder is necessary. Holes drilled in the half-plate allow filling by hypodermic needle. A cell for solution *vs.* solvent records can be made in a similar manner, with the Saran melted around the edge of the full plate, and across the diameter to divide the cell into two sections. Alternatively, cells have been made with metal spacers. A good seal is achieved with stopcock lubricant of the glycerol sugar type.[26]

Solids may be studied in Nujol suspensions smeared on half of a circular rocksalt plate. To compensate for the effect of scattering and of Nujol absorption, a paste of sulfur in Nujol can be used on the other half of the plate. Single crystals and fibers have been placed near the slit on one side of a horizontal, reflecting tongue that extends out to the sector, the latter being near the monochromator housing.

Gas cells may be constructed by soldering a highly polished brass plate between the two halves of a brass cylinder so that four semicircles of rocksalt can be fastened to the ends. The reflecting partition will return to the beams all rays that normally would cross the optic axis along its length and thus reduce light loss to a negligible level.

An opaque strip is placed across all cells to define sharply the two halves. This greatly increases the tolerances in machining the edge defining the inner and outer portions of the sector, yet can be made narrow enough to intercept not more than a very small fraction of the beam.

PERFORMANCE

One of the chief reasons for constructing this double beam instrument was the desire to eliminate from the spectra the effect of absorption by atmospheric water vapor and carbon dioxide. However, when first tested, the instrument fluctuated violently when passing through the regions of atmospheric absorption. Investi-

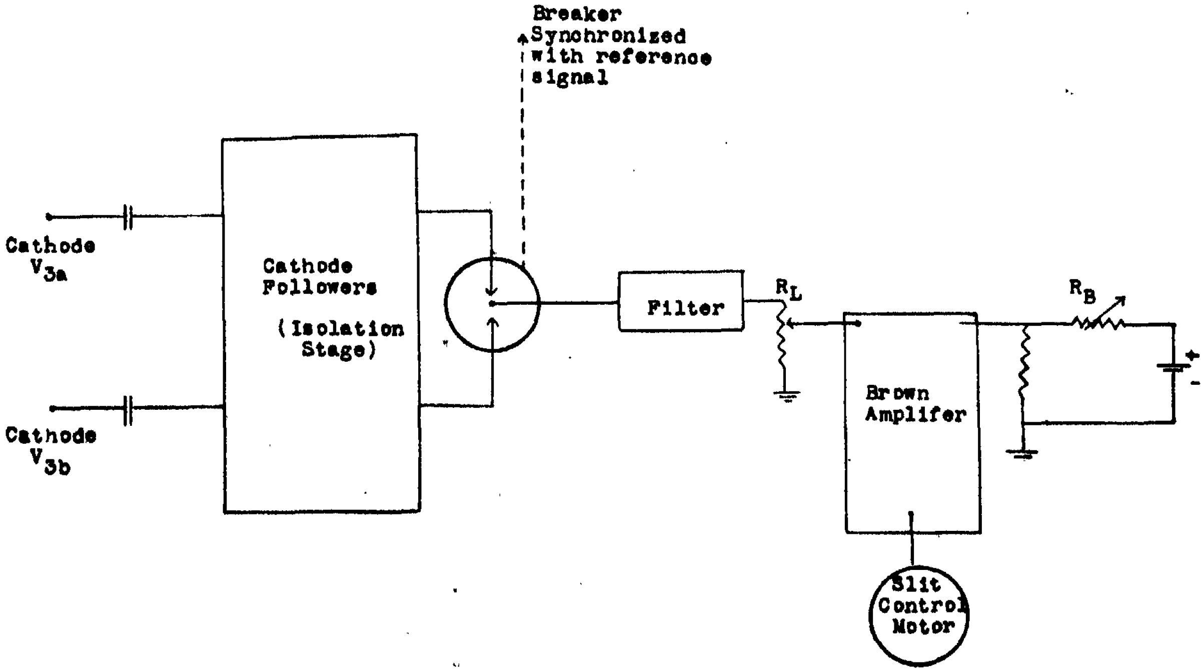

FIG. 8. Block diagram of proposed automatic slit control system. Input is taken from the cathodes of V_{3a} and V_{3b}, Fig. 5, through 1-mfd condensers. The cathode follower stage and breaker connections are exactly similar to those of V_{3a} and V_{3b}. An auxiliary Brown amplifier and control motor must be used. Slit widths are determined by the settings of R_L, R_B and the amplifier gain control.

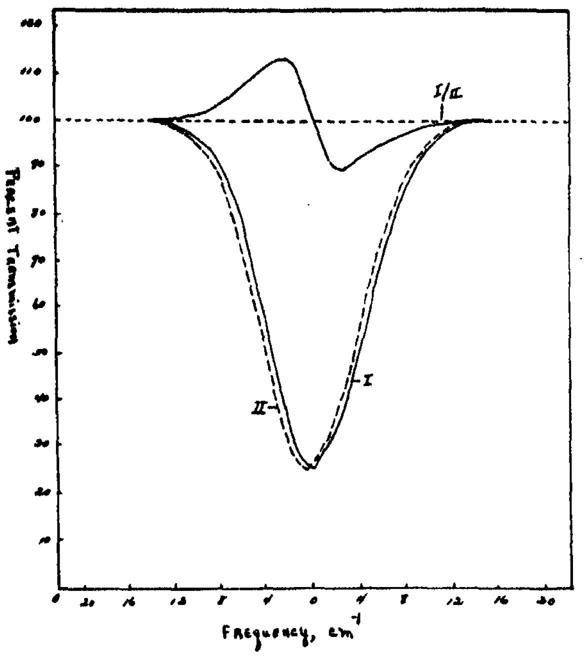

FIG. 9. I and II, Gauss error curves; half-width 10 cm⁻¹, centers displaced by 0.5 cm⁻¹, illustrating the effect of spectral displacement on the ratio I/II.

gations showed that this failure of the ratio device was due to misalignment of the spectrometer optics, in that the two beams pass through the spectrometer on slightly different paths, and the upper and lower portions of the exit slit were receiving slightly different regions of the spectrum. The effect of such displacement of the two spectra is shown in Fig. 9, where, for illustration, Gauss error curves have been drawn with half-amplitude widths of 10 cm^{-1} and with their centers displaced by only 0.5 cm^{-1}. An important characteristic of such curves is a cross-over point where the ratio passes rapidly through unity, giving rise to the violent fluctuations referred to above. Records obtained before adjustments were undertaken are quite similar to curve I/II in Fig. 9. Since the resolving power of the instrument in the water vapor region is about 10 cm^{-1} with the slit normally used, the criteria of adjustment for removal of this effect must be far higher than for ordinary operation of the spectrometer. We have found the most effective adjustment to be the tilt of the small exit mirror which is mounted at the rear of the prism table. The mirror is spring loaded against an adjusting screw which was not designed for the fine adjustment required here. However, once adjusted a prism may be removed and replaced without seriously affecting the setting of the mirror, which has had to be readjusted only once in 5 months of operation, immediately after moving the spectrometer and its accessories to a new location.

The degree of success in removal of the water vapor bands is demonstrated in Fig. 10, which shows the signal in the reference channel (I), sample channel containing anisole (II), the ratio of these two signals (III), and the ratio of reference to sample signals without an absorber in the sample beam (IV). These spectra were taken with the CaF_2 prism, which has a much higher resolving power in this region than the NaCl prism,[27] thereby exaggerating the difficulty of compensating for atmospheric absorption by sharpening the individual bands, under the scanning conditions employed. While the water bands may not have been completely eliminated, any residual bands are small, and so could be allowed for in the evaluation of the anisole spectrum without the necessity of the point by point division which would be required in the case of the direct deflection spectra. Figure 11 allows one to judge results obtained with the NaCl prism.

A part of the fluctuation in curve IV must be ascribed to increased noise to signal ratio due to the large water

vapor absorptions. This effect will appear whenever there is atmospheric or solvent absorption in the reference channel. Because the noise level is determined by the amplifier gain setting, the noise in the sample channel will be equal to the noise in the reference channel when the Ratio Fine Control is at its maximum setting, and less than the reference channel noise at any other setting of this control. If n is the noise level in signals s and s', and r the noise level in the ratio $R = s/s'$, then the noise, expressed as fraction of the ratio scale, is $r = n/s'(1+R^2)^{\frac{1}{2}}$, showing that (1) the noise for percent recording will never exceed $\sqrt{2}$ times the percent of noise in the reference channel, and (2) for a given ratio, R, the noise in the ratio is inversely proportional to the reference signal.

The foregoing relations governing propagation of noise into the ratio have been verified experimentally within the limits imposed by the difficulty of measuring noise. Moreover, for $R \leqslant 1$, $s' \geqslant (s+s')/2$, and it follows that $r \leqslant 2\sqrt{2}n/(s'+s')$. That is to say, the noise on the ratio scale should not exceed $2\sqrt{2}$ times the noise to signal ratio observed when the instrument is used in the conventional manner with a single beam including the entire aperture at the same gain and slit. The factor of 2 arises from division of the aperture into two parts while the factor of $\sqrt{2}$ comes from the usual statistical multiplication of noise in the quotient of two equally noisy signals. We have verified experimentally that the observed noise r has this theoretical value, again within the limits of error involved in any measurement of noise. The observed, theoretical noise on the ratio scale in our instrument is thus not more than twice the corresponding theoretical noise in one using the optical null method,[2–4] where each beam includes the entire aperture. On the other hand, if undesirable motions of the moving mirror, or inhomogeneities of its surface, or misalignment of the beams intersecting upon it, introduce any noise in an optical null instrument its theoretical advantage may be offset in this way. We cannot say from our own experience how the actual noise in such instruments compares with the theoretical value, inasmuch as the commercial instruments we have examined do not include provision for their use as single beam direct deflection instruments.

The amount of cross talk between channels is determined by the accuracy of phasing the breakers. Channel A is blocked, and the signal in channel B set to full scale on the recorder. Doubling the slit then gives a signal which is four times full scale. Channel A is connected to the recorder and its breaker is adjusted so that the signal is less than 1 percent of full scale, although the signal in channel B is still four times full scale. The procedure is repeated for the other channel, leaving a maximum cross talk in each signal of less than 0.25 percent.

A complete spectrum of liquid benzene from 5000 cm^{-1} to 700 cm^{-1} (the NaCl region), Fig. 11, was recorded in 50 minutes. This can be compared with spectra published by Wild[7] and the American Petroleum Institute with the National Bureau of Standards.[28] The 100 percent line (ratio blank without absorber) under the same conditions remains steady between 800 and 2500 cm^{-1}, but rises through a few percent at longer and shorter wave-lengths. The rise at short wave-lengths is caused by differential absorption in the imperfectly positioned silver chloride lens, at long wave-lengths, by stray light which is unequally distributed between the two beams. The first effect can be eliminated by substitution of reflecting optics for the lens, the second one by the use of filters.

Survey spectra are ordinarily run in 25 minutes with

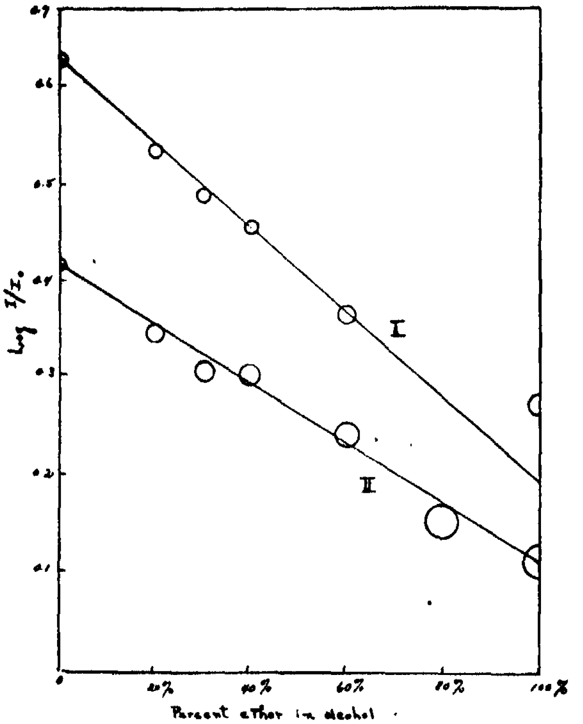

FIG. 12. Infra-red analysis of mixtures of methylethylisobutyl carbinol and its methyl ether.

slight loss of resolution in the region from 5000 cm^{-1} to 2000 cm^{-1} with the response time used here. All the resolution shown in Fig. 11 may be retained at the higher scanning speed by increasing the speed of response, with consequent increase in the noise level. The compromise between recording speed and response time is entirely at the discretion of the operator and is selected to suit the problem. Time constants (time to reach 63 percent of full deflection) of the ratio system range from 1.2 to 2.25 seconds. The lower limit is imposed by the maximum rate at which the pen can be driven (3.8 sec. for full scale deflection[14]). The accuracy of the ratio measuring device was checked by comparing calculated and measured ratios of A/B, A/C, and B/C in the range 15 percent to 90 percent, with applied signals of 1.6 to 10 millivolts. Maximum error was found to be 1.1 percent with an average deviation of ±0.4 percent, which was well within the peak to peak noise level of 1 percent. Further evidence, less accurate, but included for the sake of completeness, of the fidelity of the ratio measurement, as well as of the separation of the sample and reference signals, is given in the Beer's Law curves of Fig. 12, in which the logarithm of I/I_0 is plotted for various solutions of methylethylisobutyl carbinol and its methyl ether.[29] Curve I is based on an ether band at 810 cm^{-1}, curve II is based on an ether band at 840 cm^{-1}. The data are rough because solutions were made up by dropper to a total volume of 20 drops. Spectra were observed using a sealed cell with 0.1-mm aluminum spacer *versus* a single rocksalt plate in the reference half of the beam. The circles indicate only ±0.5 percent in transmission, while the maximum peak to peak noise level of the records was 1.5 to 2 percent.

We have verified experimentally that the ratio remains independent of slit width and amplifier gain over the whole range of adjustments available to us. The noise on the ratio scale also is observed to be independent of gain.

SUMMARY

A ratio-recording double beam infra-red spectrophotometer has been described which can be constructed with no changes in the optical system of the commercial monochromator and with no sacrifice of versatility and ease of prism interchange. There are no very exacting requirements in either the mechanical or the electrical design. Its cost is little, if any, more than the cost of conversion of a d.c. instrument to ordinary a.c. operation. Percent-transmission spectra over the complete rocksalt region can be obtained in 25 minutes with good resolution, and with no attention from an operator. With the sector moved very close to the slit, samples less than 1×6 mm in size can be studied. In the extreme cases where it is necessary to work at the limit of resolution of the monochromator, the instrument can be immediately converted to direct deflection operation but with a gain in the signal to noise ratio of at most a factor of two. Any rapid response detector, such as the nickel-strip bolometer, the Thermistor detector,[30] or fast thermocouple could be substituted for the Golay cell with appropriate changes in the amplifier, although there might be some loss in signal to noise ratio, depending on detector speed.

It should be emphasized here that this system is readily adaptable to visible and ultraviolet spectrophotometers, as well as to any infra-red instrument. Where photo-tube operation is possible, fast response of the detector is not a problem, and the signal frequency can be increased to some more conveniently handled value than 10 cycles per second.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

Focusing Properties of a Generalized Magnetic Spectrometer

David L. Judd*
California Institute of Technology, Pasadena, California

(Received August 1, 1949)

The first-order focusing properties of a magnetic spectrograph similar to that of Siegbahn and Svartholm, but differing in that both source and collector lie outside the field, are investigated. The parameters of the analogous thick lens optical system are derived. General expressions for image distance, astigmatism, magnification, solid angle, dispersion, and resolution of lines with a spread in momentum are obtained. Factors affecting the compromise between intensity and resolution are discussed. The possibility of increasing resolution without loss of intensity by introducing some astigmatism is considered. Second-order effects have not been included since they are thought to be of the same order as corrections for the fringing field. The first approximation proved adequate for the design of an instrument in which satisfactory focusing was obtained by simple empirical adjustments.

I. INTRODUCTION

In the double-focusing or anastigmatic magnetic spectrometer developed by Siegbahn and Svartholm,[1] both source and collector are located in the magnetic field. This arrangement is experimentally inconvenient, especially if the source is to be activated by artificially accelerated particles. For this reason, a study was made of the focusing properties of a modified arrangement in which both source and collector are located outside the field, as a guide to the design and construction[2] of such an instrument. The first-order theory of images formed by particles whose paths are paraxial to an optic axis, in analogy with Gaussian optics, can easily be developed from simple geometric considerations; the deviations from the equilibrium trajectory are known to be sinusoidal[3] to first order inside the field region, and rectilinear outside it. It was not considered worth while to calculate the more involved second-order aberrations since they will be of the same order of magnitude as other aberrations resulting from the effects of the fringing field[4] and other discrepancies between ideal and practically attainable fields. This opinion was justified by the fact that satisfactory focusing of the spectrometer finally constructed[2] was attained through simple empirical adjustments of source and collector positions.

II. THE MAGNETIC FIELD

The field is assumed to exist only in the wedge-shaped region between the planes $\vartheta=0$ and $\vartheta=\theta$ of a cylindrical polar coordinate system r, ϑ, z. In this region it is assumed to be symmetric about the plane $z=0$ and to be independent of ϑ. If its components are expanded in double Taylor series about the values at $r=r_0$, $z=0$, and only constant and first-order terms retained, Maxwell's equations and the symmetry conditions yield

$$H_z \approx H_{z0}[1-n(r-r_0)/r_0]; \quad H_r \approx -nH_{z0}z/r_0$$

where H_{z0} is a constant; $H_z \propto r^{-n}$ near $r=r_0$, $z=0$. The two field parameters of importance in the first-order theory are θ and n; there is no focusing unless $0<n<1$. The fringing fields near $\vartheta=0$ and $\vartheta=\theta$ are neglected since they lead to second-order corrections.

III. FOCAL DISTANCES

Let a point source of monoenergetic charged particles of rest mass m_0, velocity v, mass $m=m_0[1-v^2/c^2]^{-\frac{1}{2}}$, and charge e be placed in the plane $z=0$, outside the field at a distance d_0 from the plane $\vartheta=0$ on a line tangent to the circle $r=r_0$, $z=0$ at the edge of the field [Fig. 1(a)]. If $H_{z0}=-mv/er_0$, a particle whose path is normal to the plane $\vartheta=0$ outside the field will be bent in a circle of radius r_0 in the field, and will emerge normal to the plane $\vartheta=\theta$. Its path will lie in the plane $z=0$, and will be called the optic axis of the system. Particles following paraxial trajectories lying in the plane $z=0$ will focus on the optic axis at a distance d_r beyond the plane $\vartheta=\theta$; particles following paraxial trajectories whose projections onto the plane $z=0$ lie on the optic axis will focus on this axis at a distance d_z beyond the plane $\vartheta=\theta$ [Fig. 1(b)]. We shall measure all distances in units of r_0 to simplify the notation.

To find d_z and d_r we note[3] that inside the field $z=A\sin n^{\frac{1}{2}}(\vartheta-a)$; $r-1=B\sin(1-n)^{\frac{1}{2}}(\vartheta-b)$, where A, B, a, and b are constants. Also

$$\partial \log z/\partial\vartheta\,|_{\vartheta=0}=d_0^{-1}; \quad \partial \log z/\partial\vartheta\,|_{\vartheta=\theta}=-d_z^{-1},$$

and similarly for r; hence

$$\tan[n^{\frac{1}{2}}\theta+\tan^{-1}n^{\frac{1}{2}}d_0]+n^{\frac{1}{2}}d_z=0,$$

and d_r is obtained by replacing $n^{\frac{1}{2}}$ by $(1-n)^{\frac{1}{2}}$. We may thus obtain d_z and d_r for given d_0, θ, and n from the two equations (obtained by taking either subscripts r or z)

$$\phi_{r,z}+\phi_{r,z}'+\theta_{r,z}=\pi,$$

where

$\tan\phi_z=n^{\frac{1}{2}}d_0$, $\tan\phi_z'=n^{\frac{1}{2}}d_z$, and $\theta_z=n^{\frac{1}{2}}\theta$, and quantities

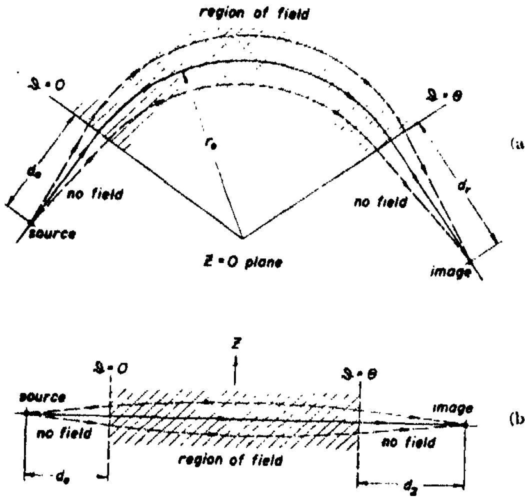

FIG. 1. (a) Radial focusing; (b) vertical focusing.

with subscripts r can be obtained by the same substitution. These equations have the simple geometric interpretation of Fig. 2. They are quite general, and include as special cases the results of Stephens[5] in which $n=0$ (uniform field) and of Siegbahn and Svartholm[1] in which $n=\frac{1}{2}$, $d_0=d_r=d_z=0$, and $\theta=2^{\frac{1}{2}}\pi$. In Stephens' case, Fig. 2(b) becomes the physical diagram of field, object, and image. The well-known semicircular focusing method comprises a special case of Stephens' result when $d_0=d_r=0$ and $\theta=\pi$. If $n=\frac{1}{2}$, Figs. 2(a) and 2(b) become identical and we have a point image for paraxial particles. The equations are not applicable to negative d's. For double-focusing, the first-order astigmatism is

$$d_z-d_r=\{d_z+(1+d_z^2/2)[\theta+d_0/(1+d_0^2/2)]\}(1-2n)$$

for n near $\frac{1}{2}$, and approximately equals $5(1-2n)$ for $d_0\sim d_z\sim d_r$ and $\theta=\pi$.

Since the system acts like a thick lens, focal points and unit planes may be located in analogy with the usual optical treatment.[6] The nodal points coincide with the unit points due to the symmetry of the lens. The principal foci are found by setting $d_0=\infty$; for vertical focusing they lie outside the field edges by distances $\Delta_z=(n^{\frac{1}{2}}\tan n^{\frac{1}{2}}\theta)^{-1}$, and Δ_r is obtained by replacing $n^{\frac{1}{2}}$ by $(1-n)^{\frac{1}{2}}$. The focal length f_z is found from the equation $(d_0-\Delta_z)(d_z-\Delta_z)=f_z^2$, yielding $f_z=(n^{\frac{1}{2}}\sin n^{\frac{1}{2}}\theta)^{-1}$, and similarly for f_r. The unit planes lie inside the field edges by distances $u_{z,r}=f_{z,r}-\Delta_{z,r}$;

$$u_z=n^{-\frac{1}{2}}(\csc n^{\frac{1}{2}}\theta-\cot n^{\frac{1}{2}}\theta)=n^{-\frac{1}{2}}\tan 2^{-1}n^{\frac{1}{2}}\theta,$$

and u_r is similarly obtained. All of these relationships are illustrated in Fig. 3. The unit planes always lie inside the field region for cases of practical interest, but the principal vertical (or radial) foci may lie either outside or inside according to whether $n^{\frac{1}{2}}\theta$[or $(1-n)^{\frac{1}{2}}\theta$] is less or greater than $\pi/2$. The Siegbahn instrument represents a limiting case in which $\Delta=f=\infty$, $u=0$.

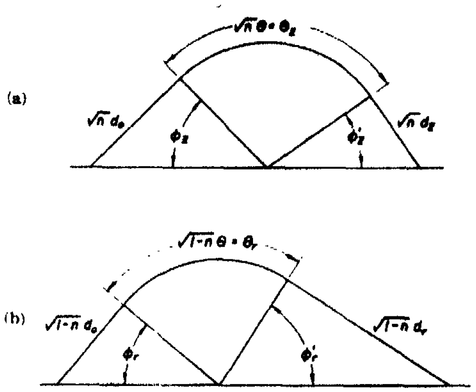

FIG. 2. Geometric relations for (a) radial focusing; (b) vertical focusing.

IV. MAGNIFICATION

The vertical magnification M_z is defined as the ratio of image height to object height measured normal to the plane $z=0$; the lateral magnification M_r is similarly defined. We define M_r and M_z to be positive if the image is inverted in the respective directions; they can be found from the equation $M=f/(d_0-\Delta)$, which results in the two equations

$$M_{r,z}=(\tan\phi_{r,z}\sin\theta_{r,z}-\cos\theta_{r,z})^{-1}.$$

These give $M_r=M_z=1$ for the Siegbahn arrangement and for any other symmetric arrangement of object and image.

V. SOLID ANGLE

If the paraxial beam of particles attains its maximum cross-sectional dimensions in the radial and vertical directions inside the field regions (i.e., if d_r and $d_z\leq\infty$, corresponding to converging or parallel outgoing beams) and if the available cross-sectional area Ar_0^2 is independent of ϑ, then the solid angle Ω in which emitted particles reach the focal points is independent of the field angle θ and of the values of ϑ at which the maxima are attained. It can be shown that

$$\Omega/A=[(1+d_0^2)/n(1-n)+d_0^4]^{-\frac{1}{2}}$$

subject to the usual cosine approximation for beams of small divergence. This function is plotted in Fig. 4;

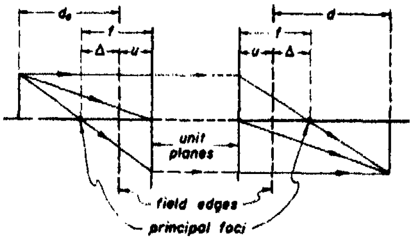

FIG. 3. Thick lens analogy.

[6] For example, P. Drude, *Theory of Optics* (Longmans, Green and Company, New York, 1939), Chapter II.

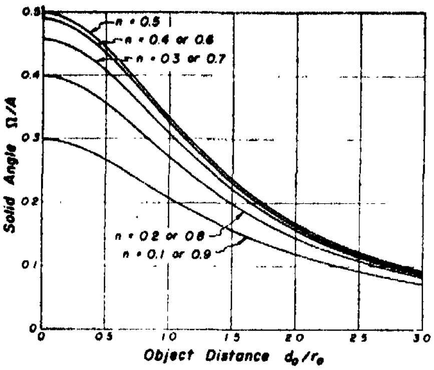

FIG. 4. Solid angle *versus* object distance for different n.

$\Omega/A=\frac{1}{2}$ for the Siegbahn case. If $n=\frac{1}{2}$,

$$\Omega/A=(d_0^2+2)^{-1}.$$

VI. DISPERSION

Suppose that the field H_{z0} is adjusted for focus of particles of momentum $p=mv$, as described previously; then, if particles of momentum $p+\delta p$ are emitted from the same point source, their focal distances d_r and d_z will increase by amounts δd_r and δd_z, and their radial focus will move outward normal to the optic axis by an amount δx. This distance is a measure of the dispersion D, defined here as $D\equiv\delta x/(\delta p/p)$. It is given by the simple formula

$$D=(1+M_r)/(1-n).$$

This reduces to $D=4$ for the Siegbahn case and to the well-known result $D=2$ for semicircular focusing. It can be shown that

$$\delta d_r/(\delta p/p)=\tfrac{1}{2}\left(\frac{n}{1-n}\right)\left[d_r+\{d_0+\theta[(1-n)d_0^2+1]\}M_r^2\right]$$

and

$$\delta d_z/(\delta p/p)=\tfrac{1}{2}\left[d_z+\{d_0+\theta[nd_0^2+1]\}M_z^2\right].$$

Both reduce to $2^{-\frac{1}{2}}\theta$ for the Siegbahn case; in semicircular focusing there is no d_z, and $\delta d_r=0$.

VII. RESOLUTION

In principle, the resolving power is a function of the size and shape of the image of a point source formed by the particles emitted in a finite solid angle; these depend on the deviations from the linearized theory, which in turn depend on the values assigned to higher derivatives of the field strength than the first, and on effects of the fringing fields. A calculation of these effects would form a generalization of the work of Svartholm[7] and of Shull and Dennison,[1] and would be qualitatively similar. In general, it will be possible to make the image very small in either the radial or vertical direction, but not in both simultaneously, by proper choice of the higher field derivatives and by appropriate shaping of the pole piece ends. However, it is believed that an empirical approach to this problem is more practical, since a second-order calculation including fringing effects would become very cumbersome.

In practice, the necessity for use of source and collector apertures of finite size for particles with broad-line momentum spectra modifies the problem of resolution. A practical criterion of resolving power is obtained by computing the fractional change in momentum required to move an image out of the collector slit so that it will not be confused with an adjacent image. If we assume that the collector slit width s' is adjusted so as to just receive the image of the source slit formed by the spectrograph, the required momentum change $\delta p/p=s'/D$; we define its reciprocal as the resolving power R. If there are no aberrations, $s'=M_rs$, where s is the source width. Actually, $s'=\alpha M_rs$, where α is a number somewhat greater than unity depending on the aberrations; we then have

$$R=(1+M_r^{-1})/\alpha s(1-n).$$

VIII. DISCUSSION

The design objectives are to attain maximum solid angle Ω and resolving power R for reasonable values of the d's; the available parameters are d_0, θ, and n. An inspection of the results obtained above shows that to maximize Ω one must take $d_0=0$ and $n=\frac{1}{2}$. These are the choices of Siegbahn, and any departure from them will decrease Ω, so that the price paid for a conveniently accessible source and collector is a reduction in intensity. However, to maximize R one must take n as large as possible and use small magnification (which requires large d_0). These requirements both conflict with those for large Ω, so the usual compromise must be made, based on the relative importance of these criteria.

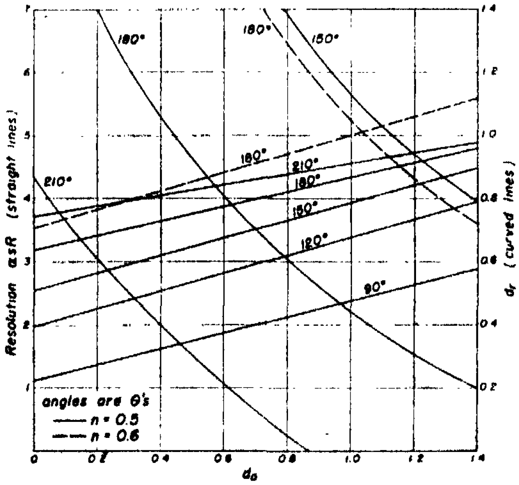

FIG. 5. Resolution and image distance for radial focusing *versus* object distance, for different n and θ.

---

[7] N. Svartholm, Arkiv. f. Mat.-Astr. o. Fys. 33A, No. 24 (1946).

We must have $n=\frac{1}{2}$ for double-focusing,* but for other values of n a point source becomes a vertical line image at d_r for a paraxial beam, as in uniform field focusing, but perhaps much shorter. By use of a line collector at this point, momentum separation could be achieved; however, some types of detectors are not appropriate for line collection. Ω is much less sensitive than R to small changes in n, which indicates that there may be an advantage in choosing n somewhat greater than $\frac{1}{2}$ for applications requiring large R, if a line collector can be used.

The general effect of decreasing θ is to weaken the power of the lens and thus to increase the d's and decrease Ω. For given d_0 and n (and hence Ω), R is increased by increasing θ, which brings the image nearer the field edge. If we require d_0 and $d_r>0.5$ to keep source and collector well out of the field, and $n=0.5$ for double-focusing, we must have $\theta<200°$. By taking $\theta=180°$, we satisfy this and leave room for some flexibility; there is the additional advantage that both pole pieces may be symmetrically machined at once, as was done in reference 2. The resolving power may then be increased by 14 percent by increasing d_0 from 0.5 to 1.0, at a loss of 18 percent in intensity. The use of smaller θ merely results in less intensity for the same resolution, or vice versa.

If we abandon double-focusing, we may improve resolving power somewhat at almost no cost in solid angle. For example, if $\theta=\pi$, $d_0=0.7$, we have 12 percent larger R with $n=0.6$ than with $n=0.5$ (see Fig. 5); it can be shown that a point source produces a line image about 0.9 times as high as the pole piece clearance in this case. The principal difficulty in devising arrangements with larger n or θ to gain further in R lies in holding down this height. The disadvantages of a line collector probably outweigh the gain in R; R can always be raised in the double-focusing instrument by stopping down to reduce the aberrations, if necessary.

IX. ACKNOWLEDGMENTS

The author wishes to express his gratitude to Dr. R. F. Christy, who suggested this investigation, and to Dr. W. A. Fowler and Dr. C. C. Lauritsen for their encouragement and helpful discussion.

---

* There exist exceptional cases in which an intermediate radial or vertical focus, but not both, occurs inside the field region, but these are uninteresting since they require a particular d_0 for given θ, and occur only for $\theta>n^{-\frac{1}{2}}\pi$ or $(1-n)^{-\frac{1}{2}}\pi$; focusing forces are widely different in the radial and vertical directions, and the system lacks flexibility.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

The Scintillation Counter as a Low Resolution Gamma-Ray Spectrometer

Robert W. Pringle, Kenneth I. Roulston, and Harry W. Taylor
Physics Department, University of Manitoba, Winnipeg, Canada

(Received October 10, 1949)

A scintillation gamma-ray spectrometer has been developed, which is of particular use for the study of isotopes of low specific activity and in which the energies of the gamma-rays are identified from the pulse height distributions of the recoil electrons produced in an activated NaI crystal. The Compton distributions are easily recognized, and a study of the gamma-radiation of Co^{60} and I^{131} shows a proportionality to exist between the total light output per scintillation and the energy of the corresponding secondary beta-ray particle. The noise level of the RCA 5819 photo-multiplier, as used in this test, corresponded to an energy on the pulse height scale of less than 20 kev. A brief description is given of a new type of differential pulse height analyzer which has been developed for work of this type.

FOR some time work has been going on in this laboratory to develop a scintillation gamma-ray spectrometer in which the energies of the gamma-rays could be found from the Compton distributions of recoil electron energies which, it was anticipated, would be identified in the differential pulse height distribution curve obtained with a suitable scintillation counter[1] exposed to the gamma-radiation. The assumption is made of a proportionality between the total light output per scintillation and the energy of the secondary beta-particles. However, for a given energy of beta-particle there will be fluctuations in the number of quanta which are emitted and which actually reach the photo-sensitive surface. This effect will determine the upper limit to the resolution of the spectrometer. Consideration must also be given to the fluctuations in the photo-multiplier amplification due to events in the first one or two stages, but with these limitations the device was expected to behave as a proportional counter. It was not anticipated at the present stage that the resolution obtainable would therefore be equal to that of the best beta-ray spectrometer measurements, but the method is unique in its extreme efficiency for counting and its obvious

R. Bell, Phys. Rev. 73, 1405 (1948); R. J. Moon, *ibid.*, 1210; R. Hofstadter, *ibid.* 75, 796 (1949); P. R. Bell, Oak Ridge Conference.

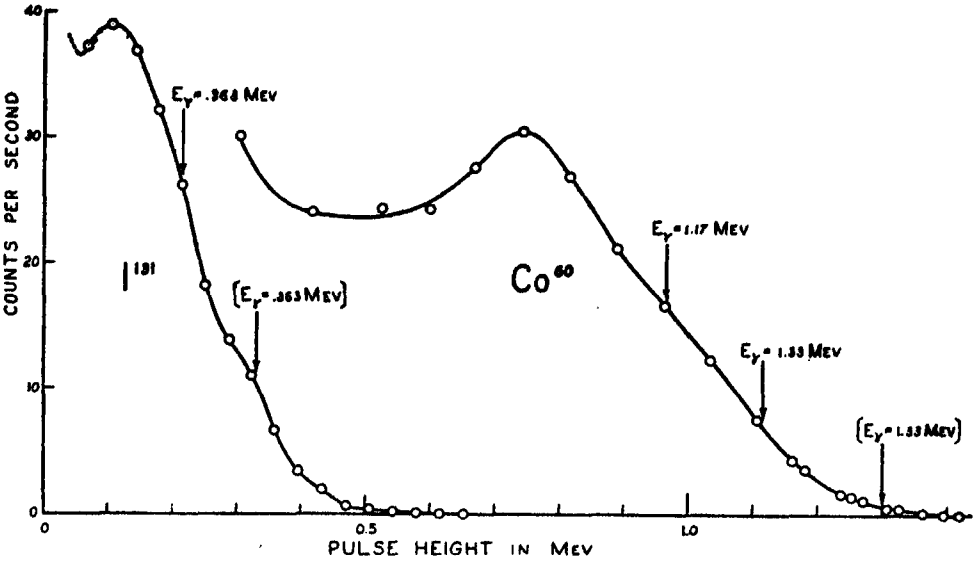

FIG. 1. Recoil electron spectra in NaI crystal. Distribution with pulse height (in Mev) of the pulses in a given range of energies.

use in the study of isotopes of low specific activity, quite apart from the relative simplicity and compactness of the equipment. Further, the ability of such a device to resolve gamma-ray energies opens up new possibilities in the study of gamma-gamma-coincidences and beta-gamma-coincidences for the elucidation of nuclear energy level schemes, where the limitations of the Geiger counter are already well known.*

The advantages of choosing a very dense crystal with a large light output per pulse lie in increased counting efficiency, higher resolution of energies and increased signal to noise ratio, but a disadvantage is the problem of light gathering owing to effects of total reflection in the crystal. It is obvious that large single crystals are desirable as the relative effect due to the secondary beta-particles which leave the surface of the crystal must be kept small, and the effective solid angles (for the collection of quanta) which are subtended at the photo-sensitive surface by the different parts of the crystal should be substantially the same—as they would not be were a polycrystalline mass used. With these considerations it was decided that the best crystal to employ was sodium iodide activated with thallium iodide. A single crystal of this material, with 1 percent thallium activation, was cut in the form of a truncated cone of maximum diameter 1¾ inches, ½ inch thick, with sides designed to throw the maximum amount of light onto the photosensitive surface. The surfaces of the crystal remote from the photo-multiplier were highly polished and covered with a reflecting layer of tinfoil. The surface adjacent to the multiplier was slightly roughened to reduce effects of total reflection and hence improve the light transmission. A good contact with the surface of the photo-tube was obtained with Canada balsam. The necessity of a maximum gathering of light limits the choice of photo-tube to the new RCA 5819 wide-angle photo-multiplier which has a 1¾-inch diameter flat transparent cathode. A multiplier voltage of 870 was used in the experiments. It is essential to integrate with the amplifier as completely as possible over the average duration of a scintillation, about ½μsec.,[2] and yet retain sufficient resolution at the counting rates involved.

Figure 1 shows the distributions with pulse height of the number of pulses in an arbitrary range of pulse heights, which were obtained with collimated gamma-rays from sources of Co^{60} (gamma-ray energies 1.17 Mev and 1.33 Mev)[3] and I^{131} (principal gamma-ray energies 80 kev, 284 kev, 363 kev, and 600 kev).[4] The probable error in the counting statistics is better than 2 percent for any of the observed points, and the counting rate for points near the peak of the Co^{60} curve is of the order of 2000/min. As no very prominent photoelectric effect was obtained with the iodine atoms in the crystal lattice the question arises as to the best procedure to adopt for the identification of gamma-ray energies. It was decided on the basis of earlier experience,[5] to associate the upper energy limit of the Compton distribution, or the limit corresponding to $\theta=0$ in the Compton formula, with the inflection point of the energy distribution curve. The inflection point may be obtained by plotting the second differential curve as the differences between the successive readings for the first differential curve. Where two Compton distribution curves are superimposed as, for example, in the Co^{60} curve, the positions of the inflections on the combined curve will not necessarily coincide with the positions of the inflections on the separate curves. If an approximate separation can be made better values can be obtained. This has been done using the results of Fig. 1 and employing a simple graphical separation of the effects near the end point on the assumption of the existence of two gamma-rays of energies 1.17 and 1.33 Mev in equal intensities. It is not suggested that the results would have been accurate enough in themselves to resolve adequately the effects of these two energies. On this basis it was possible to calibrate the pulse height in terms of beta-particle energy as in Fig. 1. All the values indicated in this figure are of known energies placed according to the calibration. The values indicated in brackets refer to possible photoelectric effects with the iodine atoms in the crystal lattice. There is no such effect very evident with the Co^{60} radiations, but with the lower energy I^{131} radiations there seems to be a partially resolved photo-electron line due to the strong 363-kev component. The weak 600-kev component produces a small Compton effect only and the inflection point for the main distribution corresponds well to that expected for the Compton effect with the 363-kev component.

---

* *Note added in proof.*—A number of natural isobaric nuclei of neighboring atomic number have been tested for possible gamma-ray activity, and the purest materials have been sought for this purpose. Lanthanum (39 g La_2O_3) showed an activity of 0.7±0.1 quanta/second/g which could not be attributed to a naturally occurring radioactive impurity, and the gamma-ray energy was estimated at 1.05±0.05 Mev. An upper limit to the half-life of La^{138} of 1.2×10 in. years is thus obtained [Phys. Rev., to be published]. The energy of the gamma-ray emitted in the disintegration of K^{40} has been estimated at 1.47±0.03 Mev [Phys. Rev. 76, 841 (March 15, 1950)], using 90 g of KCl. Sharply resolved lines due to photoelectric effects with the iodine atoms in the crystal lattice have been obtained with low energy gamma-rays (e.g., the Au^{198} 411 Mev line). A rare high energy gamma-ray of energy 1.1 Mev has been found with Au^{198}, present in less than 1 percent of the disintegrations.

In recent comparisons of gamma-ray energies it has sometimes been found easier to use the approach to the pulse height axis, rather than the inflection point of the distribution as described above. The single channel differential discriminator will shortly be replaced by a five-channel "hicksorter." A gamma-ray coincidence scintillation spectrometer has just been constructed.
R. W. P.

[2] W. C. Elmore and R. Hofstadter, Phys. Rev. 75, 203 (1949).
[3] D. A. Lind *et al.*, Phys. Rev. 76, 591 (1949).
[4] F. Metzger and M. Deutsch, Phys. Rev. 74, 1640 (1948).

Thus we see that there is no evidence to disprove the anticipated proportionality between beta-ray energies and scintillation light output in the range of energies involved. The rise in counting rate below 0.4 Mev for Co^{60} appears to be due to the presence of degenerate radiation as well as to the loss of secondary beta-particles from the surfaces of the crystal. Part of the rise below 90 kev with I^{131} is, of course, due to low energy components. The noise level in the photo-tube corresponds to an energy on our scale of less than 20 kev for beta-particles, and it is only below this level of pulse heights that the signal to noise ratio deteriorates. This is an important result inasmuch as it indicates the lower limit of beta-particles energy which can be studied effectively in this arrangement with the photo-tube operating potential of 870 volts.

The electronic equipment consists of a conventional linear amplifier and scaler, and a pulse height differential discriminator built in this laboratory. This functions as a one channel "kicksorter" and consists essentially of two Schmitt trigger circuits followed by an anticoincidence system. The bias voltages used in each trigger circuit can be adjusted with precision potentiometers and thus the minimum amplitudes of pulses necessary for triggering can be selected in each case. In practice the levels of the two circuits are set some 2–5 volts apart, and with the incoming pulses from the linear amplifier up to approximately 100 volts in magnitude this implies a subdivision of the range into 20–50 steps. The output pulses from the trigger circuits are obtained by loading the second tube in each with an inductance in parallel with an I N 34 crystal diode. This gives positive-going pulses of approximately $\frac{1}{2}$-μsec. duration.

The discriminator is required to pass a triggering pulse to the scaler when only one of the Schmitt circuits operates, but not to pass a pulse when neither operates or both operate. Thus an anticoincidence circuit is required. The circuit used here is a simple differential amplifier consisting of two tubes cathode coupled. The two Schmitt circuits are coupled to the two grids and the output for the scaler is obtained from the plate of one of the tubes.

Owing to the finite rise time of the amplifier, pulses from the Schmitt circuits caused by the same input pulse do not occur simultaneously. But they are required to cancel each other in the differential amplifier. To overcome this difficulty the tube to which the earlier pulse is applied is biased beyond cut-off so that only the center portion of the pulse is used. By this means adequate cancellation is obtained. Wire-wound and stabilized carbon resistors are used where desirable to maintain d.c. levels as constant as possible. The stability of the triggering level appears to be better than 0.1 volt and the discriminator could not have reduced the resolving power of the spectrometer by any appreciable amount.

More recent work, to be published soon, has concerned the disintegration scheme of K^{40}, and the development of new highly efficient gamma-gamma- and beta-gamma-coincidence apparatus in which the energies of the gamma-rays are analyzed by the method which has been described. Attempts are also being made to develop the measurement of fast neutron energies with the above technique using the recoil protons formed in crystals of anthracene. In particular, a study is being made of the energies of the neutrons from a Po—Be source, but the presence of gamma-radiation of high energy from the excited C^{12} nucleus makes the interpretation of the results difficult. Further work with gamma-rays is centered on the development and use of crystals containing heavy atoms, so as to render much more significant the photo-electron lines in the pulse height distribution curves.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

A Radiofrequency Spectrograph and Simple Magnetic-Field Meter*

R. V. POUND
Lyman Laboratory, Harvard University, Cambridge, Massachusetts

AND

W. D. KNIGHT**
Trinity College, Hartford, Connecticut

(Received November 21, 1949)

A simple oscillating circuit with a special feed-back circuit is employed as a tool for the search for and detailed analysis of nuclear paramagnetic absorption lines. The sensitivity approaches the optimum for a given noise band width and particularly useful is the ease of conducting slow, continuous changes of frequency while recording the output data. Spectra having several components at scattered frequencies are thus displayed. Line shapes are unambiguously recorded because of the absence of sensitivity to dispersion. Using protons in water, or solutions containing Li^7, the device can be used as a versatile and extremely precise meter for measuring magnetic field strengths in the range from about 100 to 25,000 oersteds with a minimum of auxiliary equipment.

INTRODUCTION

THE apparatus used for observing the absorption[1,2] or the dispersion associated[2–4] with nuclear paramagnetic resonance in matter has most frequently taken the form of a radiofrequency bridge circuit supplied with a fixed frequency signal from a master oscillator. Variations in the amplitude of the signal transmitted through the bridge, that occur as the magnetic field is moved through the resonance, are observed on an oscilloscope. For many of the weaker lines in solids and particularly for observation of line shapes, observation is made with a meter fed from a phase sensitive detector. To facilitate the observation of resonances of complex character and for searching for unknown lines, a spectrometer that operates with a varying frequency, while the magnetic field is held constant, is of considerable utility. Because the nuclear resonance effect is very weak in crystalline solids, any device for this use must be so designed that the available signal-to-noise ratio is very nearly achieved and it is in this respect that the device to be described here is thought to represent a useful innovation.

Others have devised devices for observing nuclear resonance using oscillators[5,6] and super-regenerative detectors.[5,7] These have been used principally for determining gyromagnetic ratios with liquid samples having short relaxation times. Little information has been given, however, on the adaptability of these devices to a range of relaxation times and line breadths, and on the degree of attainment of the signal-to-noise ratio theoretically available. The super-regenerative scheme, because of its complex signal spectrum, seems ill-fitted to the study of line breadths or shapes in crystalline samples, although, judging from the large number of nuclei for which gyromagnetic ratios have been reported,[8,9] it must approximate the optimum sensitivity.

BACKGROUND CONSIDERATIONS

Unfortunately a genuinely versatile r-f spectrometer should be variable over a wide range of r-f signal power levels and scanning rates as well as of frequencies because the nature of the resonance lines varies widely with the kind of a sample. Consider two equations taken from reference (2). First, Eq. (64)

$$A_s/A_n = 1.6\times 10^{-4} V_c^{2/3} \eta A h^2 N_0 \gamma^{11/4} \times H_0^{7/4} T_2^{*\frac{1}{2}} I(I+1)/kT(kTBF)T_1^{\frac{1}{2}} \quad (1)$$

gives, approximately, the maximum available amplitude ratio of signal-to-noise as a function of the various parameters descriptive of the sample and the conditions of the experiment. The number that results if one is concerned with a resonance in a solid having a thermal relaxation time T_1 of several seconds, a spin-spin relaxation time T_2 of, say, 10^{-4} sec. (line breadth of approximately 10 kc/sec.), a γ of 5000 radians per second per gauss (nuclear magneton, spin of one), N_0 of 10^{22} (fairly rich in the subject nuclei), in a field of 5000 gauss, for a 1-cc sample at room temperature is about $4/(FB)^{\frac{1}{2}}$ where FB is the effective noise figure[10] times the effective noise band width. Thus, this case, typical of many solid samples, requires for detection with the optimum noise figure of unity a noise band-width of only about 1 c.p.s. This may be compared with the signal available from a liquid sample containing the same nuclei where T_1 may easily be reduced to be about equal to T_2 by adding paramagnetic ions, and one obtains a 100-fold increase in available signal-to-

noise ratio. The often observed proton line in water or mineral oil can be another factor of about 1000 stronger because of the sixfold larger γ and eightfold larger N_0.

The calculation assumes, however, that the optimum r-f signal amplitude is employed, if the absorption effect is being observed, and this cannot be known in advance of knowing values for T_1 and T_2. The condition to be met is [Eq. (59) of reference (2)]

$$\gamma^2 H_1^2 T_1 T_2 = 1, \qquad (2)$$

where H_1 is the amplitude of one of the two circularly polarized signals of which the oscillating r-f field may be considered composed, or is thus one-half the amplitude of the r-f field. At a given value of γ, one might be concerned with the product T_1T_2 in a range from perhaps 10^{-2}, for very sharp lines in liquids, to 10^{-8} for broad, quickly relaxed lines in solids and liquids, a range of 10^6. Such a range cannot be accommodated in the present apparatus, but its level of operation has been found suitable for a wide variety of samples in spite of this.

PRINCIPLE OF OPERATION

As in other methods, the sample is contained in a cylindrical coil placed in the magnetic field with its axis perpendicular to the field lines. A short cable of low capacity (15 $\mu\mu$fd) connects this coil in parallel with a variable condenser forming a shunt resonant circuit. The r-f signal is supplied to this circuit by connecting it to an electronic circuit that forms a two-terminal negative resistance and thus sustains oscillations in the resonating circuit. To just sustain oscillation the magnitude of the negative resistance must be just equal to the positive shunt resistance of the tuned circuit. If it is less than this the level of oscillation rises to a point where curvature of the tube characteristics increases the magnitude of the negative resistance, averaged over a cycle, to the value of the shunt resistance, and equilibrium between the rate of generation and of dissipation of energy is obtained. The magnitude of the negative resistance used here is kept just below the level at which oscillations are sustained and, because the curvature of the tube characteristics is small for such a small voltage swing, the level of oscillation is sensitive to the small changes in shunt resistance resulting from passing through a nuclear resonance. Such variations in level are observed as variations in the amplified r-f voltage after rectification. In the region below saturation of the nuclear resonance, the signal-to-noise ratio should be proportional to the r-f voltage, if the effective noise figure were a constant independent of level. Because the tube characteristics are more non-linear at high levels, one would expect noise components originating in a wider range of frequencies to become mixed with the r-f signal, with a corresponding increase of the noise figure. The effective gain of the circuit, of course, varies widely with the operating level and is highest at the oscillation threshold. That the level of oscillation is sensitive to the shunt impedance, however, results in a very large change in level, soon reaching the limit level, as the frequency is varied, unless a special circuit is employed. The circuit feeds back, through an RC filter a long time constant (2 sec.), the d.c. rectified voltage in such a way as to control the value of the negative resistance and holds the level of oscillation constant at the level far below natural limiting. Variations of amplitude occurring at audiofrequencies are not removed.

Figure 1 is a block diagram showing the method of use of the spectrometer for weak resonances. The required small band width is obtained by modulation of the magnetic field at an audiofrequency with amplitude of a fraction of the anticipated line breadth. As the resonance is passed through by the changing frequency of the oscillator, the level of oscillation varies coherently with the modulation in a phase that reverses at the center of the line. The tuned audio-amplifier and phase sensitive detector, fed also directly with the modulating signal in the right phase, produce a d.c. output which therefore is proportional to the first derivative of the absorption line with respect to field strength. The

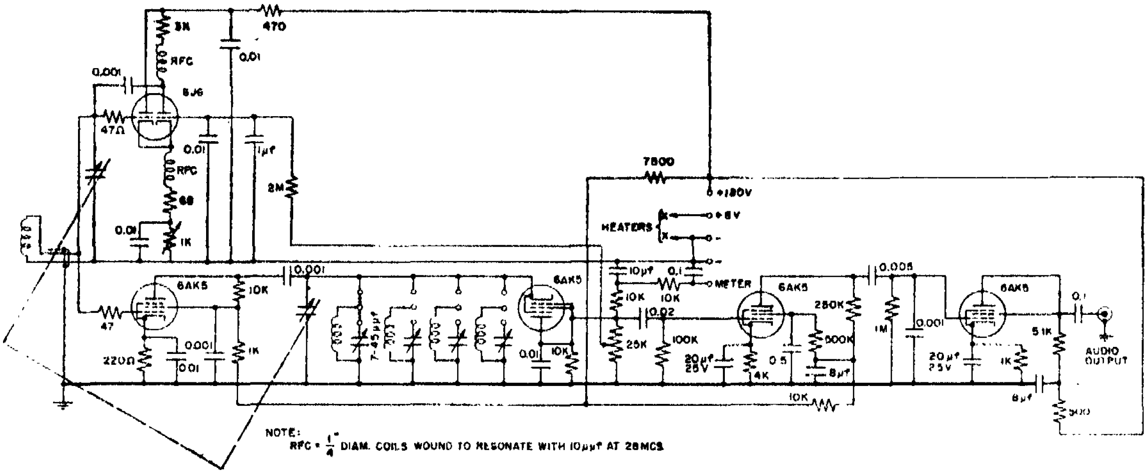

FIG. 3. Circuit diagram of an oscillator unit.

effective noise band width is approximately the reciprocal of the time constant of an RC circuit before the indicating meter. Time constants of 1 sec. and 20 sec. have most commonly been used.

One must not sweep through the resonance in a time less than several times the time constant. Therefore, a very extended search for a narrow but weak line might consume a considerable period of time. With the 20-sec. time constant and a line of 2 kc/sec. width, a sweep rate of about 1 kc/sec./min. would seem desirable. A factor of two in frequency from 6 to 12 mc/sec. can thus be covered in not less than 6000 minutes or 4 days. A 1 r.p.m. synchronous motor and a train of reduction gears is used to obtain one of several rates in this region. Visual observation of the meter would be tedious, and a recording milliammeter is used instead, allowing 24-hour-a-day operation. In this way one is enabled to search for lines without previous clues as to their frequencies.

A serious difficulty is encountered in the fact that a small amount of voltage at the modulation frequency is induced in the r-f coil even though it is ostensibly at right angles to the magnetic field. Such a voltage mixes in the oscillator and produces a strong signal in the phase sensitive detector in the absence of the nuclear resonance. Its amplitude and phase change with tuning of the oscillator, causing serious zero drift in the output indicator. The effect increases with increased modulation frequencies. Because it is found desirable, in order to avoid similar difficulties with flicker effect noise, to use a modulation frequency of several hundred cycles (280 c.p.s.) instead of the 30 c.p.s. common with bridge circuits, this becomes the most troublesome aspect of the system. Several schemes have been used to reduce the effect. One of these was to have adjustable relative positions of the r-f coil and the modulating Helmholtz coils. Two parameters were necessary to get a null in the pick-up; one coil relative to the other and the pair relative to the shield walls of the containing box. This is needed because there are eddy currents in these walls producing an out-of-phase component in the modulation field which cannot be compensated by a single-parameter adjustment. At large modulation amplitudes, the box walls and the modulation coils tend to vibrate in the field and this causes instability in the compensation. A better scheme has been found to be to shield the r-f coil with a thin-walled copper shield supported on a Bakelite form inside the modulation coils. Another coil is wound on the outside of the shield, coaxial with the r-f coil, and supplied with a current of completely variable phase and amplitude derived from the voltage supplying the principal modulation. In this way a stable null in the pick-up can be achieved. Figure 2 shows the parts of the spectrometer, with one of the plug-in r-f coils outside the unit. These are thin-wall

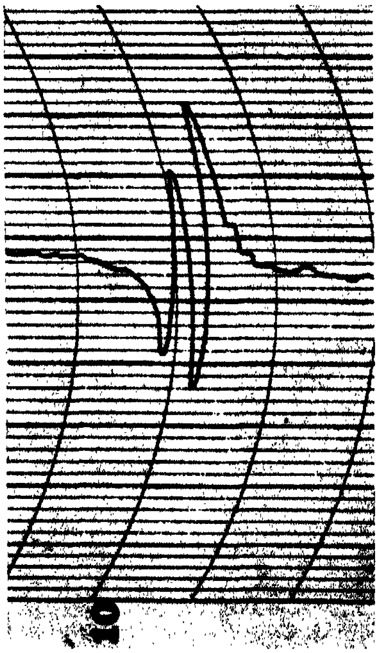

FIG. 4. Record of resonance of Li^7 in aqueous solution with modulation frequency higher (1400 c.p.s.) than line breadth.

glass forms $\frac{1}{2}$ in. i.d. with tungsten prongs fitting a standard miniature tube socket. The 0.003-in. thick copper r-f shield also serves to prevent the r-f voltage from coupling into the modulation system. Such coupling has been found to result in strong false resonances associated with the modulation circuit elements.

THE OSCILLATOR UNIT

Several circuits have been used for the oscillator, that in Fig. 3 being the most recent and most flexible so far tried. The oscillator itself is a cathode coupled 6J6[11] with a peaking coil in the cathode circuit and the second plate circuit to hold up the gain to 45 mc/sec. A one-stage r-f amplifier follows this, with its grid directly connected, except for a small parasitic suppressor, to the oscillator grid. The load circuit of the amplifier is tuned in tandem with the oscillator tuning and a 6AK5 as a diode is used as a rectifier. Two stages of audio amplification are included and r.m.s. noise in a 5 kc/sec. band width at the output is about 0.1 volt. In this version the normally grounded grid of the second half of the 6J6 is used to control the level of oscillation and with 300 μμfd-max. tuning condensers a factor of about 2.3 in frequency can be covered with each set of coils. Thus 1.5 mc/sec. to 45 mc/sec. are covered with four coils. Straight-line-capacity condensers are used. Originally a crystal rectifier was used but it was found to add noise at the higher levels of oscillation. Hence the diode detector was added.

The r-f voltage across the coil can be varied, by variation of the feedback potentiometer and of the cathode bias resistor, from less than about 0.1 v to 1.5 v r.m.s. Because the time average energy stored in the condenser is, in a resonating circuit, equal to the energy stored in the magnetic field, one can compute the region of T_1T_2 for which optimum signal results for this range of voltages with a coil of given volume.

By using Eq. (2), one finds the optimum r.m.s. r-f voltage V_1 to be

$$V_1=(V_c/2\pi\gamma^2T_1T_2C)^{\frac{1}{2}}$$

in electrostatic volts, where V_c is the volume of the coil in cc, and C is the tuning capacitance in centimeters. This leads to values of V_1 for γ in the region of 6000 (gauss sec.$^{-1}$), taking C as 200 cm, and V_c as 2 cc,

$$V_1=1/(2.5\times10^5T_1T_2)^{\frac{1}{2}},$$

where V_1 is now expressed in volts. A level of 0.065 volts is desired if $T_1=1$ sec. and $T_2=10^{-3}$ sec. for these conditions. For shorter values of T_1 a larger voltage is required to get the optimum signal-to-noise ratio but, unless one is working with a diluted sample, or a very small γ, it is not necessary to obtain the maximum signal-to-noise ratios in these cases. Note that as one uses smaller and smaller values of γ, the voltage for optimum signal increases as $1/\gamma$. In the range of small γ's, the method of detection has a strong practical advantage over a bridge method because a bridge must have a very high stability to accommodate large applied r-f voltages, which in turn necessitates a very high degree of balance. The oscillator described is thus seen to provide optimum signal level for samples having T_1T_2 in the approximate range 10^{-3} to 10^{-6} for the conditions described.

Direct measurements of noise figure were not made with this oscillator circuit. An earlier pentode circuit*

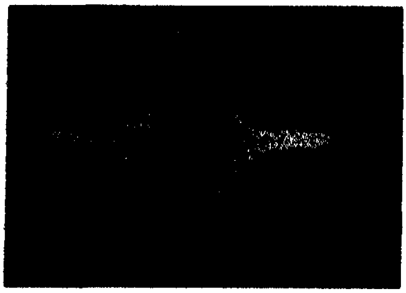

FIG. 6(a). Trace on an oscilloscope of proton resonance in 0.5 cc of mineral oil in 6400-gauss field, illustrating use as field meter. Total sweep here is about 0.5 gauss. "The Wiggles" are very prominent, owing to the good homogeneity of the field over the sample. Sweep amplitude is about 0.5-gauss peak-to-peak.

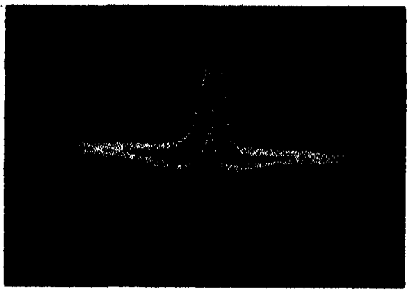

FIG. 6(b). Resonance in same magnet as (a), but in aqueous solution with added paramagnetic, $MnSO_4$. Sweep amplitude is about 5 gauss, peak-to-peak.

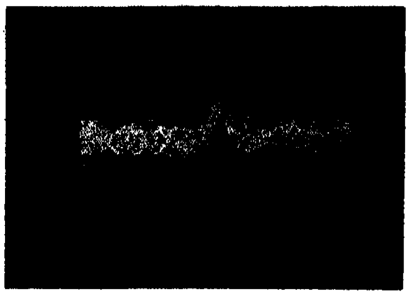

FIG. 6(c). Oscilloscope trace in field of 360 gauss, with about 0.5-gauss inhomogeneity over the sample. Sweep amplitude is about 10 gauss, peak-to-peak.

used at frequencies below 4 mc/sec. was equipped with a tungsten filament diode so arranged that shot noise current caused by a temperature limited anode current developed noise voltages across the input tuned circuit of which the shunt resistance was known. Comparison of the recorded noise amplitudes for the diode current at zero and then at a suitable small value allowed computation of the noise figure. This was found to be less than about 5 at 0.5 mc/sec. using a 30 c.p.s. phase sensitive detector but it rose sharply at higher radiofrequencies. A higher modulation frequency of 1400 c.p.s. resulted in a noise figure of about 3 at 4 mc/sec. With the present circuit, signal-to-noise ratios are as large as expected with a system of small noise figure and are as large as with bridge circuits operating under similar conditions and known to have noise figures of about 2. The modulation frequency does have to be kept high, for detection with the phase-sensitive detector, a 30-c.p.s. system having been found definitely inferior in signal-to-noise ratio.

Two disadvantages accompany the use of a high modulation frequency. First, difficulties with pick-up of the modulation frequency are enhanced and second, lines are sometimes broadened or distorted. This happens if a line has a breadth in frequency of less than the modulation frequency, which happens easily with liquid samples of small gyromagnetic ratio in a homogeneous field. Figure 4 shows a lithium line of distorted shape resulting from this effect with a 1400-c.p.s. modulation frequency. The effect may be thought to occur because the separate side bands of the modulation frequency (which, because the modulation results in frequency modulation of the precession frequency, may be thought to represent a number of discrete simultaneous precession frequencies of relative amplitude and phase determined by the modulation) interact individually at separated radio-frequencies. Thus one gets a number of lines superimposed. This effect has been observed by Brown and Purcell[12] as setting a practical artificial limit to the sharpness of resonance lines in very weak fields. R. Karplus has given an analytical treatment[13] of the effect.

OPERATION AND TYPICAL RESULTS

In conducting a search for an unknown resonance, the adjustment of the modulation level, power level and sweep rate must be so made as to fit the characteristics of the sample. A few typical spectra are shown in Figs. 5 (a), (b), and (c). In Fig. 5 (a) is a spectrum for NaBr as a solid with the resonances of the two Br isotopes and the Na all occurring in a frequency range of 10 percent. Weak lines thought to be caused by Cu^{63} and Cu^{65} in the coil can also be seen. Figure 5 (b) shows a spectrum of Li^7 in a single crystal of $Li_2SO_4 \cdot H_2O$, where a definite structure is observed in the line, this being caused by the nuclear electric quadrupole interaction with the crystalline field. Finally a spectrum of Al^{27} in a single crystal of Al_2O_3 shows five lines widely separated, again caused by the quadrupole interaction. For spectra of this last kind, the variable frequency aspect of the apparatus is almost indispensable for quantitative measurements, because the range covered is so large that it would be difficult to make known, large, changes in the field, and the spectrum one would obtain, if the field were varied, would be harder to interpret. A large permanent magnet, with a field strength of 6400 gauss, in a $1\frac{3}{8}$-in. gap of 6-in. diameter is currently being used with the spectrometer, all variations then being made in the frequency.

For somewhat reduced sensitivity compared to the phase sensitive detector but considerably greater than that obtained with direct observation of the audio output on the oscilloscope, the oscilloscope may be connected to the output of the tuned audio amplifier, as indicated by the broken lines in the block diagram. This amplifier has the effect of narrowing the noise band width to that of the amplifier (about 5 c.p.s.) and, with a modulation amplitude about equal to the line breadth, one observes the resonance as a sinusoid, synchronous with the modulation frequency. This reverses phase as the frequency of the oscillator passes through exact resonance and the associated null signal gives an accurate measurement of the point of maximum absorption. The amplitude is, of course, just the quantity to which the phase sensitive detector responds, but one avoids possible errors associated with the integrating time of the detector and the response time of the meter. The null is, on the other hand, less precisely specified because the noise band width is greater.

[12] R. M. Brown and E. M. Purcell, Phys. Rev. 75, 1262 (1949).

[13] R. Karplus, Phys. Rev. 73, 1027 (1948).

Frequency measurements are made by making marks on the chart of the recorder as the oscillator passes through zero beat with a heterodyne frequency meter. Actually, if a small amount of the frequency meter signal is allowed to leak into the oscillator, marks are made by the spectrometer itself. A crystal oscillator with multivibrators could be used to provide marker signals throughout a large frequency interval, obviating the necessity of returning to the resonance for quantitative measurement after it is found, as is done at present.

The oscilloscope connected to the tuned audio amplifier can assist in accurate frequency measurements as well because the signal that actuates the phase sensitive mixer can be observed on it. In fact, the instant of zero beat can be observed.

USE AS A METER FOR MAGNETIC FIELDS

For use as a meter for magnetic fields, the oscillator has been equipped with a small probe coil containing as a sample an almost saturated aqueous solution of LiCl with about 1N $MnSO_4$ to shorten the relaxation times. A $\frac{3}{4}$-in. copper tube, $\frac{3}{4}$ in. long has been used as a shield box around the coil containing about 0.5-ml sample. Modulation coils have been wound around each end of the tube and supplied with 60-c.p.s. current. An oscilloscope is connected directly to the output of the oscillator unit and very strong proton resonances are found in homogeneous fields, that in Fig. 6 (a) being found in the above described permanent magnet. With a sample of shorter relaxation time, the "wiggles,"[2] prominent in Fig. 6 (a), are damped out sooner. Figure 6 (b) shows a H^1 resonance in an aqueous solution of $CrCl_3$, in the same magnet. Probe coils have been used to cover a range from 45 to 1 mc/sec. thus allowing very accurate measurement of fields from 10,000 gauss to about 250 gauss. The resonance photographed in Fig. 6 (c) illustrates the line found in a field of about 360 gauss (1.5 mc/sec.) with an inhomogeneity of about 0.5 gauss over the $\frac{1}{4}$-in. diameter, $\frac{1}{2}$-in. long sample. A more uniform field increases the signal-to-noise ratio proportionately. With larger samples, in uniform fields, one can go to fields. A good signal-to-noise ratio has been observed on an oscilloscope at 350 kc/sec., or about 80 gauss, using a 20-cc sample. For fields above 10,000 gauss, the Li^7 resonance may be used. This is not nearly so strong but, by using it only in the strong fields, one obtains quite adequate signal strengths so long as the field is uniform to less than 1 gauss over the sample. For less uniform fields, the narrow-band phase sensitive detector, or perhaps just the tuned audio amplifier with oscilloscope, would have to be used. The Li^7 resonance extends the range up to about 25,000 gauss with the same set of coils. The accuracy of measurement of the field is, in practice, limited only by the homogeneity over the sample and the accuracy of the frequency measuring equipment. Conversion of the measured frequency into field strength may be done only to the precision that the absolute value of the gyromagnetic ratio is known.[14] With the phase sensitive detector, an error voltage is obtained and this has been used to provide precise regulation of an electromagnet in a standard manner.

CONCLUSIONS

It is felt that for a large variety of samples the spectrometer achieves very nearly the ultimate sensitivity determined by thermal agitation noise in the resonant circuit, consistent with its band width. It has a very great advantage over both bridge and nuclear induction techniques for studying line shapes because the device is sensitive only to the absorption part of the resonance and one always obtains records showing the derivative of the absorption. In contrast, both the electrical bridge, and the induction apparatus, are responsive to either χ'' or χ' or any mixture of the two depending on very critical and hard to make adjustments. For this same reason, the present device, especially when used in association with a permanent or proton-regulated magnet, is useful for making precision gyromagnetic ratio measurements because the centers of the lines can be so precisely designated. The dispersive part of the resonance may be shown to exist by observing the frequency modulation resulting[6] but, for the weaker resonances, this is not easily detectable. To observe this while varying frequency would require a tracking receiver, one of the parts of a more conventional scheme that has been avoided in the preferred arrangement.

As a field-strength meter, the two most serious limitations are that the field must be rather homogeneous (say, one part in 10^3 over the sample) if one wishes to use the oscilloscope as an indicator, and that the cable from the probe to the unit is only about 18 in. in length. If one were interested in observing only small changes in field in a large magnet, the wide tuning range could be temporarily discarded, allowing the addition of a one-half wave-length cable to the existing one. One would then separately control the tuning condensers and almost any magnet could be investigated in this fashion. If care were taken to avoid use of ferromagnetic materials, one could perhaps place the unit close to, or even inside, a large magnet. At low fields, and correspondingly low frequencies, one can use a longer cable of lower capacity per unit length, but at high frequencies one begins to get rather serious impedance transformations from the cable. The oscillator could probably be made to operate up to 85 mc/sec. by changing the peaking coils, allowing use of protons for field measurement up to 20,000 gauss.

---

[14] Thomas, Driscoll, and Hipple, Phys. Rev. **75**, 902 (1949).

It should finally be noted that in all oscillator circuits tried, a power supply of very low ripple and noise (about 1 mv) and d.c. heater supply were required, to avoid a large (compared to noise) a.c. component in the audio output. For field-meter use, battery operation is convenient, the total plate current drain being about 25 ma.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

On the Use of Photographic Plate Detectors in Neutron Experiments*

J. C. ALLRED, A. N. PHILLIPS, L. ROSEN, AND F. K. TALLMADGE
Los Alamos Scientific Laboratory, Los Alamos, New Mexico

(Received July 12, 1949)

A technique is discussed for utilizing photographic plate detectors in an evacuated camera, containing an appropriate radiator, to make precise determinations of the range distributions of the disintegration products of slow neutron reactions. The same technique is applied to the problem of measuring neutron energies by making range measurements on the forward recoil protons projected by fast neutrons from a thin polyethylene radiator. As an indication of the accuracy attainable with photographic plates when used in this manner, determinations have been carried out for the Q values of the $\mathrm{Li}^6(n,\alpha)\mathrm{H}^3$ reaction and the $\mathrm{B}^{10}(n,\alpha)\mathrm{Li}^7$ reaction.

IT is now well established that photographic emulsions can be used to advantage in many experiments for making, simultaneously, determinations of the energy distribution and angular intensity distribution of the products of nuclear reactions. In the case where collimated charged particles are to be detected, one essentially has in a photographic plate a "coincidence" detector in space; i.e., the tracks must originate on the surface of the emulsion and must travel in vertical and horizontal directions with respect to the surface of the emulsion as defined by the collimating system. When used in this manner a great deal of the background and track measuring difficulties are eliminated and precise results are made possible.

It would obviously be desirable to be able to do neutron experiments with the same accuracy and facility as is now attainable in charged particle experiments. This turns out to be possible if one can maintain and successfully utilize photographic emulsions in vacuums for reasonable periods of time.

We have recently found that photographic emulsions can be kept at pressures in the range of 10^{-3} mm Hg for periods of more than 20 hours without prohibitive effects, and this is ample time for many neutron experiments. In order to determine whether prolonged exposure to a vacuum changes the resolution or stopping power of photographic emulsions, the range distributions of plutonium alpha-particles were obtained as a function of time spent by photographic plates in a vacuum. Figure 1 shows the range distribution for one hour, 6½ hours, and 16½ hours of exposure to plutonium alphas while in a vacuum of 1.1×10^{-3} mm Hg. (Ilford C-2 emulsions were used in all of the experiments discussed in this paper.) It is seen that the vacuum produces no significant effect on the resolution or stopping power. (The energy of the alphas, as determined from the extrapolated range** and the range

** The procedure followed to determine the mean range from the extrapolated range of the integral curve was identical to that outlined by Livingston and Bethe in Rev. Mod. Phys. 9, 283 (1937). Errors in the measurement of track lengths were treated as additional straggling.

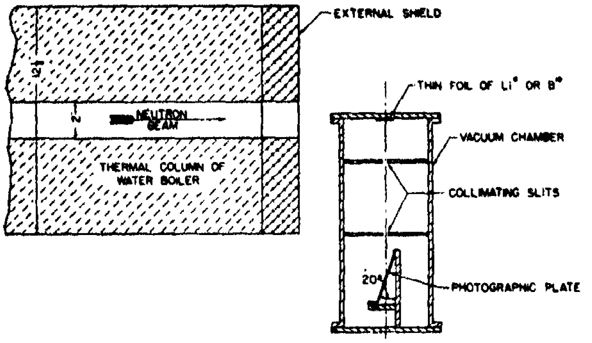

FIG. 2. Source-detector geometry for determination of energy spectra of charged particles from thermal neutron reactions.

energy relations of Lattes, Fowler, and Cuer,[1] is 5.10±0.14 Mev, in good agreement with the prevailing average value of 5.14 Mev.[2]) Having established this point, we were ready to attempt some neutron experiments using the same collimation techniques[3] heretofore reserved for charged particle experiments.

Figure 2 shows the experimental arrangement employed to determine the range distributions of charged particles from thermal neutron induced reactions, the Los Alamos slow neutron reactor being utilized as the neutron source in these experiments. The function of the slit system is to permit only those particles to enter the emulsion the angle of whose trajectories will not vary by more than eight degrees with respect to the surface of the emulsion, thus eliminating the necessity for making depth measurements. In the case of short tracks, an eyepiece scale is used to make length measurements. Thus, even if the track makes a large angle in the horizontal plane (looking down on surface of emulsion) with respect to the line between the radiator and the center of the photographic plate, no error is introduced. However, when long tracks are to be measured, it is much more convenient to measure the projection of the tracks along the line from the center of the plate to the radiator, and for this case it is necessary to collimate the particles to be detected so that only particles traveling in a cone of small angle are accepted. This can be done either by a slit system as shown in Fig. 2, or by moving the plate a sufficient distance from the radiator. The maximum error introduced in length determinations by the above method is approximately two percent for tracks which do not suffer appreciable scattering in the emulsion, and this can be in large part corrected for. An important feature of this arrangement is that the detector can see the radiator without seeing the source of neutrons, thus considerably reducing the gamma-ray and neutron-induced background on the plate.

Figure 3 gives the range distribution of the alphas and tritons from the $Li^6(n, \alpha)H^3$ reaction. Li^6 as Li_2SO_4 was converted to $LiNO_3$ by adding $Ba(NO_3)_2$ to the Li_2SO_4 and precipitating out $BaSO_4$. The $LiNO_3$ in Zapon-alcohol solution was then painted on platinum and converted by heating to Li_2CO_3. The Li_2CO_3 layer had an average thickness of 0.11 mg per cm².*** The Q for this reaction is 4.67±0.21 Mev, as again determined from the extrapolated ranges, which were determined by using the integral number *vs.* range curves for the two groups of particles and the range energy relations of

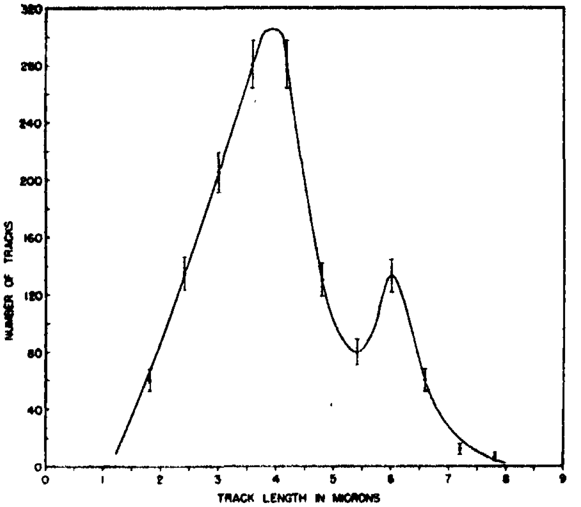

FIG. 4. Range distribution of alphas from $B^{10}(n, \alpha)Li^7$ reaction for thermal neutrons.

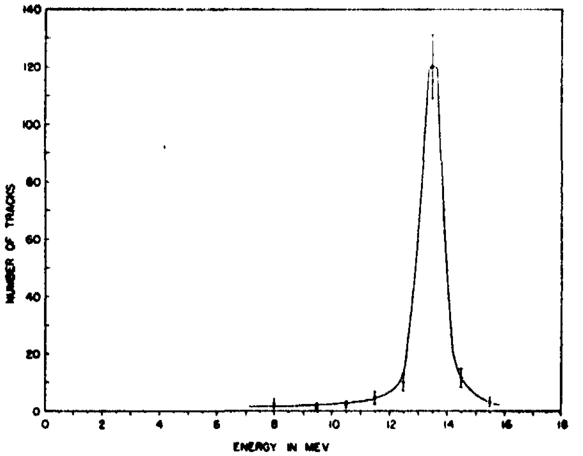

FIG. 6. Infra-Red energy distribution of 14 Mev neutrons as determined from ranges of recoil protons.

Lattes, Fowler, and Cuer. This appears to be in good agreement with previously determined values of 4.86 Mev[4] and 4.97 Mev.[5]

Figure 4 gives the range distribution of the alphas from the $B^{10}(n, \alpha)Li^7$ reaction. A slurry of B^{10} powder in alcohol was carried through successive decantations until a fine suspension was obtained. This was then painted on platinum and heated under an infra-red lamp to drive off the alcohol. The B^{10} was deposited on the platinum to an average thickness of 0.012 mg per cm^2. The peak of short range alphas, which comprise about 90 percent of the total number of alphas, is due to the well-known excited state in Li^7. The energy of the alphas giving rise to the short range group was determined to be 1.45±0.10 Mev by the method referred to above. This implies a Q value of 2.28±0.20 Mev for this group. This value is also in good agreement with previous determinations.[6] A determination of the energy of the alphas giving rise to the high energy peak would not be reliable due to interference from the group of lower energy.

An obviously important application of the above technique is to be found in the investigation of neutron energy spectra. For such experiments the radiator consists of a hydrogen or possibly deuterium containing material. In order to keep to a minimum errors in energy determinations produced by finite angular resolution, the axis of the vacuum chamber is so aligned as to make a sufficiently small angle with respect to the line from the center of the photographic plate to the neutron source. The advantage of this method for such experiments, as well as for experiments as the one described, over the method of using the plate as both radiator and detector arises chiefly from the fact that one has only to scan the surface of the emulsions for tracks; and, if proper geometry is used, those tracks starting at the surface and produced by particles originating in the radiator have a known and convenient orientation. This greatly facilitates the search for and measurement of the tracks. This technique also eliminates large corrections (especially when high energy neutrons are being investigated) arising from the fact that long tracks have a lower probability of ending in the emulsion and hence of being counted in their proper energy interval than shorter tracks.

FIG. 5. Source-detector geometry for neutron energy spectra determinations.

Figure 5 gives the experimental arrangement for determining the energy spectrum of a high energy source of neutrons. In the case of a low energy neutron source, one might well use the arrangement of Fig. 2 with an appropriately thin radiator and with the axis of the vacuum chamber making a small angle with the direction of the neutron beam so that the plate is not subjected to bombardment by the primary neutron beam.

Figure 6 gives the energy distribution of the recoil protons projected from a 0.005 inch polyethylene radiator by a monoenergetic beam of 14 Mev neutrons. Only protons making an angle of less than eight degrees with the incident neutron direction were recorded. The low energy straggling is probably due to slit penetration of the recoil protons and to the detection of recoil protons from neutrons which do not come directly from the source. Here again the slit system could have been dispensed with by sufficiently increasing the distance between the radiator and detector.

[6] W. F. Hornyak and T. Lauritsen, Rev. Mod. Phys. 20, 204 (1948).

The errors shown on the experimental points of all curves only represent the statistical probable error based on the number of tracks counted for each point. Additional uncertainties are introduced in the measurement of the absolute ranges traversed by the particles in the emulsion as well as by the finite radiator thickness and finite angular resolution. The above effects manifest themselves as an apparent range straggling and are responsible for the fact that in Fig. 4, for example, the two peaks are hardly resolved. The various experimental factors which produce the finite widths in the number *vs.* range curves do not carry equal weight at every range. In the region above 100 microns, for example, the absolute range of a particle can be determined to better than ±3 percent and this accuracy depends for the most part on the accuracy with which one can measure the projected length of the track, the effect due to finite grain spacing being relatively small. In the region of 5 microns on the other hand, the range of a particle cannot easily be determined to better than ±15 percent due in no small part to the finite spacing between the individual grains comprising the track.

This technique would be especially useful for high energy neutron spectra determinations where much thicker radiators could be used.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

An Analog Computer

J. G. Bayly
Atomic Energy Project, National Research Council of Canada, Chalk River, Ontario, Canada

(Received November 28, 1949)

An integrator has been constructed which is capable of computing the yield of nuclear reactions produced by radiation of intensity that varies arbitrarily with time. By combining the appropriate number of such machines the yield resulting from a series of consecutive reactions may be found.

While the emphasis in this paper is on applications involving the yield of radioactive isotopes produced by a pile or other source of radiation, the instrument may be used to calculate temperatures in thermodynamic problems, voltages and currents in electrical networks, and so on, wherever the quantity (x) to be determined is governed by the differential equation

$$dx/dt = -\lambda x + f(t),$$

$f(t)$ being a given function of the time, and λ a known constant.

I. INTRODUCTION

THE calculation of the yield of a radioactive nuclide produced by the irradiation of another nuclide, as in a pile, cyclotron, etc., becomes very laborious if the radiation intensity is altered often during the experiment. Unavoidable changes in intensity result from the variations in power level and complete shut-downs required for experiments, routine maintenance, and emergency conditions. To economize time and effort a need was felt for a computer which was flexible enough to solve the different types of problems with better than 1 percent accuracy, capable of being set up and operated by non-mathematicians either manually, from a record of the radiation intensity, or automatically, from a signal produced by an instrument such as an ionization chamber. The instrument described in this paper satisfies all these requirements.

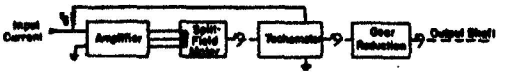

FIG. 1. Velocity-servo.

II. THE DIFFERENTIAL EQUATIONS

The simplest type of integration, i.e., the solution of the differential equation

$$dQ/dt = P, \tag{1}$$

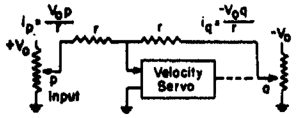
where P is a given finite, single-valued real function of time t, may be performed automatically by a servo whose angular velocity, dQ/dt, is proportional to a current which in turn is proportional to P. The actual integration is performed by the shaft of the servo, the value of the integral being read from a dial driven by the shaft.

By modifying the servo so that the angular velocity is proportional to the difference between two currents, one of which is proportional to P and the other proportional to the yield, Q, the instrument will solve equations of the type

$$dQ/dt = P - \lambda Q. \tag{2}$$

In the computers of this type that have been built at Chalk River, P is generally made proportional to

FIG. 2. Circuit for solving $dQ/dt = P - \lambda Q$.



the neutron flux, and Q represents the yield of a neutron induced reaction, usually a radioactive isotope. The quantity λ is then the disintegration constant of this isotope.

More complicated problems arise when the yield is determined by two simultaneous equations. These may be solved by using two computers, the output of the first determining the function P for the second, or in many cases by recording the output of one computer on the graph of a recording voltmeter and subsequently using this graph as the function P with the computer set up to solve the second differential equation.

When the target material is appreciably reduced by the reaction, the equations are of the form

$$dQ_t/dt = -PQ_t, \tag{3}$$

$$dQ/dt = PQ_t - \lambda Q, \tag{4}$$

where Q_t represents the number of target nuclei. Here the function PQ_t is obtained first from Eq. (3), and used as the input to solve Eq. (4).

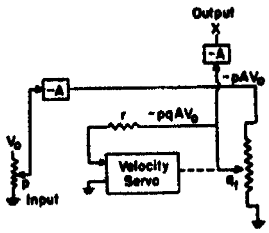
A reaction for which the computer has been frequently used is one in which two nuclear reactions take place, the yield nucleus of the first providing the target for the second. The instantaneous yield of the first reaction is found from Eq. (2) or (4), and the product PQ, which is proportional to the rate of production for the second reaction, is used as the function P for a second calculation. An example of this type of reaction is discussed in Section V.

These problems, involving addition and multiplication, represent a few of the more useful applications of the computer. Many other differential equations may be solved using the well-known circuits[1] for dividing, squaring and generating sine, cosine, logarithmic, etc. functions of quantities available as shaft rotations or voltages.

III. PRINCIPLE OF OPERATION

The integration involved in the calculation is performed by a dial driven by a velocity-servo which produces an angular shaft velocity accurately proportional to an applied current. The servo, the velodyne of Williams and Uttley,[2] Fig. 1, consists of a high gain, stable d.c. amplifier controlling a reversing motor-tachometer-generator. The tachometer voltage produces a current determined by r_g, which except under transient conditions reduces the net amplifier input current to the very small value required to overcome friction in the mechanical system. During transients caused by rapid changes in the demanded speed of the servo, the error in this current balance, occurring while the motor is accelerating or decelerating, is stored in a memory circuit in the amplifier. This remembered error is applied as a correction to the speed of the motor, so that the resultant error is zero after the transient is over. An extensive analysis of this type of servo has been given by Williams and Uttley.

FIG. 3. Circuit for solving $dQ_t/dt = -PQ_t$.



The motor also drives a gear reduction unit which is coupled, through a friction clutch, to the shaft of a helical potentiometer carrying the dial upon which the solution of the calculation is read. For simplicity, the amplifier, motor generator, gear box, and feedback portions of the calculator will be shown as a single unit with an input current connection and an output shaft, and labelled a velocity-servo in subsequent figures. The action of the velocity-servo is simply to convert an input current into an angular shaft velocity, which may be integrated by the dial.

The function P may take the form of a current from an ionization chamber monitoring the radiation intensity, or it may be given in a chart or table of intensities *versus* time. While the current, suitably amplified, may be used directly to control the computer it is generally more practical to use a chart or table of intensities. In this way the entire calculation may be performed in a small fraction of the time required for the irradiation. For this purpose an auxiliary unit has been built in which a chart of the type used in Esterline-Angus recording meters is motor driven at a constant velocity. The curve on the chart is followed manually by means of a stylus which rotates the moving arm of a potentiometer, producing a voltage proportional to P. If the curve consists of a series of radiation pulses of constant amplitude, a "square input" control is used to switch this voltage between zero and the value corresponding to the constant amplitude.

A circuit appropriate to the problem to be solved must be used to synthesize the velocity-servo input current from P, Q, λ, etc. Several examples of circuits that have been found useful in pile yield problems are given below.

IV. TYPICAL CIRCUITS

The simple calculation of the yield of an active isotope indicated by Eq. (2) is performed by the circuit shown in Fig. 2. The two potentiometers are calibrated from 0 to 1; the values p and q read on the calibrated scales are then the normalized equivalents of P and Q, the

---

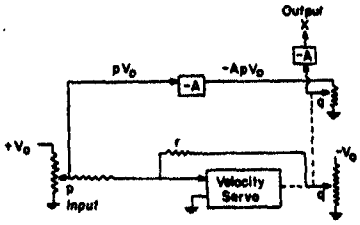

FIG. 4. Circuit for obtaining PQ from $dQ/dt=P-\lambda Q$.

maximum values of these, P_m and Q_m, corresponding to $p=1$ and $q=1$.

The angular velocity of the output shaft is proportional to the input current, which is i_p+i_q, or

$$dq/dt=c(i_p+i_q)=\lambda p-\lambda q.$$

The magnitude λ playing the role of disintegration constant is directly proportional to the voltage V_0 and the resistance r_0 (Fig. 1); inversely proportional to the resistance r, the strength of the magnetic field of the tachometer, and the gear reduction factor; and independent of the d.c. amplifier, provided only that the amplifier gain is high and the zero drift of the amplifier is negligible during the calculation.

The following information must be supplied to the calculator:

1. A record of the time variation of $p=P/P_m$, where P is the intensity of the radiation, and P_m is the maximum intensity occurring during the irradiation;
2. The disintegration constant λ of the radioactive isotope produced;
3. The saturation yield, Q_m, which would have been produced had the intensity remained constant at P_m for an indefinitely long period of time.

The yield at any time during the experiment may be found from the reading of the q dial at the corresponding time during the calculation,

$$Q=qQ_m.$$

Equation (3) may be solved by means of the circuit shown in Fig. 3. The units labeled $-A$ are current amplifiers which reverse the sign of the applied voltage and have high input and low output resistances. Their voltage amplification factor A is approximately unity. The output at x may be used as the pV_0 voltage in a second computer, or this output may be recorded on an Esterline-Angus recorder for use in a second calculation, using the circuit of Fig. 2 to solve Eq. (4).

When the yield to be calculated results from a reaction involving the yield of a previous reaction, the "p" function for the second integration may be determined from the circuit in Fig. 4. The output from the point x is proportional to the radiation intensity and to the number of target nuclei and is used immediately or stored as a chart as in the previous example.

V. USES OF THE COMPUTER

The analog computer has been used to find the yields of Ba^{139} and Ba^{140} produced when Ba^{138} is irradiated by a neutron flux.[3]

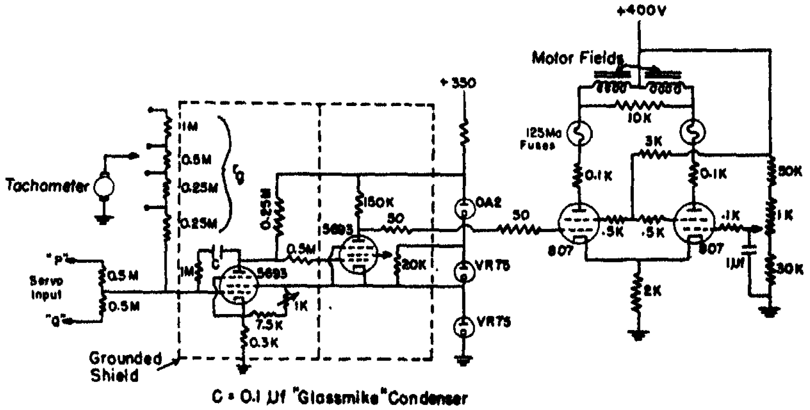

FIG. 5. Servo amplifier.

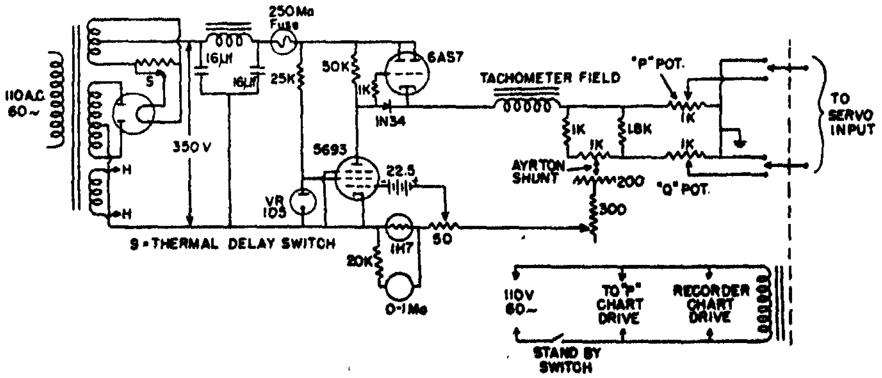

FIG. 6. Tachometer field supply.

---

[3] Yaffe, Sargent, Kirsch, Standil, and Grunlund, Phys. Rev. 76, 617 (1949).

$$\begin{tikzcd}
\mathrm{Ba}^{138} \arrow[d, "n"', "\gamma"] & & \\
\mathrm{Ba}^{139} \arrow[r, "\beta", "85\text{ min.}"'] \arrow[d, "n"', "\gamma"] & \mathrm{La}^{139} \arrow[d, "n"', "\gamma"] & \\
\mathrm{Ba}^{140} \arrow[r, "\beta", "12.8\text{ day}"'] & \mathrm{La}^{140} \arrow[r, "\beta", "40\text{ hr.}"'] & \mathrm{Ce}^{140}.
\end{tikzcd}$$

The differential equations for this chain of reactions are:

$$dQ/dt = P - \lambda_Q Q - aPQ, \quad \lambda_Q = 1.36 \times 10^{-4}\text{ sec.}^{-1}$$
$$dR/dt = aPQ - \lambda_R R, \quad \lambda_R = 6.27 \times 10^{-7}\text{ sec.}^{-1},$$

where Q is the yield of Ba^{139}, λ_Q the disintegration constant of Ba^{139}, R is the yield of Ba^{140}, λ_R the disintegration constant of Ba^{140}, and a is proportional to the capture cross section of Ba^{139}. Since aP was negligible compared with λ_Q, the circuit shown in Fig. 4 was used to give a graph of the product PQ as well as the instantaneous values of Q. The calculation of R was performed by using the PQ graph with the circuit in Fig. 2.

The amount of La^{139} present may be obtained by integrating Q, since the amount destroyed by neutron capture is small. If, during this calculation, the product of P and the yield of La^{139} is recorded, a second calculation will give the contribution to the La^{140} yield due to the chain through La^{139}. In a similar way the La^{140} yield from the Ba^{140} may be found.

VI. INSTRUMENTAL DETAILS

1. The Servo Motor

The Velodyne motor-generator Type 74 is used.[2] The motor armature is supplied with a constant direct current of 3 amperes, obtained from the 110-volt d.c. mains, using an incandescent lamp load to obtain a high dynamic resistance (constant current) characteristic. Since this current is not appreciably reduced by the back e.m.f., the motor acceleration remains at its maximum value until the demanded speed is reached.

2. Servo Amplifier

The amplifier which drives the split-field motor is shown in Fig. 5. Zero drift is made negligible by supplying the tube filaments from a stabilized power supply, and by heating the filaments for 15 minutes before applying the high voltage. It was found necessary to use a "Glassmike" condenser[4] in the memory circuit to prevent zero drift due to the variable leakage current present in ordinary condensers. As a precaution, the zero error is checked daily, but corrections are necessary only about twice per month.

3. Tachometer Field Supply

The disintegration constant is proportional to V_0, and inversely proportional to the generator field. Since, to a first approximation, the generator field is proportional to the field current, a circuit was used in which the field current and potentiometer voltage V_0 were proportional to one another. Thus, to a first approximation, the disintegration constant is independent of small changes in the supply.

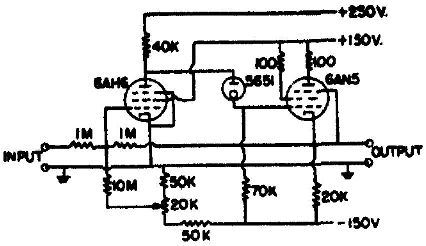

FIG. 7. Current amplifier.

Changes in the supply current were made very small by regulating the current as shown in Fig. 6. The ballast tube, 1H7, with a dynamic resistance of approximately 2500 ohms, and a static resistance of 110 ohms, produces a considerable stabilizing action, which is amplified by the pentode-series triode circuit. The internal impedance of the supply is greater than 10^6 ohms, so that changes in the generator field resistance due to the heating of the windings gives a negligible error.

Since a control whose setting was linear with the disintegration constant was desired, an Ayrton shunt was used to provide the voltage V_0 which is proportional to λ. The center-tapped rheostat ganged to the Ayrton shunt provides a rough compensation for the changes in resistance of the shunt.

To avoid hysteresis effects the field current is never allowed to exceed its normal operating value. To this end, the current is made to build up slowly after the stabilizing amplifier (5693 and 6AS7) has heated up. A thermal delay switch turns on the rectifier filament voltage 1½ minutes after the amplifier heaters are turned on, and the field current then builds up slowly as the rectifier filament heats and the filter condensers charge up. The field current is finally adjusted upward to its normal operating value by reducing the series field rheostat. A voltmeter connected to read the voltage across the 1H7 provides a very sensitive indication of the current, a change of 2 percent from the normal operating point representing a current change of 0.1 percent.

4. Current Amplifiers

A satisfactory design for these units, of which two were built, is shown in Fig. 7. These amplifiers are indicated by the symbol $-A$ in Figs. 3 and 4. By applying the methods used to minimize zero drift in the servo amplifier and by using the highly stable 5651 constant voltage tube, these amplifiers are made so stable that zero adjustments need only be made about once a week.

VII. ACKNOWLEDGMENTS

The author is indebted to Dr. B. W. Sargent for his stimulating interest and to Mr. T. Hughes for assistance in the design and construction of the first model.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

Photographic Methods of Measuring Slow Neutron Intensities

M. Blau, I. W. Ruderman, and J. Czechowski
Pupin Physics Laboratories, Columbia University, New York

(Received December 1, 1949)

The relative slow neutron sensitivities of β-sensitive emulsions, x-ray film-indium foil combinations, and boron-loaded plates were investigated. Since the detection efficiency depends upon the neutron energy, experiments were made with epithermal, thermal, and cold neutrons. β-sensitive emulsions and x-ray-indium combinations are about equally useful for the detection of epithermal neutrons. B^{10} loaded plates, which are best for the detection of thermal and cold neutrons, have the following advantages: very low neutron intensities can be measured by microscopic counting of α-tracks, neutrons can be counted in the presence of β- and γ-radiation, the number of α-tracks is essentially independent of the development conditions, and a wide range of neutron intensities can be measured with a single plate.

INTRODUCTION

For neutron diffraction and scattering experiments, it is desirable to be able to measure neutron intensities simultaneously and continuously over large areas. When large changes in neutron intensity occur within small regions, such as is the case in crystal diffraction patterns, the use of conventional BF_3 neutron counters entails the disadvantages of poor resolution and long scanning times. If photographic plates could be made sufficiently neutron sensitive, they would not be limited by these disadvantages and would constitute a valuable tool for neutron experiments. A study of various photographic emulsions suitable for slow neutron detection was therefore initiated, with the dual objective of evaluating the techniques which have already been reported in the literature and seeking, if possible, to improve these techniques for our purposes.

The following classification of neutrons according to energy will be used in this paper: fast, >10,000 ev; slow, 0–10,000 ev; epithermal, 0.3–10,000 ev; thermal, 0.01–0.3 ev; and cold, <0.01 ev.

EXPERIMENTAL METHOD

The following methods of achieving neutron sensitivity in photographic emulsions were considered: (a) utilization of the capture cross section of the elements normally present in emulsions, (b) addition of high cross section elements to the emulsion, or (c) use of a combination of a neutron absorbing metallic foil and a photographic emulsion.

Method A

The only elements in emulsions that need be considered are nitrogen and silver. The usefulness of the $N^{14}(n, p)C^{14}$ reaction is limited by its low cross section (1.7 barns at 0.025 ev),[1] which makes it relatively insensitive to slow neutrons. Silver has nuclear resonances at 56, 41, 31, 16, and 5.1 ev, and has a fairly high capture cross section for neutrons ($\sigma=6.6+9.05E^{-\frac{1}{2}}$).[2] It is therefore useful for detecting thermal and cold neutrons as well as neutrons having energies in the neighborhood of its resonances. Furthermore, Ag^{108} and Ag^{110}, which are formed from normal isotopic silver by the n, γ reaction, are β^{-}- and β-, γ-emitters with short[3] half-lives of 2.3 min.[4] and 24.2 sec.,[5] respectively. The high energy (2.6 and 2.8 Mev) β-rays emitted by these isotopes can produce tracks in the recently developed β-sensitive emulsions. Since the β-rays are produced directly in the emulsion, they should contribute more to the darkening than the γ-rays, which must first produce secondary electrons. The following types of β-sensitive emulsions were investigated: Ilford *G*5, 200μ, 37.0 mg Ag/cm²; Kodak Ltd. *NT*4, 200μ, 39.4 mg Ag/cm²; Eastman Kodak *NTB*3, 65μ, 11.0 mg Ag/cm²; and Eastman Kodak pellicles, 250μ, 42.3 mg Ag/cm².

Method B

X-ray film covered on one face by a thin sheet of indium has been successfully utilized by Wollan and Shull[6] to record neutron Laue patterns. Since no other available metallic foil appeared to offer any large advantage over indium, our experiments were conducted with *K*-type, double coated, acetate base x-ray film covered on both sides with 0.5-mm indium foil (368 mg In/cm²).

Method C

The use of B or Li loaded plates for neutron dosage measurements has recently been described by Shapiro and Barnes[7] and by Titterton.[8] Increased sensitivity may be achieved by the use of B^{10} instead of normal isotopic boron. Furthermore, if the boron is incorporated in relatively insensitive emulsions such as the Ilford D_1, the additional advantage of γ-ray insensitivity may be achieved.

The importance of achieving the highest possible concentration of boron (preferably as B^{10}) is illustrated by Fig. 1, in which the neutron transmissions of boron loaded plates containing various grams B^{10} per cm^3 of emulsion are plotted as a function of neutron energy. Ilford D_1 plates, which were used in our experiments, contain 23 mg normal boron per cm^3 emulsion, although this quantity can be doubled with special treatment.

In exploratory experiments carried out in this Laboratory, 100μ Ilford D_1 nuclear plates were soaked for one hour with agitation in a solution containing 5 g of $Na_2B_4{}^{10}O_7 \cdot 10H_2O$ per 100 ml of water. Comparison of the α-track density of these plates with Ilford B loaded plates of known boron content, after exposure to the same neutron flux, indicated B^{10} uptakes of $\sim$20 mg per cm^3 of emulsion. Experiments were carried out with these B^{10} loaded plates, without further attempts to increase the boron content. Yagoda and Kaplan[9] have recently reported that a concentration of $\sim$15 mg B^{10} per cm^3 of emulsion can be obtained by soaking 200μ Ilford C_2 plates for two hours in a solution of normal isotopic lithium borate. One could therefore expect to obtain a concentration of $\sim$80 mg B^{10} per cm^3 of emulsion if $Li_2B_4{}^{10}O_7$ were used. Plates containing such high boron contents approach conventional BF_3 proportional counters in neutron detection efficiency, as indicated in Fig. 1.

Exposures to neutrons were made in the collimated beam of the Columbia neutron velocity spectrometer.[10, 11] The photographic plates were mounted on one face of a 5-in. diameter disk of paraffin-boron carbide mixture 1 in. thick, from which several sectors had been cut (Fig. 2). The disk was placed in the neutron beam so that the face not covered with plates was perpendicular to, and facing, the neutron beam. The disks were rotated intermittently during exposure in order to minimize neutron flux variations. Because the cyclotron efficiency varies considerably with time, the exposure periods were made in terms of the number of counts from a neutron fission counter placed within the cyclotron enclosure.

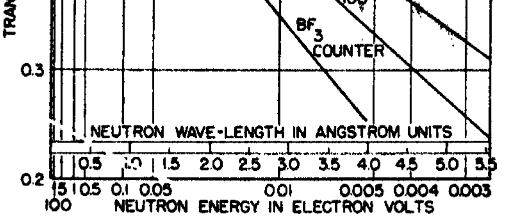

FIG. 1. The transmission as a function of neutron energy of 200 μB^{10} loaded plates containing various mg B^{10} per cm^3 of emulsion. The cross section of B^{10} was taken to be $\sigma = 627E^{-\frac{1}{2}}$. The transmission of a conventional BF_3 proportional counter, 10 cm long and filled to 50-cm pressure with pure $B^{10}F_3$, is included for comparison.

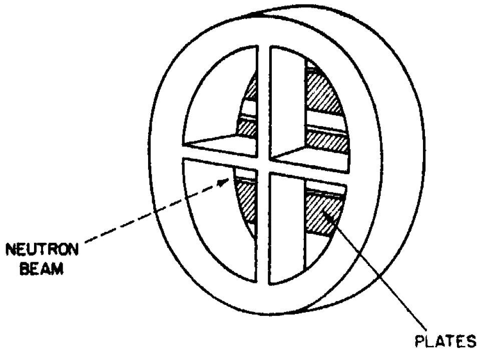

FIG. 2. Arrangement of photographic plates on paraffin-boron carbide template and position of the latter relative to the neutron beam.

Since the detection efficiency depends markedly on neutron energy, the relative merits of the different types of emulsions were determined by separate exposures to epithermal, thermal, and cold neutrons. This was accomplished by the use of a Cd filter to cut out the thermal and cold neutrons, and Be plus BeO filters to reduce the epithermal and thermal neutron flux. Figure 3 shows the different neutron energy distributions in the collimated beam obtained in this way. In all cases, the fast neutrons leaving the internal beryllium target in the cyclotron were first slowed down to an essentially thermal distribution by a 6.5-cm thick slab of paraffin placed at the beginning of the collimating system.

Development of each particular type of emulsion was carried out in the standard manner, taking care to obtain reproducible results. The optical density of the patterns produced in the plates was determined by a Baird Associates' non-recording densitometer, measurements being made both of the blackened parts and the background in their immediate neighborhood, and of unexposed plates. In the case of the boron loaded plates, the density of α-tracks was also measured by microscopic examination using magnifications up to 90×15. Curves of optical density *vs.* neutron exposure were also obtained for each of the emulsions, exposures being made with an unfiltered neutron beam.

RESULTS

The β-sensitive emulsions were rated on the basis of the gross observable blackening due to β-tracks, rather than on the detailed structure of the tracks. The sensitivity thus depends not only on the number of grains produced for equal values of the energy loss, but also on the grain size. A preliminary survey of the various β-emulsions now available led us to the conclusion that the *NT*4 emulsion (Kodak Ltd.) is the most sensitive for our purposes, although the differences between the various types are not very large. Our experiments were therefore carried out principally with *NT*4 plates.

[11] W. W. Havens, Jr. and J. Rainwater, Phys. Rev. **70**, 154 (1946).

High humidity was found to decrease seriously the sensitivity of the β-plates, just as has been found to be the case in the use of these plates for the detection of lightly ionizing particles. The loss in sensitivity results from the decrease in the number of grains corresponding to equal values of the energy loss per unit length of track.

Figures 4a and 4b give optical density curves (for full neutron beam exposure) for *NT*4 plates and for x-ray film with and without indium foil. In Fig. 4a the density is expressed as the difference between the optical density, D, of regions exposed to the neutron beam and the density, D_b, of the film shielded by the boron-paraffin disk. This defines an effective density such as is useful in neutron diffraction work when absolute intensities are required. By plotting the density as the difference between D and the density, D_0, of completely unexposed plates, as shown in Fig. 4b, an over-all density uncorrected for stray radiation is obtained. Comparison of Figs. 4a and 4b shows that, except in the case of x-ray film without indium foil, the blackening due to neutrons was much greater than the stray radiation background. The latter was mostly due to γ-radiation.

X-ray emulsion is less sensitive to high energy β-particles than is β-sensitive emulsion, and also contains much less silver than the latter. The neutron sensitivity of x-ray film is hence much less than that of a β-sensitive plate such as *NT*4 (Figs. 4a and 4b). However, when x-ray film is covered with a thin sheet of indium foil, a very large increase in sensitivity is obtained. Indium, which has a high neutron capture cross section, emits γ-radiation from the n, γ reaction and both β- and γ-rays from the radioisotopes In^{114} [12] and In^{116} [4] which are formed. That the principal contribution of the indium is the γ-radiation was demonstrated by exposing to neutrons a stack of twelve x-ray films covered only on the front face with an 0.5-mm thick indium foil. It was found that there was little attenuation in the optical density from film to film, a result which would not be the case if the β-rays from the In^{114} and In^{116} contributed significantly to the density.

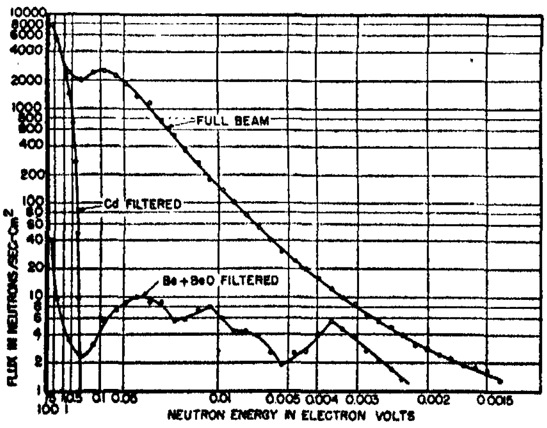

FIG. 3. Energy distributions of the full, Cd filtered, and Be plus BeO filtered neutron beams. The neutron fluxes were calculated from data obtained with the neutron velocity spectrometer.

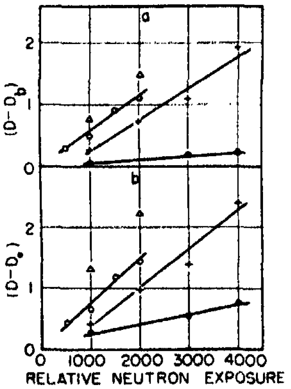
The density curves in Figs. 4a and 4b should be considered as only roughly quantitative because the known inhomogeneity of the neutron beam probably did not permit equal exposures of all the plates that were simultaneously exposed. In addition, the *NT*4 plates used for these density curves were not fresh, and had suffered some loss of sensitivity because of exposure to high humidity. In other experiments, fresh, dry *NT*4 plates were found to be somewhat more sensitive than x-ray film plus indium foil (for unfiltered neutrons).

The two triangular points in Fig. 4a and in Fig. 4b represent the total densities of a combination consisting of two *NT*4 plates placed and exposed emulsion to emulsion. It is seen that considerable improvement in effective density, without appreciable sacrifice in resolution, may be achieved in this way.



FIGS. 4a and 4b. Optical densities for different neutron exposures of x-ray film with (○ *points*) and without (● points) indium foil, and of *NT*4 emulsion (+ points). The two points in each figure indicated by Δ represent the combined densities of two *NT*4 plates placed and exposed emulsion to emulsion. D, D_b, and D_0 refer to the optical densities of the directly exposed areas, exposed background areas, and unexposed plates, respectively. Exposures were made with the full (unfiltered) neutron beam.

The results of the experiments on the dependence of detection efficiency on neutron energy are given in Table I. The x-ray-indium combination appears better, relative to the *NT*4 emulsion, for cold neutrons (Be plus BeO filtered) than for thermal and epithermal neutrons. This is reasonable in view of the higher indium absorption cross section[13] for slow neutrons and the larger amounts of indium present, compared with the silver in the β-plates. The performance of the *NT*4 plates, particularly when fresh and dry, is remarkably good, a result which may be attributed to the excellent β-sensitivity of these plates.

---

[12] S. W. Barnes, Phys. Rev. 56, 414 (1939).

[13] At 0.025 ev the absorption cross section of indium is 194 barns (see reference 1), compared with 69 barns for silver.

TABLE I. The effect of neutron energy on the relative detection efficiency of an x-ray-indium combination and *NT*4 β-sensitive emulsion.

Neutron beam	Exposure, neutrons/cm^2	Type of emulsion	Emulsion density $(D-D_b)$	Emulsion density $(D-D_0)$
Full beam	3.2×10^7	x-ray+In	1.02	1.24
	3.2×10^7	*NT*4	0.94	1.34
Filtered with 13 g/cm^2 Be plus 11 g/cm^2 BeO	1.9×10^5	x-ray+In	Not measurable	
	1.9×10^6	*NT*4	Not measurable	
Filtered with 13 g/cm^2 Be plus 11 g/cm^2 BeO	4.1×10^5	x-ray+In	0.32	0.71
	4.1×10^5	*NT*4	0.22	0.55

TABLE II. Some experiments with 100μ Ilford D_1 plates loaded with 23-mg normal boron per cm^3 emulsion. The exposures in neutrons per cm^2 were calculated from the data in Fig. 3; the corresponding counts as recorded with BF$_3$ counters were obtained with the neutron velocity spectrometer.

Neutron beam	Exposure, neutrons/cm^2	Number of α-tracks per mm^2	Number of counts in BF$_3$ counters; full beam = 100
Full Beam	3.2×10^7	3355	100
Filtered with 13 g/cm^2 Be plus 11 g/cm^2 BeO	1.9×10^5	49	1.1
Filtered with 0.48 gm/cm^2 Cd	1.5×10^7	548	13

In order to determine whether improved sensitivity of β-plates might be achieved by the use of supplementary indium foils, Ilford *G*5 plates covered on the back face (away from incident neutrons)[14] with 0.5-mm indium foil were exposed, along with control plates, to the full neutron beam. The effective optical density, $(D-D_b)$, of the *G*5 indium combination was 0.10, compared with an average value of 0.08 for the control *G*5 plates. That only such a small improvement was observed may be explained by the relatively poor sensitivity to γ-radiation of the *G*5 plates (the grain diameter is only about one-tenth as large as the grain diameter in *K*-type x-ray emulsion). Furthermore, a considerable fraction of the β-rays produced by the In^{114} and In^{116} are absorbed in the In foil. Even apart from these considerations, it does not appear to be practical to use indium foil with β-plates because these plates are very sensitive to pressure effects[15] which distort the homogeneity of the image. Improvement in sensitivity for low neutron fluxes might be achieved by counting β-tracks, and it was indeed found possible to count tracks microscopically when the track density was low. However, this method is tedious, and the accuracy is seriously limited by the cosmic-ray background.

Shull and Wollan have suggested[6] the use of fluorescent screens in conjunction with x-ray film plus indium in order to improve the sensitivity. Such an improvement might be expected for the β-radiation emitted by the indium. However, as has already been pointed out, it is mainly the γ-radiation which is responsible for the blackening effect in the x-ray-indium sandwich; and for γ-rays the intensifying effect of fluorescent screens is low. For example, the use of a calcium tungstate screen (which is perhaps the most effective for penetrating radiation) in conjunction with *F* type x-ray film can be expected to give a maximum amplification of about four over no-screen film.[16] It is assumed here that the exposure time is optimum with respect to reciprocity law failure. At the same time, however, the screen would reduce the resolution by a factor of perhaps 5 to 10.

The possibility of using an organic fluorescent material such as naphthalene or anthracene to improve the intensity of x-ray film does not appear too feasible. The large screen thickness which would be necessary for the effective use of such a screen would probably result in a prohibitive reduction in resolution. The same consideration is valid for fluorescent screens in which are incorporated elements having high cross sections for (n, α) or (n, p) reactions. Here there is the further difficulty of introducing large concentrations of such elements without impairing the luminosity of the screen.

Table II gives some results obtained with boron loaded emulsions. The ratio of the measured α-track density for unfiltered neutrons to that for Be plus BeO filtered neutrons to that for Cd filtered neutrons is seen to agree fairly well (considering the fluctuations in neutron flux) with the ratio of the respective neutron fluxes as determined with BF$_3$ proportional counters. The smallest track density which can be measured without undue effort and loss of accuracy is ~50 tracks per mm^2; the maximum density which it is convenient to measure is $\sim6\times10^4$ tracks per mm^2. Since 9.1×10^4 tracks per mm^2 was found to correspond to an effective optical density $(D-D_b)$ of 0.16, while 2.3×10^4 tracks per mm^2 gave an effective density of 0.03,[17] it would appear (as is to be expected) that the optical density is essentially linear with respect to the track density at least in this high track density region where it is feasible and convenient to measure the density with a densitometer. Boron loaded plates thus offer the distinct advantage of being useful over a very wide range of slow neutron fluxes.

Perhaps the most important thing to note is that, after an exposure of 1.9×10^5 neutrons (Be plus BeO filtered) per cm^2, no measurable darkening was produced in the *NT*4 plates or x-ray film plus indium foil

---

[14] By covering only the back face of the plate with indium, only neutrons not captured in the G5 emulsion were available for absorption by the indium.

[15] H. Yagoda, *Radioactive Measurements with Nuclear Emulsions* (John Wiley and Sons, Inc., New York, 1949), p. 14.

[16] G. M. Corney, Nondestructive Testing 7, 17 (Winter, 1948–49).

[17] This experiment was carried out by exposing simultaneously to the same neutron flux an Ilford D_1 normal boron loaded plate and a D_1 plate impregnated with pure B^{10} in this Laboratory. Both plates contained roughly the same concentration of boron, but they differed in their sensitivity by a factor of 5.3 because of the different B^{10} contents.

(Table I). However, this same exposure produced a measurable density of 49 tracks per mm^2 in the Ilford D_1 plates loaded with normal boron (Table II). Boron loaded plates therefore offer a large advantage over β-sensitive plates and the x-ray-indium combination for the measurement of low thermal and cold neutron intensities. This advantage can be increased several fold by the use of higher boron concentrations in the emulsion and by the substitution of B^{10} for normal isotopic boron. Thus, if the quantity of boron was doubled (from 23 to 46 mg per cm^3 of emulsion), and pure B^{10} was used, a total exposure to only 2×10^4 neutrons (Be+BeO filtered) per cm^2 would be necessary to give a measurable number of tracks per mm^2. This high neutron sensitivity should make it more feasible to carry out neutron scattering and diffraction experiments.

A further very valuable advantage of boron loaded plates lies in their specific sensitivity to neutrons, provided that the density is measured by α-track counting. By selecting the proper type of emulsion, such as Ilford D_1, the sensitivity to β- and γ-radiation can be kept relatively low. Thus, after an exposure of a D_1 plate to ~80 r of γ-radiation (from a Ra source), the γ-ray background was still low enough to allow short alpha-, or even proton, tracks to be counted readily.

Another important advantage of boron plates lies in the fact that the recognition of α-tracks is largely independent of the development conditions, contrary to other photographic methods based on the density of the image.

The disadvantage of boron plates for low neutron fluxes lies in the necessity for microscopic scanning. However, in scattering experiments where accurate position and intensity measurements of the scattered neutrons are required, the additional time spent in counting tracks (0.5–2 hours depending on the track density and the required accuracy) is not too serious.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

A Microcalorimeter Suitable for Study of Easily Absorbed Nuclear Radiations*

C. V. CANNON† AND G. H. JENKS
Chemistry Division, Oak Ridge National Laboratory

(Received December 5, 1949)

A microcalorimeter suitable for measuring the energy of easily absorbed nuclear radiations is described. The calorimeter is an isothermal type operating at the temperature of liquid nitrogen and using the rate of vaporization of nitrogen under constant pressure as a measure of the heat input. The calorimeter is fairly simple to construct and to operate and has a short equilibration period. Heat inputs to the calorimeter as low as 7×10^{-6} cal./sec. can be measured with an accuracy of one percent.

INTRODUCTION

CALORIMETRIC measurement of the heat evolved upon absorption of nuclear radiations is a method for exact determination of the total energy of the radiations and may be applied to the study of radioactive isotopes in several ways. For example, calorimetric measurements may be employed in checking and correlating information on the energetics of decay derived from more sensitive though less absolute instruments, in exact determinations of average β-ray and γ-ray energies, and in standardization of other instruments. However, a great majority of the isotopes of interest are available in only small quantities, and it is generally necessary to employ microcalorimetric methods in studies of this nature.

A microcalorimeter which is of relatively simple construction and operation and which may be applied to the measurement of nuclear radiation energies has been developed at this Laboratory. The calorimeter is an isothermal type operating at the temperature of liquid nitrogen. Heat from a source within the calorimeter volatilizes nitrogen, and the volume of nitrogen gas evolved is measured at a constant room temperature. The relationship between the rate of vaporization and the heat input is determined with a resistance heater.[1]

The sensitivity which can be achieved with this calorimeter, as with others, is limited by two factors: (1) the uncertainty in the measurement of the quantity of heat entering the calorimeter, and (2) the uncertainty existing as to what fraction of the heat entering the calorimeter is due to the source and what fraction is due to thermal leakage from the surroundings.

---

† Present address: Physics Department, Antioch College, Yellow Springs, Ohio.

[1] Calorimetric methods involving the volatilization of nitrogen have been described by (a) J. W. Stout and W. M. Jones, Phys. Rev. 71, 582 (1947) and (b) James Dewar, Proc. Roy. Soc. A76, 325 (1905), but no previous attempt to use the technique with calorimeters of very high sensitivity has been reported.

The first of these factors is determined mainly by the accuracy with which the quantity of vapor evolved corresponds to the quantity of heat which has entered the calorimeter. Were there no temperature fluctuations within the calorimeter during a measurement, the heat absorbed would determine completely the volume of vapor evolved. In practice, of course, the temperature does not remain perfectly constant but varies as the pressure of vapor within the calorimeter varies. Condensation or vaporization of liquid independent of the rate of heat flow can then occur, introducing an uncertainty into a measurement which is equivalent to the product of the values for the temperature fluctuation and heat capacity of the calorimeter. In order to minimize temperature fluctuations, the nitrogen vapor pressure within the calorimeter was held constant within close limits.

The other factor affecting the sensitivity, i.e., the uncertainty as to the source of heat, was minimized by two procedures: (1) the calorimeter proper was insulated by a vacuum jacket to reduce thermal exchange with the surroundings, and (2) the jacket was immersed in a bath of liquid nitrogen the temperature of which could be regulated and maintained close to that of the calorimeter. As with the calorimeter proper, temperature regulation in the bath was effected by control of vapor pressure.

Two calorimeters of this type have been constructed and their working characteristics investigated. One of the instruments contained considerable mass and was used in the study of γ-rays of moderate energy. The other contained only a small amount of mass and was used for measuring easily absorbed radiations such as β-particles. Only the latter calorimeter will be described here.

DESCRIPTION OF APPARATUS

Calorimeter

The calorimeter assembly was constructed entirely of glass and consisted basically of three concentric Dewar-type flasks. The innermost of these was the calorimeter proper. It contained the heat source to be measured together with some liquid nitrogen. The intermediate flask served as a container for the calorimeter bath. The outer Dewar held liquid nitrogen and was used to prevent excessive influx of heat to the bath region. Both the inner and intermediate flasks were connected with external pressure regulating systems. The calorimeter connecting tube was enclosed by a silvered vacuum jacket in the region which passed through the surface of the outer liquid bath in order to minimize changes in temperature gradients along the tube. Ground glass joints were used to permit access to the two inner flasks.

The arrangement of this apparatus is shown in the scale drawing, Fig. 1. The three flasks mentioned are identified in the drawing as *A*, *B*, and *M*, respectively, and the closures for flasks *A* and *B* are shown at *E* and *F*. The tube connecting the calorimeter with the external system is shown at *C* and the tube leading from the bath region at *D*. Electrical leads which consisted of 36-gauge copper wire were passed into the calorimeter through tungsten-glass seals at *G* and *E*.

The volume of the calorimeter bulb was about 10 ml and a heat source 2.5 cm in length could be accommodated. Restrictions imposed by the neck limited the diameter of a source to 6 mm or less. In operation the bulb was almost filled with liquid nitrogen. The heat

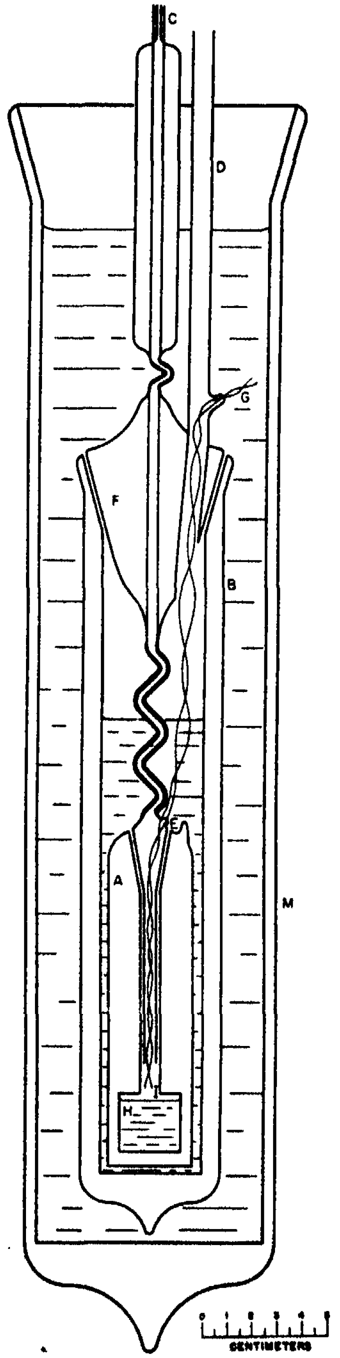

FIG. 1. Calorimeter assembly.

capacity of this liquid plus that of the glass walls made up the total heat capacity of the calorimeter, about 6 cal./deg.

The procedure adopted in assembling the calorimeter was the following: The heat source to be measured was placed in bulb *H* or, in the case of the resistance heater, attached to the lead wires at *I*. About 10 ml of liquid were then transferred into the bulb, and the flask placed on the ground joint *E*. A tight seal was made at this joint using a cement which consisted of a mixture of rubber cement, Apiezon *N* lubricant, and toluene.[3] When frozen, the cement served also to hold the flask in place. Flask *B*, filled with sufficient liquid to bring the level to the approximate height indicated, was next placed in position and the joint then sealed as above. To complete the assembly flask *M* was brought into place and filled with liquid nitrogen.

Maintenance of Pressure and Metering of Gas Evolution Rate

A fixed pressure within the calorimeter was maintained by adjusting the external volume of the system to counteract deviations from the desired pressure. In the apparatus designed for this purpose, the net increase in the external volume of the system represented the volume of gas evolved during the given period and served as a measure of the rate of gas evolution.

A sketch of the apparatus employed to control pressure and meter the gas evolution is shown in Fig. 2. The volume-adjusting device pictured at the right was made up of the glass syringe *D*, the split-phase motor *E*, and the mercury column *B*. The shaft of the motor was coupled to the plunger of the syringe so that rotation of the shaft would displace the plunger and thus change the level of mercury in *B*. This system responded to pressure deviations detected by the mercury manometer-metallic probe arrangement at *A*. The manometer contact and the motor were connected through an electronic relay and a Brown amplifier so that the motor would rotate in a forward or reverse direction depending on whether the contact was made or broken. Thus as a deviation in pressure altered the height of mercury in the manometer, the level of mercury in *B* would be changed to counteract the deviations.

The sensitivity of the mercury-metal contact was, of course, very important in getting close pressure control. It was found that a platinum wire prepared by heating to redness and then coating with a thin layer of Aqua-Dag was exceedingly sensitive, and that it would remain so for several days of operation if the current through the relay were kept to less than a micro-

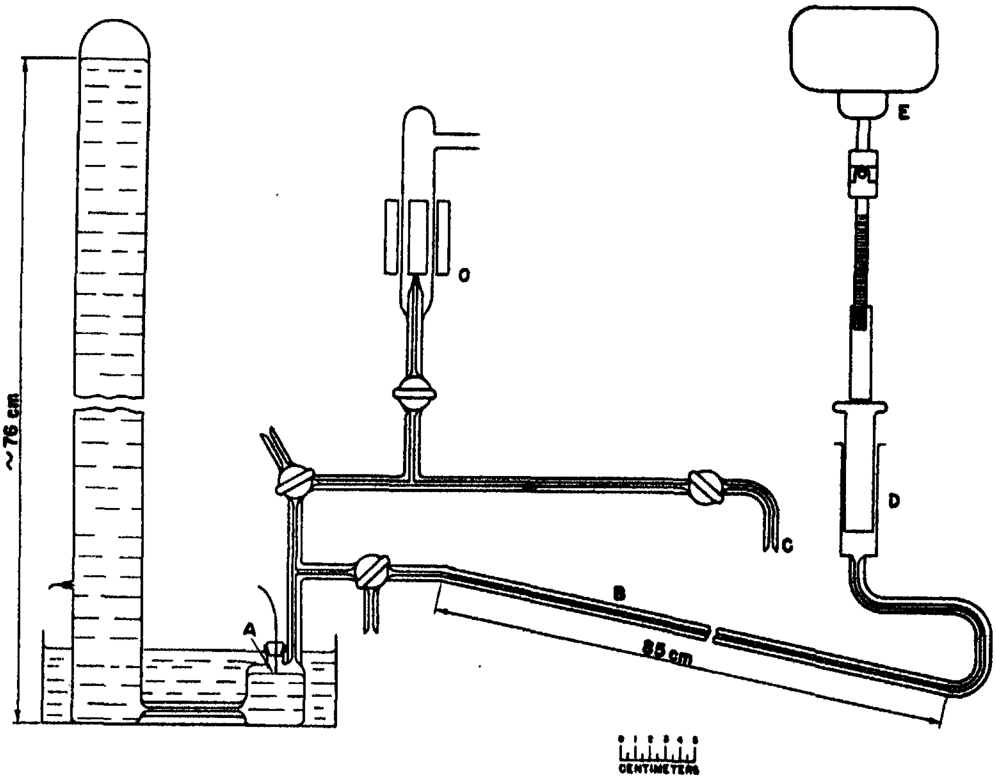

FIG. 2. Apparatus for controlling pressure and measuring gas evolution.

---

[3] Stout and Jones, see reference 1(a), have reported the successful use of rubber cement diluted with toluene as a sealing agent at liquid nitrogen temperature. We have found that the addition of Apiezon lubricant to the mixture increases the reliability of forming a gas-tight seal.

ampere. It was also found that if a slight vibration were imposed on the mercury surface, the sensitivity of the control was increased. With the vibration occurring, the mercury-metal contact was made and broken many times a second. However, the motor would appear to remain stationary when no change in the quantity of gas within the system was taking place. When the quantity of gas was changing, the motor would rotate slowly in the direction necessary to compensate for the change.

In addition to the volume adjusting system, a solenoid operated gas outlet at 0, Fig. 2, was also provided. This valve, which could be controlled by the contact at *A*, was used when only a relatively rough control of the pressure (±0.1 mm) was required. A similar system consisting of a manometer and solenoid valve was used in regulating pressure over the calorimeter bath.

OPERATION OF CALORIMETER

The procedure for setting the calorimeter into operation was fairly simple. The source to be measured was placed in the calorimeter Dewar and the whole Dewar system assembled as previously described. The calorimeter was then connected to the pressure control system from which air had been previously excluded. To complete the assembly, the bath region was joined to its pressure regulating system. This assembly procedure was repeated for each series of measurements on a given source, and of course whenever a new source was substituted.

When the calorimeter was first assembled, its temperature was far from the equilibrium temperature, and the rate of gas evolution was high. The solenoid valve arrangement was then used to control the pressure until the rate had become sufficiently low to permit the convenient use of the volume-adjusting system. After the calorimeter had reached the equilibrium temperature, as indicated by the rate of gas evolution, measurements were started.

To carry out a measurement the mercury in tube *B*, Fig. 2, was first brought to the top by allowing gas to leak from the solenoid valve at a constant slow rate which the volume adjusting system could follow without disturbing the pressure. The solenoid valve was then closed, and the time required for the mercury level to be lowered through a given distance, usually the length of the capillary, was observed. To repeat the measurement, the mercury level was returned to the top as before, and the rate of depression of the level again measured.

To preclude the possibility of condensation within the calorimeter system, the pressure regulator for the bath was set to maintain a pressure approximately 1 mm greater than that within the calorimeter. No change in this relative pressure was made between calibration determinations and measurements on an unknown source. The pressure at which the calorimeter was operated was about 2 cm below average atmospheric pressure at this Laboratory.

TABLE I. Calibration data.

Calorimeter assembly no.	Power level watts ×10^4	Rate of N_2 production arbitrary units 1	2	Computed	Percent deviation of average
1	2.498	1.22	1.21	1.218	+0.41
1	1.800	0.898	0.892	0.888	−0.79
2	1.100	0.562	0.558	0.556	−0.71
3	0.662	0.347	0.347	0.349	+0.57
4	0.200	0.129		0.130	+0.77

The liquid nitrogen which was used in all work was obtained from the Linde Air Products Company. Although only customary precautions to prevent oxygen contamination of the liquid were observed, an added precaution was taken to insure that the compositions of liquids in the calorimeter and bath were the same. In filling the flasks they were first pre-cooled to the temperature of liquid nitrogen and then refilled with liquid taken directly from the shipping tank.

PERFORMANCE

Studies of the performance of the calorimeter as well as calibration determinations were carried out using a resistance heater to produce precisely known power levels within the calorimeter. The resistance used was a ½-watt, Allen-Bradley, carbon resistor measuring ∼5700 ohms at room temperature and ∼11,000 ohms at the low temperature. The resistance of the small copper lead wires could therefore be neglected. The power developed in the resistor was determined by measuring, with a Type *K* potentiometer, the voltage drops across the heater and across a standard resistor in series with the heater.

The results of a representative series of studies which were carried out with the heater are presented in Table I. The energy input is given in the second column and the observed rates of gas evolution for successive measurements are given in the next two columns. Column five contains a list of rate values computed from the equation,

$$R = 0.4732 \times 10^4 W + 0.0358,$$

(R = rate in arbitrary units and W = power level in watts), which was determined from the experimental data by the method of least squares. The percentage deviation of the measured from the computed values is shown in the final column.

Additional calibration data are tabulated in Table II. These data were obtained using a capillary which differed slightly in cross-sectional area from that previously used and thus cannot be directly correlated with those shown in Table I.

The calibration data exhibit a reproducibility of better than ±1 percent for any energy input within the range calibrated. Because of the directness of the electrical calibration and the accuracy with which the power may be measured, it is believed that the probable error

TABLE II. Calibration data.

of determinations on any source falling within the calibrated range is less than ± 1 percent.

Some conclusions regarding the degree of pressure control and the magnitude and reproducibility of the heat leakage may also be drawn from the calibration data. Each rate value reported is the average rate at which a total of 3.0 to 3.5 ml of nitrogen gas were evolved. Since the heat of vaporization of nitrogen is such that 1 ml of gas is evolved by 0.06 cal., the data indicate reproducibility to $\pm 2\times 10^{-3}$ cal. Assuming that all variations between consecutive measurements during a single assembly of the instrument were produced by fluctuations from the given temperature of the calorimeter, and using the value of 6 cal./deg. for the heat capacity of the calorimeter, it may be estimated that the maximum variation in temperature was $\pm 3\times 10^{-4}$ deg. From this value it follows that the maximum detectable variation of the pressure within the calorimeter was $\pm 2\times 10^{-2}$ mm. Actually the pressure control was probably somewhat better than this since a part of the observed deviation between consecutive measurements could be accounted for by a small variation of the temperature at which the gas volume determinations were made.

By reference to the equation relating the experimental data, it can be seen that at zero power the calorimeter still exhibited an appreciable rate of gas evolution. This background rate was undoubtedly caused by heat flowing into the calorimeter from the bath region. The precision of the calibration data show that the uncertainty introduced by any change in the background between different assemblies of the calorimeter was at least as small as that arising from temperature fluctuations within the calorimeter.

If fluctuations of the calorimeter temperature were the only source of uncertainty, still smaller power levels could be measured by extending the observation period. However, the total uncertainty arising from the background would not be affected by longer measurements, and the percentage error would increase as the power of the source decreased. Several attempts were made to reduce the magnitude of the background by reducing the pressure difference between calorimeter and bath. These attempts usually failed because of the occurrence of condensation within the calorimeter before the background was decreased appreciably. This phenomenon was probably caused by the large depth of liquid nitrogen within the bath and the low thermal conductivity of the liquid and of the materials in contact with the liquid. In the absence of stirring it was possible, if heat entered the bath by any path which did not lead through the surface, for liquid surrounding the calorimeter to be warmer than the surface liquid. The tube which conducted vapor from the calorimeter was in contact with the surface and vapor could therefore be condensed at that point while heat was being transferred into the calorimeter from a lower region of the bath.

The length of time required to carry out a measurement with the calorimeter depended upon the power generated by the source under investigation. As noted above, a total of 3 to 3.5 ml of nitrogen gas, corresponding to a total heat input of ~0.2 cal., were evolved during each measurement. Thus the duration of a measurement ranged from ~60 min. for the highest power level calibrated to ~500 min. for the lowest. The time required for the equilibrium temperature to be established after the calorimeter was assembled was independent of the source and was usually 1.5 to 2 hr. In passing from one power level to another after the calorimeter was at the equilibrium temperature, a constant rate of gas evolution was achieved within less than 10 min.

DISCUSSION

The described calorimeter has several characteristics which recommend its use in measuring the heat from nuclear radiations. The sensitivity of the instrument is such that 10 mC of an activity decaying with an energy of 1 Mev form a conveniently measured source. The short period required for equilibration after changing the power level enables study of fairly short-lived activities (>10 hr.) without the necessity of correcting for "lag." Furthermore, no difficulty arises in obtaining good thermal contact between the source and the calorimeter.

This instrument has been used[3,4] in a study of the half-life of tritium and the average β-energy released in its decay. It has also been used in connection with an absolute β-disintegration rate study, using P^{32}. The former of these measurements will be reported in detail elsewhere.

The calorimeter employing the same principle of operation but containing considerably more mass has been used for gamma-absorption measurements at this Laboratory. The sensitivity which could be achieved with the instrument was less than that of the one described here by a factor proportional to the increase of heat capacity, and its use was limited to the measurement of relatively large activity levels.

A Study of Plateau Slopes in Self-Quenching Geiger-Müller Counters*

SANBORN C. BROWN AND CLAUDINE MARONI†
Department of Physics and the Radioactivity Center of the Laboratory for Nuclear Science and Engineering, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received December 12, 1949)

A study of plateau slopes of self-quenching Geiger-Müller counters shows that no quenching vapor tested produced flat characteristics. On the assumption that the slopes were given by spurious counts arising from the gas discharge phenomena, a study was made of the controlling factors. Neither the quenching gas nor the vehicular gas positive ions were found to be significant. A study of the negative ions produced by molecular dissociation of the quenching gas at the cathode, and electron attachment in the body of the gas shows that these factors are directly correlated with the slopes of the plateau characteristics.

IT is a well-known fact that the slopes of the plateau curves of Geiger-Müller counters are markedly affected by the nature of the gas filling. It is not obvious from theoretical studies of the discharge mechanisms why the plateau characteristics of counters incorporating an organic quenching agent are not flat. After the discharge has broken down, having been initiated by an external charged particle, the electric field of the anode falls below threshold and remains so until the positive ion sheath has moved from the anode to allow the field to return to a value sufficient to support a discharge once more. During this period of so-called dead time, the counter is insensitive. The positive ions continue to move toward the cathode making collisions on the way such that if the counter is behaving properly, the positive ions of the vehicular gas will, before reaching the cathode, have transferred their charge by collision to neutral quenching agent atoms, forming quenching agent ions and neutral vehicular gas atoms. By this mechanism, no vehicular gas ions reach the cathode. A proper quenching agent will be one whose ions will produce no secondary electrons or negative ions on collision with the cathode wall. If electrons or negative ions were produced at any time after the dead time, the counter would break down in a spurious count, since it would be the result of an internal mechanism and not an indication of the arrival of an external ionizing particle. In the present study, the assumption is made that the cause of the slope of a plateau curve is spurious counts arising from mechanisms involved in the counter discharge, and that a study of the causes of the plateau slopes gives information on the causes of spurious counts.

EXPERIMENTAL PROCEDURE

An experimental procedure was evolved for obtaining reproducible and consistent results. Two identical counters were constructed with tantalum cathodes. These cathodes were five inches long and one inch in diameter. The anode wires, 0.006 inch in diameter, had an effective length slightly shorter than that of the cathode. This was accomplished by having the large tungsten leads which sealed through the glass envelope extend within the cathode, the anode wire being hard soldered between these two leads. The two counters were connected to an evacuating and filling system which was free from mercury. The low pressure was measured with thermocouple and ionization gauges, and filling pressures were measured with a mechanical Bourdon gauge. Between runs the counters were pumped to a pressure of 10^{-6} mm of mercury by an oil diffusion pump. Whenever the system was let up to air, or any vehicular gas change took place, the counters were outgassed by baking at 400°C for several hours at a pressure of 10^{-6} mm of mercury. To obtain reproducible results, it was found essential to use spectroscopically pure vehicular gas and carefully distilled organic vapors.

Both counters were filled together, and the data were considered significant only if the results from both counters were the same. Whenever the counters began to give erratic results, they were removed from the system and their cathodes cleaned chemically. Unsatisfactory behavior of the counters was tested in two ways: the plateau characteristics of both counters had to be the same within the experimental error, and the normalized slope had to be independent of counting rate. The normalized slope is defined as the ratio of the change in counting rate divided by the total counting rate, to the change in voltage divided by the total voltage at the onset of the plateau. These criteria lead to an average of steeper plateau slopes than the customary practice of accepting only the flattest plateaus, but since this study was directed toward an understanding of the spurious count mechanism and not toward producing good counters, this procedure seemed more significant.

POSITIVE ION EFFECTS

A study was first made of the effect of changing the relative concentration of the polyatomic quenching gas. Although the plateau slope changes for small concentrations of the quenching agent, it was found that after a certain minimum concentration, the plateau slope was independent of the amount of polyatomic gas present. This is interpreted in the following way. The role of

TABLE I. Average normalized plateau slopes.

	Benzene	Acetone	Methyl alcohol	Ethyl alcohol	Iso-amyl acetate
Helium	1.1	0.9	1.1	0.8	0.4
Neon	0.9	0.9	1.0	1.0	0.4
Argon		0.8	0.8		0.5

the quenching gas is to serve as a trap to prevent the vehicular gas ions from reaching the cathode and producing secondary electrons. The trapping is achieved through a charge transfer mechanism in which the ionized vehicular gas transfers its charge on collision to the polyatomic gas molecule, causing a polyatomic ion and a neutral vehicular gas atom. In order for this mechanism to be successful, two criteria must be met: first, the ionization potential of the vehicular gas must be greater than that of the polyatomic gas; and, second, the polyatomic ion must dissociate on or before collision with the cathode to prevent its ionization energy from releasing a secondary electron from the wall.

With this picture of the operating mechanism, we can see the reason for the observed behavior of the plateau slope with polyatomic gas concentration. If an insufficient number of polyatomic atoms are present, too few charge transfer collisions occur to prevent some vehicular gas ions from reaching the cathode. If this occurs, spurious counts are caused by the resulting secondary electrons from the vehicular gas ions colliding with the cathode. After the concentration of polyatomic molecules is sufficient to act as a complete trap for the vehicular gas ions, the number of spurious counts caused by the vehicular gas should be zero, and the slope should be independent of quenching agent concentration, as observed.

If the above description of the mechanism is correct, it would strongly suggest that the vehicular gas should have no effect on the plateau slope, provided that the polyatomic gas concentration is sufficient. This has been checked by an extensive series of tests using helium, neon, and argon gas with several polyatomic quenching agents. The results of this study are shown in Table I. The numbers tabulated are the average normalized slopes of the plateau curves. Each value is the average of between twenty- and thirty-plateau determinations with widely differing quenching gas concentrations.

The charge transfer mechanism, upon which we are relying to remove the vehicular gas ions from the discharge, is dependent upon the ionization potentials of the ions and atoms involved. The transfer can occur only when the ionization potential of the vehicular gas is higher than the ionization potential of the quenching gas. Furthermore, the probability of the transfer occurring on collision is greater when the ionization potentials are almost equal than when they are far apart. The ionization potentials for the vehicular gases vary from 24.5 volts for helium to 15.7 volts for argon while the quenching vapors have ionization potentials between 9 and 11 volts. If the charge transfer were not complete, the greater probability of transfer from argon than helium would be expected to be a significant factor. Since this is not the case, we have further evidence of the completeness of charge transfer. These data strongly support the conclusion that we have eliminated the noble gases as a source of spurious counts. If we make the assumption that the probability of producing a significant number of secondary electrons by positive polyatomic ion collision with the cathode is negligible, all positive ions are eliminated as a source of spurious counts.

NEGATIVE ION TESTS

A study of the literature does not show that any of the quenching agents used in the positive ion tests have been analyzed for negative ions produced by electron bombardment. Therefore, the negative ion part of the study was made with different quenching vapors from the positive ion studies. Negative ion measurements have been made[1] in carbon tetrachloride, freon-12, ammonia, and methane. The result of a study of the normalized plateau slopes using these gases as quenching agents is plotted in Fig. 1 as a function of the intensity of the most abundant negative ion referred to the most abundant ion of either sign, as determined by mass spectroscopic studies.[1] These values of the normalized slopes are average values determined as described in the positive ion studies, the slopes being independent of quenching agent concentration in a given mixture.

It is obvious from an examination of the data in Fig. 1, that a definite correlation exists between the normalized plateau slope and the relative intensity of the negative ions produced in an electrical discharge. Since the normalized slope is independent of the quenching agent concentration in a given mixture, one can

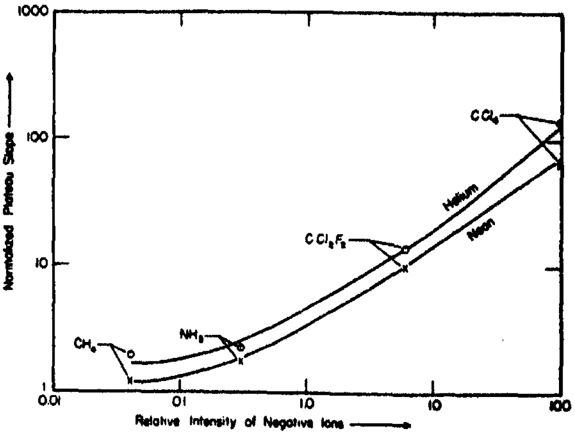

FIG. 1. Average normalized plateau slopes are plotted as a function of mass spectroscopically measured relative intensities of negative ions, for helium and neon vehicular gases.

conclude that a constant number of negative ions is produced independent of the concentration of quenching gas. This is evidence that the negative ions in these quenching gases are produced in the dissociation of the positive molecular ion on collision with the wall, since apparently only the ions produced by charge transfer with the vehicular gas affect the production of negative ions. If the negative ions were produced either by direct attachment or by electron bombardment in the body of the gas, increasing the concentration of the attaching gas should increase the negative ion population, and this is found not to be the case.

Another phenomenon apparent in these negative ion tests, and in which they differ from the positive ion tests, is the fact that the normalized plateau slopes are dependent upon the vehicular gas. We are unable to offer a definite explanation for this observation, although one can examine in more detail the behavior of negative ions in producing a spurious discharge. A spurious count will only be produced when a negative ion arrives in the high field region after the counter has recovered from its dead time. If the negative ions are produced by molecular dissociation at the cathode, they all would produce spurious counts, since the positive ion space charge does not reach the cathode until after the dead time is over. Thus, the mobility characteristics in the vehicular gas of the negative ions produced at the cathode should not be a significant variable. This is consistent with our observations. The ions will have their highest mobility in helium and, therefore, if they could be swept out before the end of the dead time, they would have the greatest chance of doing so in this gas. Yet, we find that the greatest number of spurious counts occur in helium showing that the mobility characteristic is not significant. It has been found experimentally[2] in the noble gases that the second Townsend coefficient increases with increasing ionization potential, the possible mechanisms for the second Townsend coefficient in these experiments being the production of secondary electrons produced either at the walls or in the gas due to photons created in the discharge. It is possible to explain the increased production of spurious counts in helium over neon by the photo-ionization in the gas since this would increase the population of positive vehicular gas ions, and hence by charge transfer, the number of quenching agent ions which will subsequently dissociate into negative ions. The ionization potential of helium is 24.5 volts and that of neon 21.5 volts, and, therefore, these gases are in the correct relation to each other for this explanation to be valid, but no check of this hypothesis is available.

The halogen gases show quenching characteristics and the atomic ions are known to have high electron attachment probabilities; therefore, studies were made using chlorine as a quenching gas. This gas was chosen, since its behavior would be expected to differ from those gases producing negative ions by molecular dissociation. Negative ion attachment in the volume of the gas is known to occur, and so far as is known, negatively charged ions are not produced in the molecular dissociation at the cathode which gives rise to the self-quenching properties. Since the negative ions are not associated with a charge transfer mechanism, but are produced by direct attachment to chlorine atoms in the discharge, one would expect the number of ions produced would depend on the chlorine concentration. This is in fact the case, as shown in Fig. 2.

Although electron attachment to the atom has a high probability, it does not occur to the chlorine molecule. Therefore, one would expect the negative ions to be formed only close to the discharge region. Since the negative ions would not move very far before losing their electrons in the high field, one might expect that very few would be left by the time the counter dead time is over. It is because the residual number is small, that chlorine can make a practical self-quenching counter. Those negative ions which produce spurious counts will be only those that have not been swept out by the electric field before the dead time has elapsed, and hence the number of spurious counts produced by these ions should depend upon the ionic mobility in the vehicular gas. The mobility of chlorine ions in argon is lower than the mobility in neon, and hence more negative ions are left at the end of the dead time in argon than in neon. This offers an explanation for the behavior of the data shown in Fig. 2, where the normalized slopes in argon are greater than in neon.

CONCLUSION

The quenching agents that we have studied fall into three groups. The first group are those for which we could find no information concerning their negative ion production. These gases include most of the common quenching agents and show low normalized plateau slopes which are independent of the quenching agent concentration and independent of the vehicular gas.

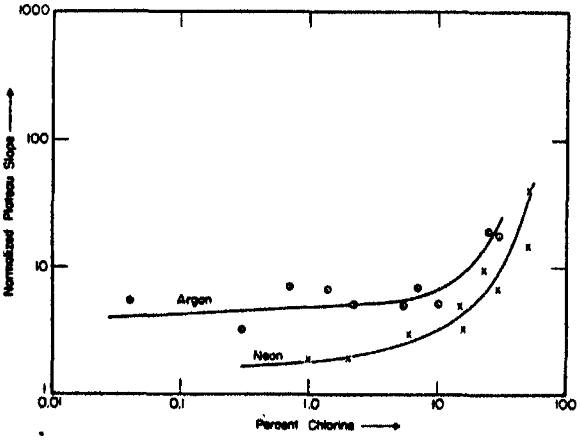

FIG. 2. Normalized plateau slopes are plotted as a function of percent chlorine quenching gas for argon and neon vehicular gases.

---

[2] M. J. Druyvesteyn and F. M. Penning, Rev. Mod. Phys. 12, 110 (1940).

The gases in this group which we studied include benzene, acetone, methyl and ethyl alcohol, and iso-amyl acetate. These quenching vapors show plateau curves of low but not constant slope and it seems probable that these gases exhibit very small negative ion production by dissociation of the positive ions at the cathode.

The second group of quenching gases are those which form negative ions by dissociation of positive ions at the cathode. These gases show increasing normalized plateau slopes with increasing negative ion production, independent of the quenching agent concentration but dependent upon the type of vehicular gas. These gases include methane, ammonia, freon, and carbon tetrachloride.

Only one gas, chlorine, of a third group was studied; this group contains those which form negative ions by electron attachment in the gas. Gases of this group are characterized by increasing normalized plateau slopes with increasing quenching gas concentration and the slopes are dependent on the type of vehicular gas.

None of the plateau characteristics were flat, and the variation in plateau slopes for the cases of the usual quenching agents shown in Table I might be the result of such factors as the changes in sensitivity from gas to gas and the end effects of the electric field. These factors, however, account for only small variations in the plateau slopes and not the large variations illustrated in Figs. 1 and 2.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

Time Lags in Geiger Counters

ARTHUR R. LAUFER[*]
New York University, University Heights, New York

(Received December 5, 1949)

Light from a spark was used to produce a primary ionizing event in a Geiger counter by means of the photoelectric effect. The time lag between this event and the detection of the pulse on the counter wire was studied as a function of counter filling, pressure, and overvoltage. The measured lags, ranging from tenths of microseconds to many microseconds, were used to calculate electron mobilities, sheath spread velocities, and electron attachment coefficients. The lags appear to be the result of the transit time required by the initial electrons to move from their point of origin to the high field region, and the time required by the sheath to spread laterally along the wire and to move radially outward far enough to produce an electrical pulse which can be detected.

INTRODUCTION

Several investigators[1] have reported the observation of a time lag between the time at which a primary ionizing event occurs in a Geiger counter and the time at which the electrical pulse is detected. The magnitudes of such delays appear to range, in different reports, from several hundredths to many tens of microseconds. It has been suggested that the causes of these delays are the transit time required by the initial electrons to move from their point of birth to the avalanche region near the wire,[2] and the capture of electrons to form negative ions[3] which require an even longer transit time. However, lags are obtained[4] even when the initial electrons are formed close to the wire surface in counters containing fillings which do not form negative ions.

In all but one of the previous investigations, only relative lags could be observed, since measurements were made of the differences in the firing times of two counters actuated by the same primary ionizing event. In the one case[5] of observation of absolute delays, the technique used did not permit the detection of very short lags, and only a negative-ion-forming gas (oxygen) was studied.

Such time lags may limit the counting rate in high speed counting, and may cause real coincidences to be missed in the method of coincidence counting. In addition, a fuller understanding of the causes of the lags may give further insight into the processes involved in Geiger counter action. For these reasons a study of the magnitudes and causes of time lags in Geiger counters was undertaken in the present investigation.

EXPERIMENTAL TECHNIQUE

The central problem in the determination of the absolute time lag in a Geiger counter is the production of a primary ionizing event in the counter at a known instant. The use of a second Geiger counter to determine this instant can give only the relative lag between the two counters and not the absolute lag.

The procedure employed in the present work can be simply stated. Each Geiger counter used had one or

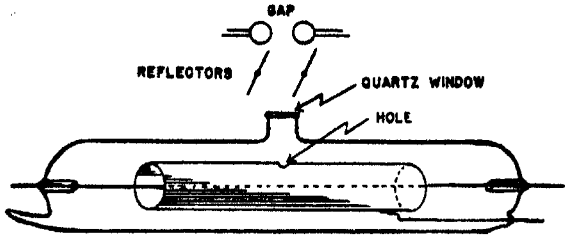

FIG. 1. Spark gap, reflectors, and Geiger counter.

more small holes drilled in the cylinder wall, and light from a fast spark[5] was admitted to each hole through a quartz window, as indicated in Fig. 1. The spark light, which ejected photo-electrons from the inner wall of the cylinder, was taken to be the primary ionizing event. At the same instant some of the spark light fell upon a vacuum photo-tube. Since no time lag has ever been observed in a vacuum photo-tube, the electrical pulse from the tube was taken to be coincident with the time of ejection of the photo-electrons in the Geiger counter. The time interval between the photo-tube pulse and the electrical pulse from the counter was measured with a fast-sweep synchroscope, and was taken to be the absolute time lag in the Geiger counter.

The spark light was obtained from an overvolted spark gap with a 3-ohm resistance in series to damp the oscillation critically. The time of duration of the spark light was measured to be less than 0.1 μsec. by viewing the photo-tube pulse on the synchroscope, and was independently checked by measuring the blurring of the cannelure of a bullet in flight photographed with the light of the same spark.

The counter used for most of the work had a 4-mil wire and a 2.5-cm diameter copper cylinder, 20 cm in length. A series of $\frac{1}{16}$-in. holes was drilled in a straight line along 18 cm of the cylinder length. The quartz windows, transparent to radiation down to about 1500A, permitted the ejection of photo-electrons from the cylinder, which has a work function of about 4.4 volts (2800A). Photo-ionization of the counter gases used, however, was quite improbable,[6] since this process requires radiation of at least 1100A.

In the main recording circuit, Fig. 2, part of the pulse from the photo-tube was differentiated and used to trigger the sweep of the synchroscope. The remainder of the pulse passed successively through a cathode follower, a delay line, and a one-stage, low gain, wide-band amplifier. The Geiger counter pulse passed through an almost identical circuit, and the amplifier stages of the two circuits were coupled by the use of a common plate load resistor. This coupling mixed the photo-tube and Geiger pulses to give a single output which was applied to the vertical deflecting plates of the synchroscope. The multivibrator section of a Sylvania P4

synchroscope was rebuilt to provide an externally triggered, single-sweep arrangement, with sweep speeds of 0.5, 2, 6, and 25 μsec. per in. A 2-Mc crystal oscillator was built and employed to calibrate the synchroscope. It was also possible to pass a given photo-tube pulse alone through both the photo-tube circuit and the counter circuit to obtain a measure of "zero lag."

Part of the data was taken photographically, and part visually, the results proving reproducible to within experimental error. A DuMont oscilloscope camera was refitted with a xenon $f{:}2$, 50-mm, coated lens. This lens, together with Linagraph Pan film and Kodak SD19a developer, permitted satisfactory photography of the traces on the synchroscope screen.

Figure 3 presents several typical photographs. The differentiated part of the photo-tube pulse triggered the synchroscope and started the motion of the cathode-ray beam toward the right. After a fixed delay, the remainder of the photo-tube pulse caused the initial rise in the pattern. This rise was taken to correspond to the instant at which photo-electrons were released in the Geiger counter. The photo-tube pulse was "limited" in size by the cathode follower, and since the photo-tube charge was allowed to leak off through a high resistance, the pulse maintained its height and served as a base line for the succeeding Geiger pulse. Then, after another fixed delay of 0.5 μsec., if there had been zero time lag in the Geiger counter, the second rise in the trace would have indicated the arrival of the counter pulse. The *increase* in this time was taken to be a measure of the absolute lag in the counter.

By rotating a pair of cardboard reflectors mounted between the spark gap and the counter, the intensity of spark light incident upon the counter could be varied. With zero intensity the synchroscope trace exhibited the initial rise due to the photo-tube pulse, but did not show the second rise since no electrons were produced in the counter and no counter pulse was generated. One trace of this kind is shown in Fig. 3. When the intensity was increased, some of the sparks ejected electrons in

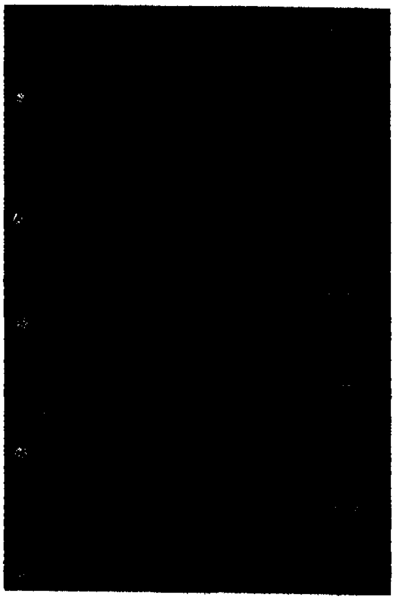

FIG. 3. Photographs of time-lag traces on synchroscope.

the counter and therefore a certain fraction, ρ, of the traces showed Geiger pulses. At full intensity all traces exhibited Geiger pulses.

EXPERIMENTAL RESULTS

Tables I and II present the averaged data obtained in this experiment. The gases used were of 99.8 percent purity, and the organic vapors were of C.P. grade. For the counters used, it was found that the pulse size was very nearly equal to the overvoltage on the counter. For most of the measurements the gain of the recording circuit was set at unity, at which gain the pulse on the counter wire had to be at least six volts in magnitude before it could be detected.

Measurements were made in the following manner: First, black masking tape was used to block the spark light from all the holes of the cylinder except one at its midpoint, and the lags thus observed were named "total" lags; second, the spark light was admitted through all the holes of the cylinder and the (different) lags thus obtained were named "transit" lags. For all counter fillings, sets of measurements were made using the full spark light intensity.

In addition, with argon-oxygen and oxygen fillings and with only the hole at the cylinder midpoint open, the intensity of the light incident upon the counter was reduced until the ratio of the number of sparks yielding a Geiger pulse to the total number of sparks was $\rho = 0.45$. Using this intensity, which produced few enough electrons in the counter to permit all of them to be captured, the ratio of the number of sparks resulting in time lags greater than 5 μsec. to the total number of sparks was measured under various conditions.

Inasmuch as all of the processes involved in a Geiger counter discharge are statistical in nature, the measured time lags also gave a statistical distribution. Therefore, for the determination of the lag in each case, one hundred measurements were made and the arithmetic mean was taken to be the time lag. In a typical case, the measured distribution of lags had a mean value of 0.56 μsec. and a root-mean-square deviation of 0.04 μsec. The root-mean-square deviations in the various cases exhibited no significant trend.

THEORETICAL ASPECTS

When a primary ionizing event takes place in a Geiger counter the initial electrons produced are accelerated toward the wire, near the surface of which Townsend avalanches[7] produce a large number of additional free electrons. By means of photo-ionization, photons produced in the avalanches cause the discharge to spread with a measurable velocity[8] along the entire length of the wire, and the collection of the electrons by the wire anode leaves behind a positive ion sheath closely surrounding the wire. The radially outward motion of the sheath produces a drop in the potential of the wire.[9]

The time lags observed in Geiger counters appear to be the result of the transit time required by the initial electrons to move from their point of origin in to a point at which the field is great enough to produce avalanches, and the time required for the sheath to spread laterally along the wire and to move radially outward far enough to produce an electrical pulse which can be detected. In order to analyze these hypotheses, mathematical expressions are required for the electron transit time and for the rate of fall of the potential of the wire, i.e., for the pulse shape.

Consider an electron ejected by the spark light, at a time $t=0$, from the cylinder wall, at a distance $r=b$ from the wire axis, where b is the cylinder radius. Assuming a constant "mobility," k_e, for the electron in the gas of the counter at the existing pressure, the drift speed of the electron toward the wire is

$$dr/dt = -k_e E, \tag{1}$$

where the field intensity is given by

$$E = V_0/(r \ln b/a). \tag{2}$$

Here V_0 is the operating potential across the counter, and a is the wire radius. At a time t_t the electron reaches the high field region, effectively at the wire surface where $r=a$. Integration of (1), with the aid of (2), between the given limits, yields

[9] W. E. Ramsey, Phys. Rev. **57**, 1022 (1940).

$$t_t=\frac{\ln b/a}{2k_eV_0}(b^2-a^2) \tag{3}$$

as the "transit time" of the electron, a result similar to that obtained by Den Hartog *et al.*[2]

Assume that the electron produces the initial avalanche at a time $t=0$ on a new time scale, and at a distance D from the nearer end of the counter wire. Then the sheath spreads with a speed v toward both ends of the counter simultaneously. Assume also that the sheath is formed at the wire surface, and that the positive charge per unit length in the sheath is q_1. If the output capacitance of the counter is C, the energy of the counter before a discharge takes place is $\frac{1}{2}CV_0^2$. Consider an element of charge q_1dx situated at a distance x along the counter wire from the position of the initial avalanche. In moving the charge q_1dx from $r=a$ to $r=r$ the field does work on the charge in the amount $\int_a^r(q_1dx)Edr$, the energy of the counter drops to the value $\frac{1}{2}CV_t^2$, and the wire potential drops to the value V_t.[10] Hence,

$$\tfrac{1}{2}CV_t^2=\tfrac{1}{2}CV_0^2-\int_a^r(q_1dx)Edr. \tag{4}$$

The pulse size, or drop in potential of the wire, due to the outward motion of this element of charge is $dV=V_t-V_0$. Using (2) and the fact that the pulse size is small compared with the operating voltage, (4) becomes

$$dV=-\frac{q_1dx}{C\ln b/a}\ln\left(\frac{r}{a}\right). \tag{5}$$

As the sheath spreads along the wire from the position ($x=0$) of the initial avalanche, it reaches the point $x=x$ at the time $t=x/v$ and immediately thereafter the element of charge, q_1dx, begins to move radially outward. Therefore, $r=a$ at $t=x/v$, and $r=r$ at $t=t$. The outward drift velocity of the element of charge is given by $dr/dt=KE$, where K is the mobility (here assumed constant) of the positive ions in the gas used and at the pressure existing in the counter. Integration between the given limits gives

$$r^2=a^2+\frac{2KV_0}{\ln b/a}\left(t-\frac{x}{v}\right),\quad \text{for } 0\leqslant x\leqslant vt. \tag{6}$$

Since, for $t\leqslant D/v$, the sheath is spreading simultaneously toward both ends of the counter, there is another element q_1dx at a distance x on the other side of the position of the initial avalanche. Therefore, doubling (5), combining with (6), and integrating from $x=0$ to $x=vt$, we can obtain the total pulse size, V, as a function of t. If L is the length of the counter wire, the maximum pulse size is $V_m=-Lq_1/C$. Then the fractional pulse size is given by

$$\frac{V}{V_m}=\frac{v}{L\ln b/a}\left[\left(t+\frac{a^2\ln b/a}{2KV_0}\right)\ln\left(\frac{2KV_0t}{a^2\ln b/a}+1\right)-t\right], \tag{7}$$

for $t\leqslant D/v$.

This analysis may be easily extended to the time ranges $D/v\leqslant t\leqslant (L-D)/v$ and $t\geqslant (L-D)/v$. The pulse shapes for several special cases are plotted in Fig. 4. If the primary ionizing event produces initial electrons at more than one point along the wire length, the sheath spread begins almost simultaneously at all of these points. Therefore, as indicated by curve C in Fig. 4, the initial rise of the pulse is much more rapid.

The contribution of the electron collection by the anode to the pulse magnitude has here been assumed to be negligible. If we assume that the center of gravity of the ion sheath when initially formed is at a distance d from the wire surface, then the average electron moves in to the wire from $r=a+d$ to $r=a$. Applying the above theory to the electron motion, the ratio of the electron pulse, V_-, to the positive sheath pulse, V_+, is found to be

$$V_-/V_+=\ln[1+(d/a)]/\ln[b/(a+d)]. \tag{8}$$

The center of gravity of the initial ion distribution can be roughly assumed to be one and one-half mean free paths from the wire surface. Using the Ramsauer curve for argon, we find $d=6\times10^{-6}$ cm. Hence, $V_-/V_+=0.2$ percent, and the neglect of the electron contribution is justified.

If the initial electrons produced by the primary

ionizing event are captured, as they travel toward the wire, by molecules with a high electron affinity, the low mobility of the negative ions thus formed may result in a time lag of many microseconds. When the ions reach the high field region, at about $E/p=90$ according to Loeb,[11] the electrons are torn away from the ions and then produce the usual avalanches and pulse. The total time required for the electrons and ions to reach the high field region will be called the "ion lag."

In the present experiment a large number of photons from the spark are incident upon the counter cylinder, and the probability of the ejection of a photo-electron by a given photon is very small (about 10^{-4}). To this situation Poisson's probability density law applies. If n is the average number of electrons ejected per spark, then $P=\epsilon^{-n}n^k/k!$ is the probability that k electrons be ejected per spark, and n is also the mean value of k. Then the probability that *at least one* electron be ejected is $\rho=(1-\epsilon^{-n})$. It may be assumed that if at least one electron is ejected by the spark, a counter pulse will result. Therefore, the ratio of the number of counter pulses to the number of sparks is merely ρ.

In order that an "ion lag" be produced, all n electrons ejected by a given spark must be captured. Call q the probability that a given electron be captured to produce an ion lag equal to or greater than t_i, where t_i is the sum of the times required by the electron to move from $r=b$ in to the point of capture, $r=R$, and by the ion to move from $r=R$ in to $r=a$. If the electron is captured at $r\geqslant R$, then the resulting ion lag will be $\geqslant t_i$. Then it can be shown[6] that the probability that a given *spark* give an ion lag $\geqslant t_i$ is

$$P_q=\epsilon^{-n}(\epsilon^{qn}-1). \tag{9}$$

Since ρ and P_q may be observed experimentally, q may be calculated. Also, the probability that an electron be captured to give an ion lag $\geqslant t_i$ is equal to the probability that the electron be captured within a distance $(b-R)$ of the cylinder wall. Hence,

$$q=1-\exp[-N_1A(b-R)], \tag{10}$$

where N_1 is the number of gas molecules per unit volume, and A is the effective capture cross section of a molecule for an electron. If σ is the collision cross section of the molecule for an electron, and if h is the probability of capture per collision, or attachment coefficient, then $A=\sigma h$. Equation (3) may be used for ion transit times if k_e is replaced by the mobility of the negative ion, and if b is replaced by R. The equation may then be used to compute R, which may in turn be used in (10) to compute A. From the Ramsauer curve for a given gas and electron energy, σ may be obtained, and it is therefore possible to calculate h, the attachment coefficient.

COMPARISON OF THEORY WITH EXPERIMENT

Each "total lag" listed in Tables I and II, observed with the use of a single cylinder hole and the full spark light intensity, is presumed to be the sum of the "transit lag," or the time required by the electron to move from the cylinder wall in to the avalanche region, and the "sheath lag," or the time required for the sheath

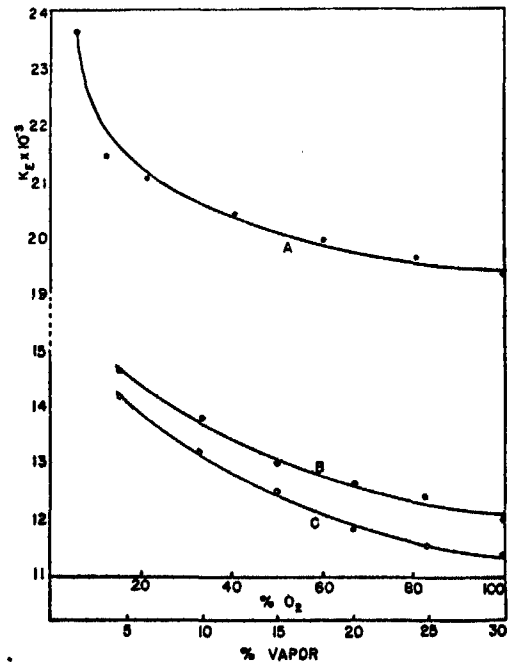

FIG. 6. Electron mobilities, k_e, as a function of percentage constitution at 10-cm total counter pressure. A. Argon-oxygen B. Argon-ethyl alcohol. C. Argon-amyl acetate.

---

[11] L. B. Loeb, Phys. Rev. 48, 684 (1935).

to spread laterally along the wire and radially outward far enough to permit detection of the pulse. The use of many cylinder holes and the full light intensity, producing photo-electrons all along the cylinder length, effectively eliminates the sheath lag, and the lags observed in this manner are presumed to be the transit lags alone, as listed in Tables I and II. The difference between each total lag and the corresponding transit lag should thus be the sheath lag alone. It has been observed elsewhere[12] that lightly ionizing particles give delays which are substantially longer than those found with heavily ionizing particles, which appears to confirm the hypothesis that the lags depend in part on the initial ionization produced by the primary ionizing event.

Using the measured transit lags and counter data of Tables I and II, and Eq. (3), the electron mobility, k_e, was calculated for each case and the results graphed in Figs. 5 and 6. The values so obtained are of the same order of magnitude as the mobilities observed by other investigators. Considering the fact that, strictly speaking, there is no real electron "mobility constant," and the fact that almost imperceptible traces of unrecognizable "impurities" have an enormous power over the electron "mobility," this agreement appears to be fortuitous.

For a given gas mixture, the electron mobilities appear to be inversely proportional to the square root of the product of pressure and operating voltage. The mobility in hydrogen appears to be *lower* than that in the mixtures of argon and organic vapors, which may result from the fact that the drift velocity and mobility of an electron in a gas are inversely proportional to the average thermal agitation velocity of the electron. The organic vapors, with many low lying energy levels, hold the electron's thermal energy to a low value and thereby increase the mobility. Therefore, although the mobility of an electron in pure hydrogen is greater than that in pure argon, a vapor added to the argon increases the mobility of the mixture to a value higher than that in hydrogen.[13] In oxygen, which has several low energy levels, the electron mobility appears to be higher than that in either hydrogen or the mixtures.

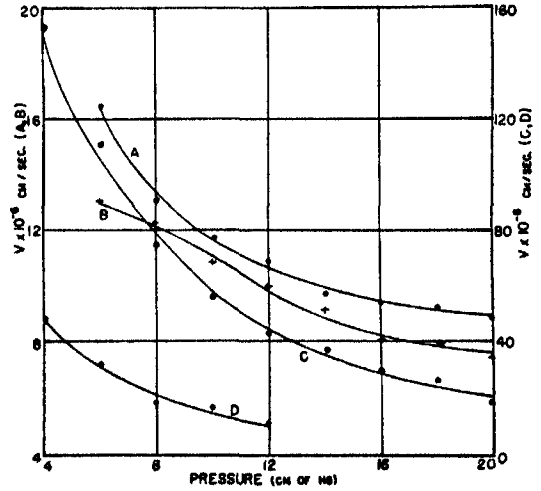

FIG. 7. Sheath spread velocity, v, as a function of total counter pressure. A. 90 percent argon-10 percent ethyl alcohol. B. 90 percent argon-10 percent amyl acetate. C. Hydrogen. D. Oxygen.

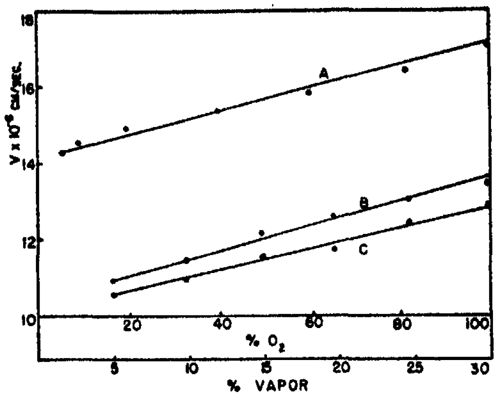

FIG. 8. Sheath spread velocity, v, as a function of percentage constitution at 10-cm total counter pressure. A. Argon-oxygen. B. Argon-ethyl alcohol. C. Argon-amyl acetate.

The sheath lag was computed for each case from the data of Tables I and II. In this experiment the sheath lag is the time required for the pulse, once it has begun, to reach the fractional size $V/V_m = 0.06$. Using reasonable values for the ion mobilities, K, Eq. (7) was employed to calculate the sheath spread velocity, v, for each case, and the results are graphed in Figs. 7–9. The values obtained in this way are of the same order of magnitude as those obtained by the more direct methods of other observers.[14] Figure 7 indicates that for all counter fillings v decreases as the total pressure increases, and Fig. 9 indicates that v increases rapidly as the overvoltage increases. Figure 8 is particularly interesting in that it indicates an increase in v as the percentage of quenching vapor is raised.

While an avalanche is being formed, photons of various energies are emitted by the return of excited and ionized molecules to their ground states. This radiation is composed of two types of photons: photons which are energetically capable of ionization (11 to 15 volts, or more); and lower energy photons which are incapable of ionization but have enough energy (about five volts) to eject photo-electrons from the cylinder wall. The ionizing radiation is highly absorbable in all counter fillings, in noble gases as well as in vapors. Jaffe *et al.*,[15] find that 99 percent of this radiation is absorbed within a distance of 1 mm. The photons of lower energy are only slightly absorbed by noble gases, but are strongly absorbed by polyatomic molecules with subsequent predissociation.

[14] J. Hill and J. Dunworth, Nature **158**, 833 (1946); Knowles, Balakrishnan, and Craggs, Phys. Rev. **74**, 627 (1947); D. H. Wilkinson, Phys. Rev. **74**, 1417 (1948); also see reference 8.

[15] Jaffe, Craggs, and Balakrishnan, Proc. Phys. Soc. **62**, 39 (1949).

The ionizing photons, absorbed within a millimeter or two of the wire surface, serve to propagate the discharge along the wire by producing new electrons which in turn produce new avalanches. The average new electron produced by photo-ionization is born within a millimeter or two of the wire surface. This electron then travels in to the high field region, which begins at less than half a millimeter from the wire surface. The travel time of the photons themselves, and the time required to complete an avalanche once it has begun, are very small.[16] It is therefore likely that the major part of the time required for a given step in the propagation process is the 10^{-9} sec. or so occupied by the new electron in traveling in to the high field region.

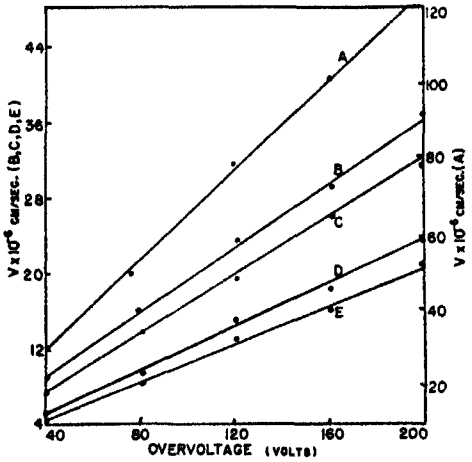

FIG. 9. Sheath spread velocity, v, as a function of overvoltage at 10-cm total counter pressure. A. Hydrogen. B. Oxygen. C. Argon+10 percent oxygen. D. Argon+10 percent ethyl alcohol. E. Argon+10 percent amyl acetate.

Therefore the sheath spread velocity, v, should depend primarily upon the electron velocity, v_e, in the particular counter filling and field. If it is assumed that $v_e=k_eE$, where E is proportional to V_0, the curves of Figs. 7–9 appear to be consistent with the above hypotheses. As the percentage of quenching vapor increases, the electron mobility decreases (Fig. 6), but the operating voltage required for a given overvoltage increases by a bigger factor. Therefore v_e increases, and we find that v increases as the percentage of vapor increases.

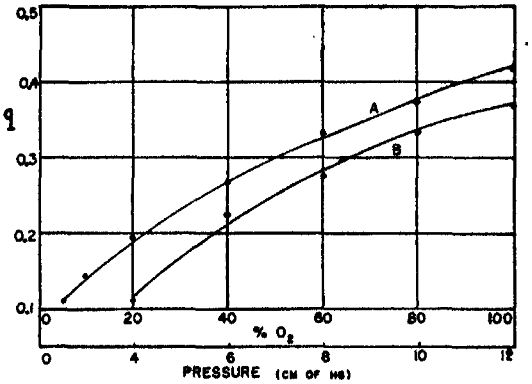

FIG. 10. Probability, q, that an electron be captured to give an ion lag $\geqslant 5$ μsec. A. 10-cm total pressure of argon-oxygen, as a function of percent of oxygen. B. Oxygen, as a function of total counter pressure.

For a given percentage constitution, an increase in total pressure decreases the mean free path for ionization of the high energy photons, reduces the length of each step, and lowers v. As the overvoltage is raised, the radius of the high field region and thus of the sheath about the wire increases. More photons of a longer mean free path for ionization are produced per avalanche, each step is lengthened, and v increases. Although k_e has been found to be lower for hydrogen than for the vapor mixtures, V_0 is materially higher for a hydrogen counter than for the vapor counters. Therefore, $v_e=k_eE$, and v are higher for hydrogen.

Using the value $t_i=5$ μsec., and Ramsauer's values for σ, for each case in Table II a value of q was computed and the results are graphed in Fig. 10. The curves indicate that q rises more slowly than linearly as the oxygen constituent increases, which is to be expected from Eq. (10). For each case a value of the attachment coefficient, h, was also calculated. These values showed no trend and had a mean value of 3.3×10^{-4}, which is at least of the correct order of magnitude.

CONCLUSIONS

The satisfying simplicity of the direct observation of the absolute counter time lags on the synchroscope screen gives the measured values a certain measure of reliability. Although the calculation of electron mobilities, sheath spread velocities, and attachment coefficients had only an indirect bearing on the purposes of this investigation, the fact that the theory and the measured time lags yielded results of the correct orders of magnitude for these quantities permits some confidence to be placed in the proposed mechanisms.

The results suggest the procedure to be used in order to minimize time lags in Geiger counters. The particles to be detected should be introduced as close to the wire as possible, and in a direction as nearly parallel to the wire as possible. The counter filling should not contain any constituents which possess high electron affinities. A high overvoltage and a fairly high gain, wide-band amplifier should be employed. These precautions should make it possible to determine the instant of passage of a particle through the counter to within a few hundredths of a microsecond.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

The Electric Field in a Geiger Counter

Arthur R. Laufer
University of Missouri, Columbia, Missouri

(Received December 1, 1949)

The mechanism of the reduction and recovery of the electric field in a Geiger counter is discussed, and the role of the series resistance is analyzed. The contribution of the collection of the electrons to the total pulse size is shown to be negligible.

THE literature contains a large number of papers dealing with Geiger counter action, but certain aspects of the reduction and recovery of the electric field intensity around the wire, though implied in some of them, are not treated explicitly. An analysis of these aspects may therefore serve a useful purpose.

In its usual form the Geiger counter consists of a pair of concentric cylindrical electrodes mounted in a glass or metal envelope which contains a gas at relatively low pressure. The central electrode, normally operated as the anode, is a wire of small diameter, whereas the concentric cathode is a hollow cylinder of much greater diameter. For this geometry, with a voltage source supplying a difference of potential V_0 between the electrodes, the radial field distribution is given by

$$E=\frac{V_0}{r\ \ln b/a}, \tag{1}$$

where a and b are the wire and cylinder radii respectively, and r is the distance from the wire axis. Hence, as indicated in Fig. 1 by the curve ABC, the field is of low value throughout most of the counter volume, but rises very sharply to a high value as the wire surface is approached.

Suppose that a primary ionizing event produces a free electron somewhere within the sensitive volume of the counter. This electron is accelerated toward the high field region near the wire surface, where it can gain enough energy in a free path to initiate the cumulative process of ionization by collision known as a Townsend avalanche. Photons emitted from the avalanche produce photo-ionization at other points in the counter, resulting in a spread of the discharge laterally along the wire. For a "Geiger" counter, the probability is unity that the discharge will spread along the entire length of the wire. The free electrons produced in the avalanches are rapidly collected by the wire anode, leaving behind a cylindrical shell of positive ions which closely surrounds the wire. It will presently be shown that the collection of the electrons makes only a negligibly small contribution to the final pulse size delivered by the counter. It is the relatively slow subsequent outward motion of the low mobility positive ion sheath which permits the wire potential to drop, and which therefore produces the Geiger pulse which is normally observed.

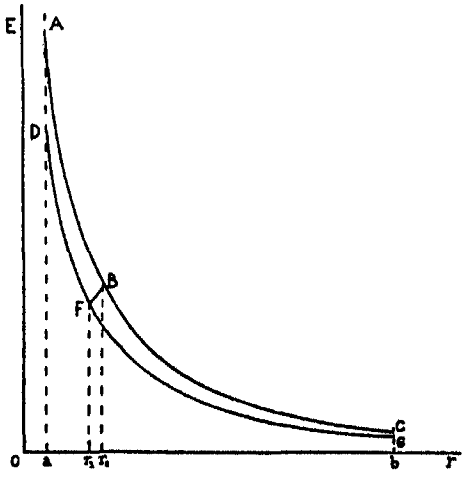

Fig. 1. The electric field in a Geiger counter.

The collection of the free electrons reduces the field between the wire and the positive ion sheath to a value below the critical value required for avalanche production. If a new primary ionizing event were now to occur in the counter, no further avalanches could be formed and the event would not be detected. The counter is now said to be "dead," or insensitive to new ionizing events. Therefore, immediately after the electrons have been collected, the wire potential has not been altered by any appreciable amount, the positive ion sheath has moved outward through only a negligible distance, and the field around the wire is reduced below the critical value. The occurrence of the primary ionizing event has, as yet, produced no change in the counter which could be detected by an external recording circuit, and the counter is in the "dead" condition. It is the outward motion of the positive ion sheath which *may* permit the wire potential to drop, producing an externally detectable pulse, and which *may* permit the field around the wire to recover, restoring the counter to its former sensitivity. The italics are used advisedly, inasmuch as both the drop in potential of the wire and the recovery of the sensitivity of the counter depend entirely upon the magnitude of the resistance R, Fig. 2, in series with the counter.

If the counter has a sensitive length L and a capacitance C, prior to a discharge the positive charge per unit length on the wire is $q=CV_0/L$, and the electric field intensity at a distance r from the wire axis is given by $E=2q/r$. This field distribution is represented by curve ABC in Fig. 1. When a discharge subsequently occurs, the collection of the electrons reduces the net positive charge per unit length on the wire to some lower value, q'. The positive ion sheath, of course, plays no part in the reduction of the field intensity near the wire, inasmuch as the field inside a long cylindrical shell of charge, due to the shell itself, is zero. The field reduction is the result of the collection of the electrons by the wire, reducing the charge per unit length from q to q'. Hence the field between the wire and the sheath is reduced to $E'=2q'/r$. If the sheath is located between $r=r_1$ and $r=r_2$, Fig. 1, then the reduced field distribution between the wire and the sheath is represented by curve DF. The field *outside* a cylindrical shell of charge is determined by the total charge within the shell. Therefore the field rises from F to B in passing through the sheath, and maintains its initial distribution, BC, outside the sheath. It may be noted in passing that even though the sheath contains about 10^{10} positive ions, these ions constitute only one part in 10^7 of the total number of gas molecules in the region occupied by the sheath.

Now suppose that the series resistance, R, is infinite. This condition may be attained by merely disconnecting the source of V_0 from the counter wire. Since potential is a scalar quantity depending on charge distribution, as the positive sheath moves outward the wire potential, V, drops below V_0 and continues to drop until the sheath is collected at the cylinder, at which time the wire potential has attained its minimum value. The wire potential for this case is plotted as a function of the time in Fig. 3. As the sheath moves outward, the field surrounding the wire *does not recover at all.* Since the wire is isolated, the charge, q', per unit length on the wire cannot change as the sheath moves outward. Hence, the reduced field, $E'=2q'/r$, around the wire remains reduced, and after the sheath has been collected at the cylinder the field distribution in the counter is represented by curve DFG, Fig. 1. With an infinite series resistance, therefore, if a primary ionizing event occurs in the counter the wire potential drops, yielding a pulse which can be detected by an external recording circuit, but at the same time the counter becomes permanently insensitive to new ionizing events.

Suppose, next, that the series resistance is zero. In this case the wire potential must remain fixed at the value V_0. As the positive ion sheath moves outward, the wire potential tends to drop, but since the potential must remain fixed, the net result is that electrons flow off the wire into the source of the applied voltage. Thus the net positive charge, q', per unit length on the wire gradually increases as the sheath moves outward, and the field, $E'=2q'/r$, gradually recovers. When the sheath reaches a certain critical distance from the wire axis, the field near the wire is far enough recovered so that a new primary ionizing event would be capable of just barely producing a new avalanche. The time of duration of the previous insensitive condition is known as the "dead time" of the counter. At the time that the sheath reaches the cylinder, the field is fully recovered, and a new primary ionizing event would be able to produce another full discharge. The time interval between the end of the dead time and the time of full recovery is called the "recovery time" of the counter. Hence, with zero series resistance the electric field in the counter can achieve full recovery, but since the wire potential is fixed at V_0, the counter discharge cannot be detected by an external recording circuit. This constant wire potential is also indicated in Fig. 3.

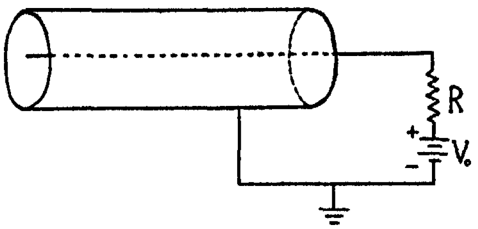

FIG. 2. Geiger counter circuit.

Thus an infinite series resistance permits the delivery of a counter pulse but does not permit recovery, whereas a zero series resistance permits full recovery but does not permit the delivery of any pulse at all. Of course, neither of these extreme cases is ever used. A series resistance of about 10^6 ohms will permit both the delivery of a pulse and the recovery of the counter, but the pulse size is smaller in this case than that obtained with an infinite series resistance. As indicated in Fig. 3, for a resistance of 10^6 ohms the wire potential begins to drop as in the case of infinite resistance. At the very beginning of the pulse the rate of fall of the wire potential due to the motion of the sheath is greater than the rate of rise due to the electrons leaking off the wire. Therefore the wire potential drops. At some later time when the rate of fall due to the sheath motion has decreased, the two rates become equal and the wire potential reaches its minimum value. Even later, the rate of rise of the wire potential due to the electrons leaking off exceeds the rate of fall due to the sheath motion, and then the wire potential rises back to its initial value, V_0.

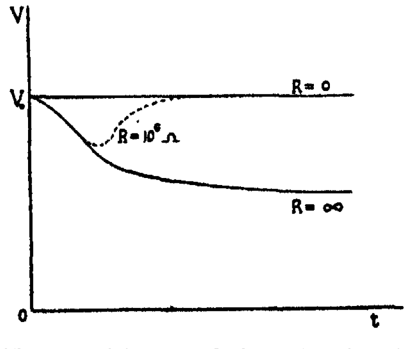

FIG. 3. Wire potential, V, graphed as a function of the time, t, for various values of the resistance, R, in series with the Geiger counter.

From this time on, the wire potential remains at the value V_0 and the counter action simulates the case of zero resistance, permitting full recovery to obtain.

In the case of a counter filled with a self-quenching gas mixture, collection of the sheath at the cylinder completes the counter action and leaves the counter ready for the next primary ionizing event. In the case of a counter employing a non-self-quenching gas, however, collection of the sheath at the cylinder results in the ejection of secondary electrons from the cylinder, and these secondaries initiate another discharge even though no new primary ionizing event has occurred in the counter. Thus the counter goes into a state of intermittent, self-perpetuating discharge. In order to use a counter containing the latter type of filling, "external quenching" must be invoked. Effectively, the counter wire must be isolated from the power supply, as in the case of an infinite series resistance, until some time after the positive ion sheath has been neutralized at the cathode. Thus the counter is not permitted to recover its sensitivity until after the act of neutralization is completed. The secondary electrons produced during this act are produced during the period of insensitivity and therefore are incapable of producing additional avalanches and spurious counts.

The required temporary isolation of the counter wire from the power supply can most easily be achieved through the use of a series resistance of the order of 10^9 ohms. For a counter having a typical capacitance of 10^{-11} farad, this means a time constant of 10^{-2} second. Since the time required for the collection of the positive ion sheath is of the order of 10^{-4} second, the need for a time constant as long as 10^{-2} second to quench the discharge may require explanation. The time constant, RC, of the counter circuit is the time required for all but $1/e$ of the free electrons deposited during the discharge to flow off the wire. If this time constant were 10^{-4} second, at the time of neutralization of the sheath at the cylinder the field at the wire would have recovered by an appreciable amount and the counter would be in a sensitive condition. Secondary electrons from the cylinder would be able to produce a spurious discharge. However, if the time constant is 10^{-2} second, at the time of neutralization of the sheath at the cylinder only $1-\exp(-10^{-4}/10^{-2})$, or about one percent, of the electrons have leaked off the wire and the field about the wire is too low to permit a spurious count. Hence, the time constant of the circuit must be made much longer than the time actually required for the collection of the sheath. The use of an electronic quenching circuit instead of the high resistance, though not as simple, is usually desirable since it eliminates the need for a long time constant and therefore permits more rapid counting.

Corson and Wilson have shown[1] that the drop in the potential of the wire due to the motion of a positive ion in the sheath from a point at $r=r_0$ to a point at $r=r$ is given by

$$-\frac{1}{V_0C}\int_{r_0}^{r} eEdr, \tag{2}$$

where e is the charge on the ion. Suppose that the center of gravity of the ion distribution in the sheath, when initially formed, is at a distance d from the wire surface, i.e., at $r_0=a+d$. Then the drop in the potential of the wire produced by the m positive ions in the sheath as a result of their radially outward motion to the cylinder, where $r=b$, may be obtained by performing the integration in (2), with the use of (1), between these limits. This integration yields

$$V_+=-\frac{me}{C\ln b/a}[\ln b-\ln(a+d)]. \tag{3}$$

The mean electron collected by the wire must move from $r_0=a+d$ in to the wire surface, where $r=a$. A similar integration yields, for the drop in the potential of the wire due to the collection of the electrons,

$$V_-=-\frac{me}{C\ln b/a}[\ln(a+d)-\ln a]. \tag{4}$$

The total pulse size, of course, is merely $V_m=V_++V_-=-(me)/C$. The ratio of the electron pulse to the positive ion pulse is

$$\frac{V_-}{V_+}=\frac{\ln[1+(d/a)]}{\ln[b/(a+d)]}. \tag{5}$$

The kinetic theory value of the mean free path, l_e, of an electron in a gas can be calculated from

$$l_e=\frac{1}{\pi N_1\sigma^2}, \tag{6}$$

where N_1 is the number of gas molecules per unit volume and σ is the radius of a gas molecule. For argon at a pressure of 10 cm of Hg, $N_1=3.54\times10^{18}$, and σ can be taken to be 1.5×10^{-8} cm, giving $l_e=4\times10^{-4}$ cm. According to the Ramsauer curve for argon, as reproduced in Loeb,[2] at electron energies of about 16 volts (the electron energy in the avalanche region) the mean free path is roughly one-tenth of the kinetic theory value. Therefore the mean free path of the electrons in this region can be taken to be 4×10^{-5} cm. The center of gravity of the initial ion distribution may be assumed to be roughly one and one-half mean free paths from the wire surface. Therefore the value $d=6\times10^{-5}$ cm is obtained. Using the dimensions of a typical counter, the ratio V_-/V_+ is found to be 0.2 percent. Therefore the assumption that the electron pulse is a negligible fraction of the total pulse size was a valid assumption.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 3 MARCH, 1950

Laboratory Modifications in the RCA Model EMC Electron Microscope

S. G. Ellis
RCA Laboratories, Princeton, New Jersey

(Received December 8, 1949)

The anode opening was reduced to reduce thermal expansion in the specimen stage. The asymmetry of the objective lens was compensated. Working at the lowest possible angular aperture of illumination and focusing critically (by using a carefully settled fluorescent screen and a high magnification viewer) a resolving power of approximately 50 A.U. was demonstrated on suitable specimens.

INTRODUCTION

In the course of experiments made to test the performance of a standard RCA model EMC electron microscope, it became apparent that some minor modifications of the column would result in improvement of the performance of the instrument. Since the modifications could be made in any laboratory machine shop, they are described here for the benefit of other operators. It is believed that these modifications bring the resolution of the instrument close to its ultimate value, approximately 50 A.U.

It is worth emphasizing that the work described here was done on only one instrument. If one repeated the work on other instruments, it is not unlikely that the problems encountered would differ in degree from those described here. It is believed however, that the major problems have been discussed below, and that if the basic principles are grasped, there should be no great difficulty in repeating this work in other laboratories. To facilitate this end, the experimental work is described below in the order in which it was done.

EXPERIMENTAL WORK

The microscope on which this work was done had been in use in another laboratory. As a first step, it was thoroughly cleaned and the fluorescent screen was replaced.

The cleanliness of an electron microscope may be tested in the following way: Employ as a specimen, a filmless mount of carbon on a rigid copper mesh so that thermal drifting of the specimen is minimized. Obtain a focused image at top magnification (×5000 approximately) and vary the intensity of illumination either by changing the filament temperature or by moving the gun tilt screws. If the column is clean, an *accurately* focused image will move by much less than one-thirty-second of an inch, as measured on the fluorescent screen. It will be seen from what is said later, that it may not always be easy to distinguish between thermal drifting of the specimen and a deflection of the imaging beam by the charging up of dirt or contamination in the column.

In cleaning the electron microscope, dirt and contamination must be removed from all surfaces which can "see" the electron beam, until only the bare, polished, substrate metal remains. Cleanliness is more important in regions close to the imaging beam, particularly so where the beam current density is high. Surfaces which are not machined with high precision, may be cleaned with steel wool.[1] These include: the grid-cylinder (or shield), the anode aperture holder, and the specimen stage. When it is necessary to clean such parts, they should be removed from the column, and when they have been cleaned, all shreds of steel wool should be removed from them with a strong bar magnet.

Critically machined surfaces, such as the pole-pieces, should be cleaned with a very thin paste of Linde *B* polishing powder in water.[2] This paste may be taken up on soft tooth-picks,[3] or on suitably shaped sticks of soft wood. Orange sticks are too hard to be used safely on the soft iron of the pole-pieces. The pole-piece openings should be gently cleaned with a rotary motion until they shine. The polishing powder should be removed by washing with hot water and soap. The pole-pieces may then be polished dry with a lint-free lens tissue.[4] They should not be dried by allowing the water to evaporate from them.

In the work reported here, both the objective and projector apertures were removed. No completely satisfactory method is known for cleaning these apertures, and it would therefore seem imperative to remove the objective aperture in the preliminary tuning-up of the microscope.

A settled fluorescent screen was made using 33Z607 phosphor,[5] following the directions of Sadowsky.[6]

It is extremely important to have an efficient fine grain fluorescent screen, since the screen limits the accuracy with which the microscope can be focused and also the precision with which image shifts and other defects can be examined. In all the work with this microscope, the fluorescent screen has been examined through a reversed ×10 eye-piece, from a light microscope, used as a high magnification viewer. Under these conditions, the grain has been barely visible, and the out-of-focus Fresnel fringes at major discontinuities in the specimen, have been seen easily.

The filament in the electron gun was pinched-up to give the minimum radius of curvature at its apex so that it would provide a small effective source of illumination. The filament height was set by trial and error until it gave the minimum saturation beam current consistent with adequate intensity of illumination. The procedure finally adopted, was to turn the grid cap until the filament apex was in the plane of the grid hole. The grid cap was then turned off (anti-clockwise) four turns. This gave a beam current of less than 100 micro amps, the bias resistor being 700,000 ohms. Bias resistors between 0.5 and 1.0 megohm are probably satisfactory but their value will determine the best filament height. In the trial and error determination of the filament height to be used, it is best to start at the smaller filament heights (corresponding to the higher beam currents) since if the filament height is greater than a certain, rather critical amount, the intensity of illumination becomes completely inadequate. The filament should always be run hot enough for the saturation beam current to be reached.

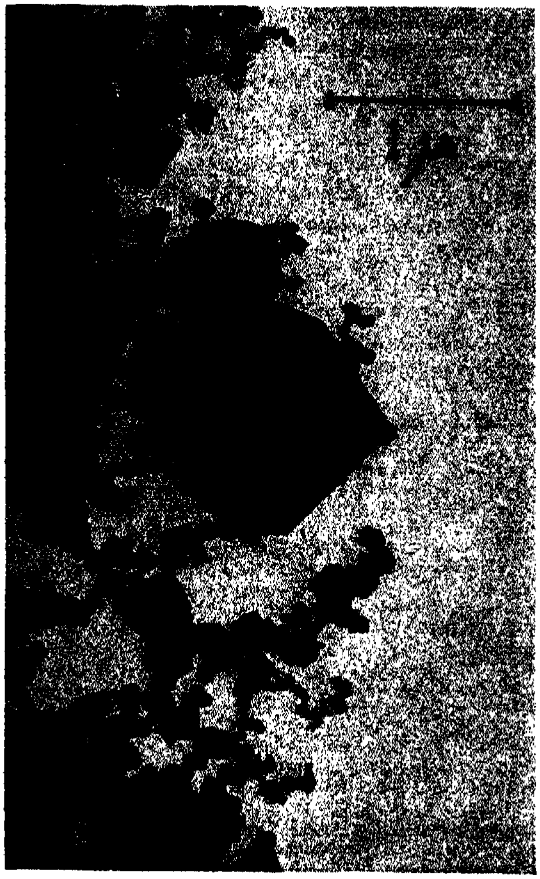

FIG. 2. Magnesium oxide smoke. Filmless mount.

These preparations having been completed, the instrument was run using carbon on a copper mesh as a test specimen. The images were acceptable in quality but it was noticed that for a short time after the instrument was turned on, and for a short time after the specimen was changed, there were thermal drifts in the image. In the particular model EMC electron microscope under test, the diaphragm which limits the beam current reaching the specimen, was mounted on the same posts which carry the snubbing springs for the specimen stage. Heat generated in this diaphragm, was causing thermal expansion of the specimen stage. To overcome this difficulty, a plug with a central 0.5 mm diameter knife edged aperture, was pressed into the opening of the anode. This reduced the current reaching the movable beam limiting diaphragm and no further trouble was encountered with thermal drifts. On days when the microscope was to be used, the low voltage circuit was turned on at the beginning of the day and allowed to run continuously.

At this stage of the work, it became apparent that the objective lens asymmetry was the major remaining defect in the instrument. The asymmetry was reduced by a modification of the method of Hillier and Ramberg.[7] As shown in Fig. 1, twelve holes were drilled and tapped in the objective section of the pole-pieces, and two tightly fitting soft iron screws were made to fit them. The holes should be accurately radial and the tips of the screws should not wander when the screws are advanced, but should move radially. The procedure for correcting the asymmetry is then:

(i) With no screws in the lens, switch the lens on and off several times to standardize its magnetic state, align the microscope and take a picture of a filmless mount of carbon which will demonstrate the asymmetry. Project this picture onto a screen so that it appears in the same orientation as it did on the fluorescent screen. Mark the direction of the natural lens asymmetry, N, as a double ended vector, perpendicular to the high side Fresnel fringes.

(ii) Put the pair of screws into the lens in opposite holes and advance them as far as possible towards the axis, so that the asymmetry they produce will swamp the natural lens asymmetry. Put the lens back in the microscope in the same orientation as before and determine the direction of the new asymmetry T.

(iii) From the angle between T and N deduce the pair of holes into which the screws must be put, in order to introduce a correcting asymmetry C most nearly perpendicular to N. Put the pair of screws into these holes and advance them by trial and error until the asymmetry is minimized.

---

[7] J. Hillier and E. G. Ramberg, J. App. Phys. 18, 48 (1947).

In the least favorable case, where the desired direction is midway between two available pairs of holes, theory shows that the natural lens asymmetry should be reducible to half its initial value. In the work reported here, the asymmetry was rapidly reduced until it was no longer detectable. In a less favorable case, it is possible that a second pair of screws would have to be inserted to complete the correction.

PERFORMANCE

When the lens asymmetry had been compensated, the instrument demonstrated a resolving power of approximately 50 A.U. on suitable specimens. This resolving power was maintained during several months of intermittent operation. At the end of this time, the objective was becoming slightly contaminated.

By observing the fluorescent screen with the magnifier, it was possible to focus the microscope accurately with very good consistancy. This does, however, require experience of the nature of the contour phenomena, and of the changes in contrast on going through focus.

Some further attempts were made to improve the performance of the instrument, since micrographs taken on an RCA model EMU electron microscope, operated at an accelerating voltage of 30 kv showed crisper images. This observation indicated that the accelerating voltage was not the limiting factor in the model EMC microscope. It was concluded that the angular aperture of the illumination was the parameter that was restricting the resolution to 50 A.U. Since, in the absence of a condenser lens, the aperture of illumination could only be reduced by increasing the filament to grid-cylinder spacing, and since, as has been said above, this reduces the intensity of illumination to less than an acceptable level, it is believed that the resolution reported here is close to the ultimate resolving power of an instrument of this design.

Figures 2 and 3 demonstrate the performance of the instrument.

OPERATION AND MAINTENANCE

The reduced size of the anode opening makes the instrument somewhat more tedious to align. If, however, one starts by removing the gun and placing a flash-light bulb in the position of the filament to obtain mechanical alignment of the beam limiting diaphragm by looking along the column from the camera end and then proceeds to the electronic alignment at low magnification, the whole alignment procedure will not be found difficult. Once the gun traverse adjustment has been made and locked, it should be possible to change filaments and rapidly realign the microscope with the tilt controls alone. The alignment is not too critical; it will usually be sufficient to bring the current center onto the final viewing screen. To have the current center near the center of the screen, does however, facilitate focusing, since the image does not sweep on changing the lens strength.

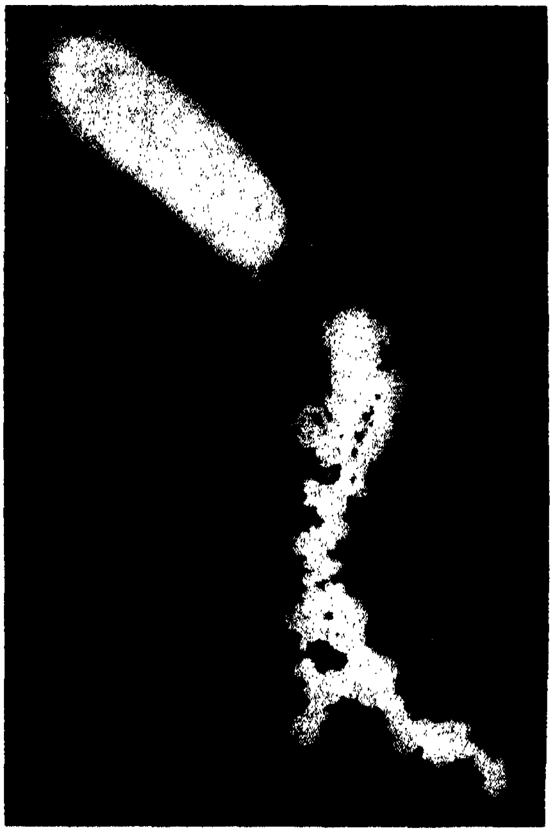

FIG. 3. Proteus bacterium and carbon, shadowed with chromium.

No objective apertures were used in the work reported here. Their use might be justified in the examination of thick specimens where the specimen lowers the resolution in any case. It is desirable to use a projector aperture since without it, the electrons which pass through the peripheral parts of the projector strike the walls of the viewing chamber and are scattered into the final image causing an appreciable loss of contrast.

Laboratory and Shop Notes

Degassing Extended Glass Systems

Albert B. Stewart
Antioch College, Yellow Springs, Ohio
January 11, 1950

By using infra-red heating it is possible to degas an extended glass vacuum system without building a large oven to enclose the entire apparatus. In preparing tubes for studying glow discharge phenomena* the writer has found the following procedure very satisfactory.

The glass tubing to be degassed is painted with a suspension of lampblack in water, the suspension being obtained with the help of a wetting agent. Stopcocks and other parts of the system that should not be heated are left unpainted and covered with aluminum foil. A battery of 375-watt reflector-type infra-red bulbs is placed a centimeter or so from the tubing and the bulbs and tube surrounded with aluminum foil which effectively traps the radiation. A mercury thermometer with bulb blackened records a temperature of about 400°C within five minutes after the bulbs are turned on. One to two hours of application of heat suffices to degas the glass to the point that an ionization gauge in the system reads the same pressure with the bulbs on as off. The infra-red bulbs can be left in place or removed and the glass tubing cleaned with a damp rag.

Liquid Air Level Control

Mark S. Fred and Everett G. Rauh
Argonne National Laboratory, Chicago, Illinois
January 25, 1950

A simple device has been designed and constructed which automatically maintains within predetermined limits the level of liquid air or liquid nitrogen in a bath. Control is based on the large negative temperature coefficient of resistance of an ordinary carbon resistor. By incorporating the resistor in a voltage divider there is obtained, with a change of temperature of the resistor, a large voltage change which actuates an electronically controlled liquid air pump. In Fig. 1 the grid controlled thyratron will fire during the positive half-cycle of the line voltage if the starting anode is sufficiently positive with respect to the cathode. When the thyratron is conducting, the relay opens a solenoid valve which admits air pressure to a liquid air reservoir and forces liquid air into the Dewar until *R*1 is immersed. The resistance of *R*1 increases and lowers the fraction of the line voltage applied to the starting anode to a value below the firing potential, closing the solenoid valve. The resistance increase for a change +20°C→−180°C is about a factor of 1.7, causing a change of voltage of about 15 volts. Since a change of a few volts is sufficient to control the thyratron, some choice in the lower limit to which the liquid air falls is possible by adjustment of *R*3.

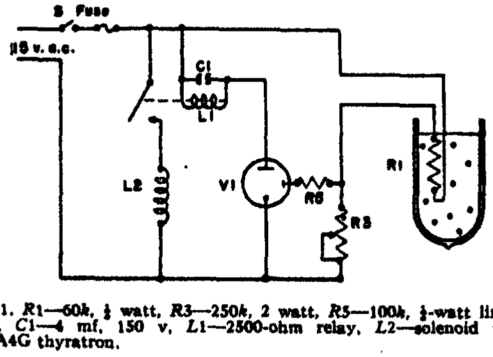

Fig. 1. *R*1—60*k*, ½ watt, *R*3—250*k*, 2 watt, *R*5—100*k*, ½-watt limiting resistor, *C*1—4 mf, 150 v, *L*1—2500-ohm relay, *L*2—solenoid valve, *V*1—OA4G thyratron.

The upper level for the liquid air is fixed fairly sharply at the lower edge of the resistor, and the lower level can be set by *R*3 at several millimeters to several centimeters below the resistor. However, for a larger swing, the resistor must warm to nearly room temperature and control becomes uncertain. Hence the system shown in Fig. 2 was devised with independent resistors and thyratrons for controlling the upper and lower levels. Permitting a larger change in level while retaining positive control leads to a greater economy of liquid air.

*R*1 and *R*2 form with *R*3 and *R*4 voltage dividers which determine the potential of the starting anodes of *V*1 and *V*2. *R*3 and *R*4 are adjusted so that the starting anodes vary below and above the firing potentials as *R*1 and *R*2 are and are not immersed in liquid air. Examination of the circuit shown in Fig. 2 will show that *L*1 is closed only by *V*1 and opened only by *V*2. Therefore *R*1, the lower resistor, must warm slightly before pumping begins, and *R*2, the upper resistor, must become immersed before pumping ceases.

*R*3 and *R*4 are adjusted in the following manner: *R*3 is set at minimum resistance, *R*4 to maximum, and *S* is opened momentarily to insure *L*1's being open. *R*3 is increased until the relays close and pumping begins. Pumping is allowed to continue until the liquid air level reaches *R*2, then *R*4 is decreased until the relays open.

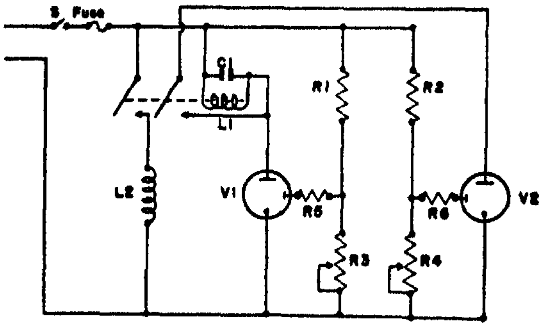

Fig. 2. *R*1, *R*2—60*k*, ½ watt, *R*3, *R*4—250*k*, 2 watt, *R*5, *R*6—100*k*, ½-watt limiting resistor, *C*1—4 mf, 150 v, *V*1, *V*2—OA4G thyratrons, *L*1—2500 ohm relay with DPST normally open contacts, *L*2—solenoid valve (Asco Type P32X, manufactured by the Automatic Switch Company, Orange, New Jersey).

Should it be desirable to maintain a level varying only a few millimeters, it is only necessary to set *R*4 at zero resistance. *R*1 then controls both the opening and closing of *L*1.

This control principle can be used with many tube types. The OA4G thyratron, however, is convenient because it is of the cold cathode type requiring no heater supply and its firing potential is near the mean for the voltage divider swing which is a maximum when $R3=(R1R1')^{\frac{1}{2}}$, where $R1'$ is the resistance of *R*1 at −180°C. Furthermore, the OA4G requires no d.c. supply and permits complete a.c. operation which is an advantage in itself in that it allows the starting anode to regain control after each cycle. If a vacuum triode is used, a battery is required to obtain proper grid bias and still retain the maximum voltage change.

An Asco type P32x solenoid valve, manufactured by the Automatic Switch Company of Orange, New Jersey, was found suitable because it operates on 115-v a.c. and allows venting the pressure created by evaporation of liquid air in the reservoir. The ports are marked *A*, *B*, and *C* on the commercial item. *A* was led to the reservoir, *B* to the line pressure, and *C* was left open to the atmosphere.

The chief advantage of this system is its flexibility obtained because the controlling elements require very little space and may be adjusted for a wide range of requirements. Control has proved to be positive and reliable.

A Series Parallel Linear Thermopile with Interchangeable Receiving Units

Robert A. Crane* and Francis E. Blacet
Chemistry Department, University of California, Los Angeles 24, California

September 14, 1949

In order to determine the quantum yields of certain photochemical reactions it was necessary to measure the absolute intensity of ultraviolet light passing through a reaction cell 30 mm in diameter. Examination of the existing literature did not disclose a suitable instrument for this purpose. The thermopile type described by Leighton and Leighton[1] and previously used in these laboratories was not as sensitive as desired and the design by F. A. Firestone[2] did not cover a large enough area.

Figure 1 gives a perspective view of one of the receiver elements which are the basic units in the thermopile which was constructed to meet our needs. As many of these units as required in order to cover a given area may be held together by means of insulated bolts placed through the two holes, *C*. The receivers in this way are connected in a series parallel manner reducing the total resistance for the thermopile considerably below that for the same number of units arranged in a series manner.

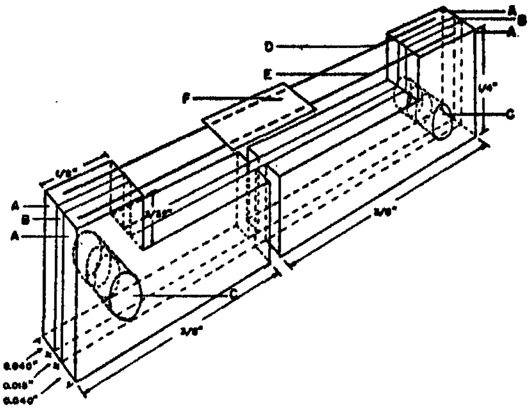

Fig. 1. Perspective view of a single thermopile unit. A. Brass cold junction, B. fiber insulator, C. assembly rod hole, D. bismuth wire, E. bismuth-tin wire, F. platinum receiver.

The cold junctions consist of four "*L*" shaped brass pieces, *A*, cemented to a fiber board insulating piece, *B*, in such a manner that each "*L*" is electrically insulated from the others. The brass pieces were cut from 18-gauge sheet brass, drilled and machined in a group to make them of uniform size. The topmost edges of the brass "*L*" 's were tinned using Wood's metal as a solder.

The radiation receivers were made from platinum foil, 0.0005 inch thick, in the following manner. Using a soldering iron, one side of the platinum foil was covered uniformly with a thin layer of tin. To remove small irregularities, the tinned foil was rolled until the combined thickness of the tin and platinum was about 0.0007 inch. Receivers about 2.4 by 4.0 millimeters were cut from this material. Pure bismuth and 95 percent bismuth-5 percent tin wires 0.004 inch in diameter, obtained from Baker and Company, Inc., Newark, New Jersey were cut to three-quarters of an inch, and soldered to the tinned backs of the platinum receivers in the following way. A receiver was laid on a glass plate, tinned side up, and one of each type of wire placed the long way of the receiver about one-half millimeter from each edge. A thin mica sheet, having on its under side a small drop of zinc-hydrochloric acid flux, was then laid over the wires so as to wet the entire receiver and wires. Heat was applied by means of a miniature soldering iron pressed directly on the mica sheet until the wires fused to the tin layer covering the platinum. The completed receiver and wires were washed in warm water to remove the excess flux.

The receivers next were soldered to the "*L*" shaped cold junctions making use of the Wood's metal previously applied. Heat was administered with extreme caution to avoid melting the wires at the point of contact with the cold junctions.

The shiny platinum surface was plated using a solution of 0.025N hydrochloric acid containing 0.3 percent platinum chloride and 0.025 percent lead acetate.[3] A sufficient amount of this plating solution was placed in a small platinum boat so that the solution, due to surface tension, extended a little above the edges. The thermopile unit was suspended platinum face down and then lowered by means of a screw device until the platinum just touched the surface of the plating solution. It was important to cover the entire surface of the platinum but yet not to allow any of the solution to cover the back side of the unit because the platinizing solution would react with the tin causing poor electrical connections where the wire was bonded to the tinned platinum. Plating for approximately five minutes with a current of about 2 milliamperes resulted in a uniform velvety black surface. The plated units after rinsing in warm water and drying were ready for testing and final assembly.

Two linear thermopiles were assembled from units of this design each with an exposed area of 3 mm by 30 mm and consisting of 14 and 16 receiving junctions. The total resistance of the thermopiles was 27 and 32 ohms respectively. The sensitivity of each of these thermopiles was nearly double that of a thermopile covering the same area but constructed following the design described by Leighton and Leighton[1] and using bismuth and silver wires. The response of the most sensitive thermopile was 0.068 microvolt for a radiation intensity of one microwatt per square centimeter. This figure was calculated from the galvanometer characteristics and the deflections obtained using standard lamps from the Bureau of Standards. The time constant for the maximum response was less than four seconds, under the conditions used.

The response of the thermopiles was linear over the range of intensities covered, from 0 to 300 microwatts per square centimeter. The surface linearity of the instruments was checked by moving a 4-mm slit along the sensitive receivers so that only this portion was exposed at one time. In both the variation in surface sensitivity was less than 5 percent compared with about 15 percent for the silver-bismuth thermopile. Thus, the bismuth-bismuth alloy thermopiles represent a decided improvement over the silver bismuth thermopile both in increased sensitivity, which is expected in view of the more favorable thermal e.m.f. of the metals used in their construction, and in more uniformity of the absorbing surface attained by the platinum black plating process, as well as by interchanging and matching the individual units making up the complete instrument.

Low Temperature Gasket

A. Wexler, W. S. Corak, and G. T. Cunningham
Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania

November 17, 1949

In the assembly of low temperature apparatus the closure technique presents several problems. In the first instance, securing a reproducible vacuum-tight seal is complicated by the fact that joints which are tight to helium gas may not be tight to superfluid He II.[1] Second, in some cases the necessity of heating the apparatus, when a standard soldering procedure is used, is detrimental to the materials it contains. Finally, the presence of ordinary solder, which becomes superconducting, and hence strongly diamagnetic, interferes with magnetic measurements that may be made at low temperatures.[2]

From the room temperature thermal expansion coefficients, it appeared that gold should function satisfactorily as a gasket in copper containers, which are most frequently used. Gold gaskets have been used previously in these Laboratories in high temperature apparatus.[3] The use of a gold gasket in a low temperature

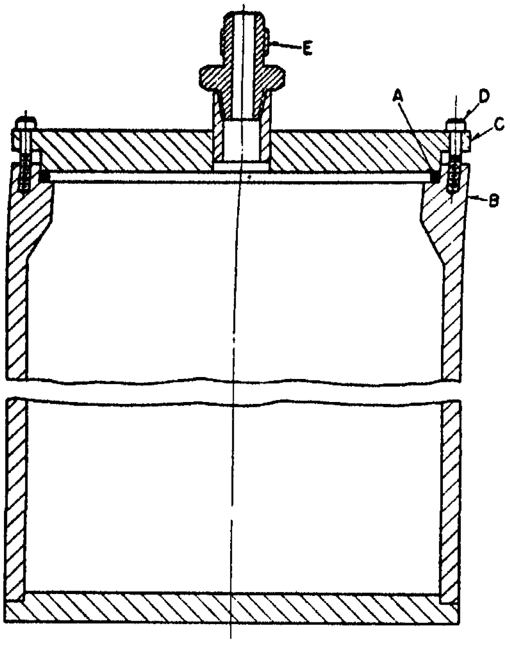

Fig. 1. Low temperature gasket.

container is indicated in Fig. 1. The gold wire, *A*, 0.020 in. in diameter, sealed the copper container, *B*, which in this application happened to be 8×4 in. (diameter), when the copper cap, *C*, was forced down onto it by twenty-two 4–40 Allen-head screws. The initial tightening of the cap caused the gold to flow and to take up any irregularities in the sealing surfaces. At the same time it became work-hardened and elastic. The gasket adhered well to the container and was not removed during subsequent disassembly operations. In the application in which this arrangement was used, the presence of magnetic bodies was not objectionable; hence standard steel screws were used. For experiments in which this is a consideration, strong, non-magnetic screws will be employed; beryllium copper screws appear to be a good choice for this purpose.

The arrangement was checked for tightness with a helium mass spectrometer leak detector.[4] Preliminary measurements, made with the leak detector operating in routine fashion, that is, with the diffusion pump associated with the device open to the system under test, gave a conservative lower limit to the size of leak detectable equal to 5×10^{-6} (micron-liter)/sec., measured at room temperature. Within this limit, no leak was detectable with the apparatus exposed to helium gas at one atmosphere in the temperature range room temperature to *ca.* 4.2°K, or to liquid helium between *ca.* 4.2° and 1.92°K.

Because of the general interest in the tightness of the gasket when the seal is exposed to superfluid helium, the test method was elaborated so as to decrease the lower limit to 5×10^{-9} (micron-liter)/sec. with the apparatus immersed in liquid helium below the λ-point. The container was filled with a machined piece of aluminum which decreased the gas space in the container practically to zero. The container communicated with a 1.5-liter volume at room temperature by way of the pumping line. When the liquid helium in which the container was immersed reached the λ-point, the container was isolated from the pumping system of the leak detector, and any helium leaking in was allowed to collect in the room temperature volume. The collection time was 100 min., during which time the liquid helium, whose vapor was being pumped away continually, reached a vapor pressure of 18.2 mm, corresponding to 1.92°K. At the end of the collection time, the system was quickly opened to the mass spectrometer, and, from independent calibrations, the lower limit already noted could be deduced. There exists the possibility that the actual leakage rate is higher than the value given because of the adsorption of helium gas on the low temperature surfaces of the container. No further work was done on this possibility.

There was no ambiguity associated with the temperature measurement. It was determined from the vapor pressure as indicated by both an ordinary mercury manometer and a Dubrovin gauge having a ninefold amplification factor and readable to ±0.1 mm Hg. The gauges were connected to a tube having an I.D. of 0.175 in. and immersed in the liquid helium. The attainment of the λ-point was indicated by a discontinuity in the slope of the vapor pressure, time relation for the evaporating liquid and corresponded accurately to the λ-point pressure as read on the gauges.

The assembly survived 12 cooling-heating cycles between room temperature and 77°K, as well as six separate openings and closures, with no evidence of leakage. Parenthetically, it is interesting to note that the leak test included any possible contribution by the S.A.E. brass to copper flare fitting which was therefore free of leaks to the limit and under the conditions described.

It is evident that the seals described here are sufficiently tight to permit the use of the practice widely employed in the case of glass Dewar vessels.[5] Thus it would be possible to rough pump a copper vacuum container using a gold gasket and to allow the pressure to drop to a negligible value when low temperatures are reached. In other words, no kinetic diffusion pump system need be used.

In conclusion, the authors are happy to acknowledge the cooperation of Dr. R. E. Fox and Mr. D. J. Grove in certain phases of the use of the mass spectrometer leak detector.

Simple Method to Seal Liquids of High Vapor Pressure into Glass or Quartz Capillaries

Z. V. Harvalik
University of Arkansas, Fayetteville, Arkansas

August 1, 1949

A SIMPLE method of sealing a liquid of high vapor pressure (water, ethyl ether, ethyl alcohol, carbon disulphide) into heavy-walled glass or quartz tubes and capillaries is described as follows.

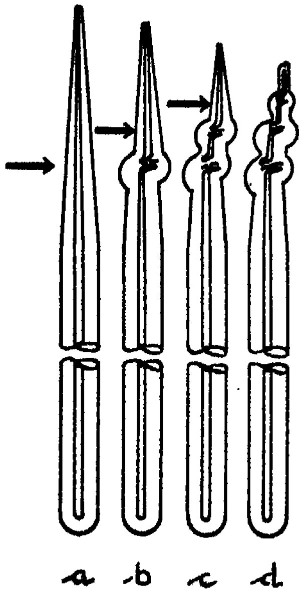

Fig. 1.

The glass or quartz tubing or capillary is drawn into a heavy-walled capillary of tapering bore of approximately 10 to 15 cm length, and filled with the liquid to be sealed in. Then the beginning of the capillary is carefully heated (see arrow in Fig. 1a) until the glass (or quartz) becomes soft. Compress gently and dislocate the compression bulb laterally 2 to 3 mm. Figure 1b shows the seal after compression and dislocation. Then heat the capillary about 5 to 10 mm above the first compression seal (see arrow in Fig. 1b) until glass becomes soft, compress and dislocate laterally again. This second compression seal (Fig. 1c) will prevent any escape of vapor of the liquid of large amounts through the capillary. By heating the end of the capillary 5 to 10 mm above the second compression seal, a perfect closing of the tube can be achieved (Fig. 1d).

Capillaries have been filled with liquids to two-thirds of the length of the tube, and sealed by using the method described above. The capillaries are heated electrically in a tube-like furnace to the critical temperature of the liquids. When the critical temperature was reached the meniscus disappeared.

As testing liquids, water (critical temperature, 374°C; critical pressure, 218 atmospheres), ethyl ether (193°C, 35 atmospheres), ethyl alcohol (243°C, 63 atmospheres), and carbon disulphide (273°C, 75 atmospheres) were sealed into Pyrex and quartz capillaries of 2- to 3-mm original bore.

Carefully annealed seals withstand pressures of the magnitude of the critical pressures of the liquids mentioned above.

During the testing the disappearance of the meniscus was observed through a shield of safety glass. It is recommended not to attempt to heat the capillary in an open flame while holding it in the hand.

A Simple Recording Manometer*

Fraser P. Price and Paul D. Zemany
Research Laboratory of the General Electric Company, Schenectady, New York

January 5, 1950

In the course of some work on gas reactions the problem of obtaining a record of pressure changes of the order of 100 mm Hg occurring over periods of 10–20 seconds was encountered. The problem was solved in a simple and as we believe novel manner, since no reference to a similar device could be found in the literature. A diagram of the apparatus is presented in Fig. 1.

It consisted of a conventional *U*-type mercury manometer in the evacuated side of which was stretched a length of 20-mil nichrome wire (*C*). This was kept taut and centered by two tungsten wire springs (*B*) which were connected to heavy wire leads (*A*) sealed through the glass, all metal-metal connections being spot welded. The two ends (*A*) were connected to a 1.5-v dry cell in series with a resistance of about 500 w. In this manner the current through the wire was kept constant and the voltage drop (about 1 mv) across the portion of the wire untouched by the mercury was a function of the height of the mercury in that limb.

This voltage drop was amplified by a G.E. self-balancing potentiometer which in turn actuated a G.E. photoelectric recorder. The short limb of the manometer was about 1¼ in. I.D. while the long limb was of ⅜ in. I.D. tubing. Thus more than 90 percent of the pressure rise was effective in changing the voltage drop. Also the relatively large diameter of the long limb prevented the wire from coming too close to the side thus giving rise to undesirable wall effect.

In order to get reproducible results it was found necessary to use scrupulously clean mercury and to flash the nichrome wire several times in about 3 mm of H_2, pumping out to about 20 microns between flashings. With these precautions two such manometers, one 1 meter long and one 100 mm long have functioned without discernable change in calibration over periods of months.

The calibrations of the smaller one taken every day for the period of a month were plotted on the same graph. They all fell on the same line showing no hysteresis and were reproducible to within the error in reading the recorder chart, i.e., ±2 percent. Since this was sufficient for the problem at hand, no attempt was made to find whether or not this error could have been reduced by a more precise recorder.

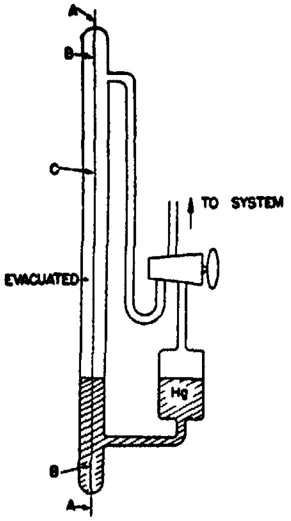

Fig. 1.

In preliminary models of this instrument, in order to get the change of resistance per unit length as high as possible, attempts were made to use very fine (about 0.5 mil) tungsten wire as the filament. However it was found that it was not possible to get good calibrations presumably due to the inability of the mercury to make reproducible contact with so fine a wire. Also since the filament apparently has to be in the evacuated limb a manometer having a wire in each side connected to a bridge circuit so as to accentuate the unbalance probably would not prove feasible.

With the manometer described here no attempt was made to use a.c. on the manometer filament, principally due to the fact that the d.c. amplifier and recorder were available. However we can see no reason why the use of a.c. should not be possible and perhaps even desirable as the problems connected with amplification and recording would probably be simpler.

A High Pressure Fitting for Scintillation Counting

K. D. Timmerhaus, E. B. Giller, L. H. Tung,
R. B. Duffield, and H. G. Drickamer
University of Illinois, Urbana, Illinois

January 5, 1950

The use of a scintillating crystal with a photo-multiplier has opened up a number of new techniques in tracer work. It is now possible to make continuous analyses without sampling. This is especially advantageous in high pressure systems, particularly near the critical point where sampling would considerably disturb conditions. For these cases the crystal is placed inside the apparatus and the light is conducted out by a Lucite or quartz rod.

Figure 1 shows a high pressure seal for the operation. The seal is made with *O*-ring, and the shoulder and nut are merely to keep the rod from sliding out. The rod goes to a photo-multiplier tube in a cooled box. Considerable care is necessary to make the whole system light tight.

The above system has been pressure tested to 2000 p.s.i.a., and would probably go considerably higher. With Lucite rods, a temperature of 55°C has been maintained for five days with no appreciable effect on the seal or light conducting properties. At 60°C some softening takes place, and at 65° the rod deforms and loses seal in less than 24 hours. There is no apparent temperature limitation on the quartz, within the limits permissible for *O*-rings.

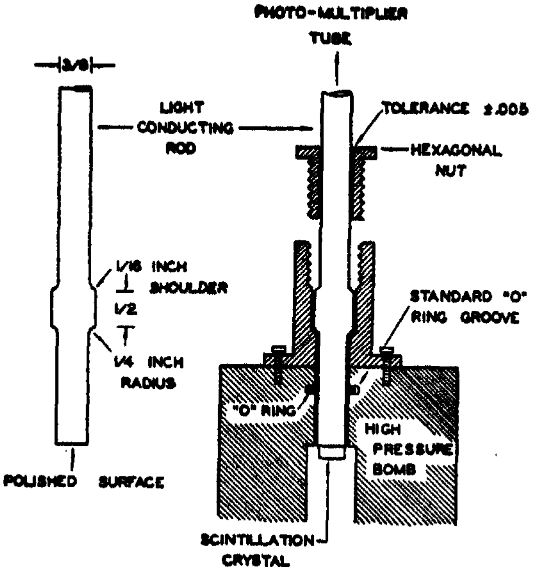

FIG. 1. Fitting for high pressure scintillation counter.

The crystal can be sealed to the rod with a glue made from Lucite dissolved in ethylene dichloride. This also makes an effective coating for anthracene crystals to prevent attack by paraffin hydrocarbons without significantly decreasing the counting rate even for such weak beta-emitters as C^{14}.

Automatic Equipment for Electrolyzing Heavy Water

RALPH W. WANIEK
Institut fuer Radiumforschung, Akademie der Wissenschaften, Vienna, Austria

January 5, 1950

FOR the production of deuterium necessary for the supply of the ion source of a neutron generator, we devised a very simple and automatically working equipment. The apparatus avoids the heated palladium tube which might be very difficult to obtain and is much simpler than the unit described by Slack and Ehrke.[1] Figure 1 shows the construction of the V-shaped cell made of Pyrex glass which contains about 5 cc of heavy water. We employed, as electrodes, 0.5-mm thick platinum wires which were sealed into the glass walls, and produced the necessary electrical contact by means of small mercury columns. Thus, the whole cell can be easily dipped into a beaker with water to produce the right cooling. The shape of the cell permits keeping the "dead volume" (i.e., the quantity of electrolyte which cannot be reached by the electrodes) at a minimum.

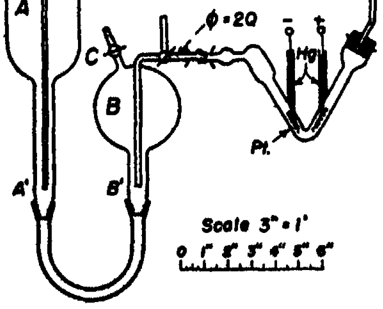

FIG. 1.

The problem of equalizing the different pressures on the two sides of the electrolyzing apparatus was solved as shown in Fig. 1. The cross section of the glass tubing of the deuterium line is twice that of the oxygen tubing. Before a run is started, bulb B is filled completely with a special liquid which does not show a too accentuated exchange effect between heavy and light component. High vacuum oils or benzene may therefore suit the purpose. During the production, deuterium is stored in bulb B and the liquid rises in A. Thus, the same hydrostatic pressure is to be expected at both points A' and B' which are at the same height. The oxygen escapes through A. By means of stopcock C, deuterium can be filled into an evacuated bulb which provides the ion source with gas through a needle valve. Voltage and current of the equipment can be controlled accurately. The apparatus works automatically for hours and represents a satisfactory solution in all cases of this kind.

Optical Centering System for X-Ray Diffraction Samples

EUGENE L. PERRINE
Armour Research Foundation of the Illinois Institute of Technology, Chicago, Illinois

January 16, 1950

WHEN samples are to be rotated during exposure to a narrow beam of x-rays, as is frequently done when x-ray diffraction studies are made, it is necessary to place the sample on the axis of rotation so that it does not move in and out of the x-ray beam during exposure. This positioning is frequently done by observing the sample with a low power microscope while it is rotated manually and placed on the proper axis. This results in correct placement, but it is inconvenient because the positioning operation must be carried out while the worker is looking through the microscope. He is unable to watch what he is doing with his hands.

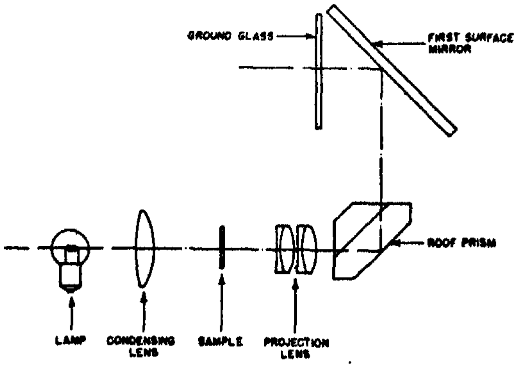

FIG. 1.

The instrument described was constructed to avoid this difficulty (see Figs. 1 and 2). The device consists of a light source, a condensing lens, a folded projection system, and a viewing screen. The light source is a six-volt lamp which is powered from the line by means of a transformer. The light from this lamp is concentrated on the sample by a single condensing lens which is focused slightly beyond the projection lens. The projection lens itself is a petzval with a focal length of one inch. With the path length provided it gives a magnification of approximately four and one-half times. The optical path is folded by a roof prism and a first surface mirror. The roof prism corrects the left to right transposition of the projection lens and the folding of the optical system corrects inversion which is also produced by the projection lens.

FIG. 2.

With these compensations the image produced is erect and correct with respect to left and right. It is, therefore, easy to position the sample because all movements are in the same direction when viewed through the optical system as they are when viewed directly. The ground glass viewing screen is placed above and slightly behind the sample so that the sample and the image can be viewed simultaneously. A vertical line on the ground glass shows the axis of rotation and a horizontal line indicates the point at which the x-ray beam intersects this axis. The same pilot pins which are used to position the sample holder on the x-ray diffraction camera are used to position it on the alignment unit.

Electronic Water-Level Control

R. D. Miller and J. S. Hopkins
Division of Soils, University of California, Berkeley 4, California

October 18, 1949

In the construction of a recirculating, constant volume soil permeability apparatus, it was necessary to devise a means of producing and maintaining a controlled hydraulic gradient across the sample chamber and flow meter. This reduced to a matter of pumping water from one arm of a manometer to the other at such intervals as were necessary to maintain the water-level in one arm within narrow limits. An electronic control was used to direct the action of the pump (see Fig. 1).

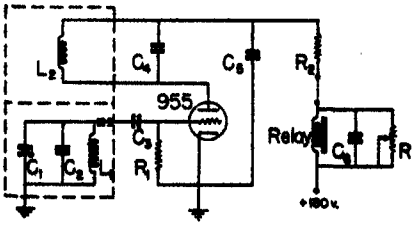

FIG. 1. Circuit of electronic water-level control. The distributed capacities of the shielded lead and of the coils are not indicated. C_1 2–10-mmf variable air condenser; C_2 2-mmf silvered ceramic; C_3 150-mmf mica; C_4 10-mmf silvered ceramic; C_5 500-mmf silvered mica button; C_6 16-mf paper; R_1 100 K ½ watt carbon; R_2 5 K 1 watt carbon; R_3 10 K w.w. pot; L_1, L_2 32 turns No. 32-scc enameled wire, open wound on ½ in. i.d., 1/16-in. wall polystyrene tubing; relay d.c. resistance 4000, 4 ma to close, open at 2.5 ma. Observed operating frequency: 10.5 megacycles.

The high dielectric constant of water suggested that if a manometer arm passed through the coil of a tuned circuit, its resonant frequency would be altered by a change in water-level within the coil. A tuned-plate tuned-grid oscillator was constructed in which a manometer arm passed through the plate coil. If the water-level subsided, resonance between plate and grid circuits was destroyed, and the resultant increase in plate current closed a relay, starting the pump. Pumping continued until the water-level in the manometer arm rose to a point at which oscillation was resumed and the relay opened.

By careful shielding of plate and grid coils to minimize coupling, a control cycle was obtained in which the maximum displacement of the water surface was less than 2 mm. The pressure control range was reduced to less than 0.5 mm of water by using USP white oil as the manometer fluid in an inverted manometer. Any desired head could be obtained by sliding the unit to the appropriate point on the manometer arm.

A Manometer Leveling Procedure

John E. Wertz*
The George Herbert Jones Chemistry Laboratory, University of Chicago, Chicago, Illinois

November 21, 1949

In numerous gasometric procedures it is necessary to balance gas pressures against one another, making use of a manometer as a null instrument. To establish the point of equality of levels of manometric liquid without reading their positions on a scale, the following procedure is found to be rapid and probably as accurate as is possible with the unaided eye.

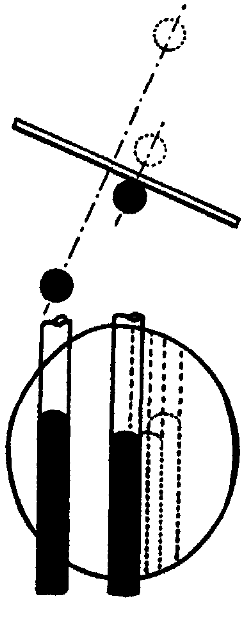

FIG. 1. Monometer leveling procedure using a mirror.

A plane mirror is held vertically against the back of one leg o the manometer, but at an angle to the plane of the latter, as in Fig. 1. (It is essential that this leg be truly vertical.) To avoid parallax, the eye is adjusted to such a level that the meniscus and its image are superimposed. By rotating the mirror about the leg of the manometer, the image of the other meniscus can be brought into juxtaposition with the first, so that any inequality in levels is easily discernible. This permits equalization to within 0.1 mm.

New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

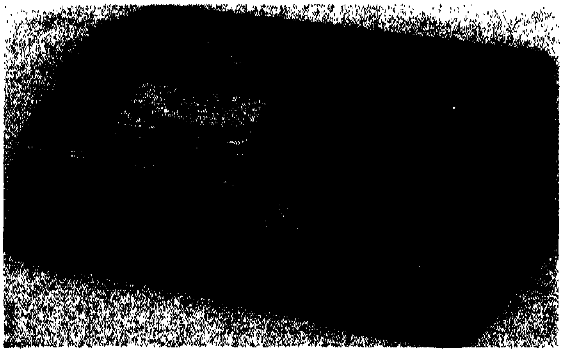
These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. The Review *assumes no responsibility for their correctness.*

Spectrophotometer

The new Beckman Model B spectrophotometer is a low-priced instrument designed for rapid, convenient, and accurate measurements in the wave-length range 320 to 1000 mμ.

The instrument is applicable to a wide variety of measurements and carries convenient provisions for attaching accessories. It features: direct-reading absorbance, transmittance and wave-length scales; a simple, inexpensive optical system of high resolution, high wave-length accuracy and minimum stray light; a variable slit mechanism of novel design insuring smooth operation, reproducibility and freedom from lost motion and backlash; high photometric sensitivity; and an accurate, stable d.c. amplifier of rapid response.

The low cost of this new instrument will enable the rapid, accurate methods of spectrophotometry to be used for a large number of routine analyses now accomplished by colorimetry or by gravimetric, titrametric, or other tedious methods.



The dispersive element of the Model B spectrophotometer is a borosilicate glass prism with curved faces, of the type first described in 1910 by Charles Féry. The auto-collimating action of the prism eliminates the need for a collimating mirror, thereby simplifying the monochromator optical system.

The effect of the natural astigmatism of the Féry prism is overcome in the Model B spectrophotometer by employing a curved entrance slit. The exit slit is straight. This slit design also enables narrower absorption cells to be used and reduces exit beam deflections caused by test tube type cells. The prism is subject to a simultaneous rotational and translational motion by means of a compact quadrilateral framework hinged with beryllium copper spring reeds, which accommodates for the change in focal length with wave-length.

The high resolution of the Model B allows the spectral range 320 to 1000 mμ to be covered with maximum effective band widths of 5 mμ.

The amplifier is a.c.-operated, employing miniature and subminiature tubes in a negative feed-back circuit. An electronic regulator compensates for the effect of line voltage variations on the amplifier. Lamp power is provided through the built-in transformer, but for the most accurate work, the lamp should be operated from a battery or auxiliary voltage regulator.

Two interchangeable photo-tubes are available for measurement: a red-sensitive photo-tube for the range 600 to 1000 mμ, and a blue photo-tube supplied with the instrument for the range 320 to 700 mμ. A Corning No. 9863 filter is provided for use below

400 mμ, reducing stray light to less than 1.5 percent at 320 mμ. Stray light decreases at longer wave-lengths.

Readings on the transmittance scale can be reproduced to 0.3 percent. The scale can be expanded, by use of a precision amplifier sensitivity control, to further increase measurement accuracy.

Presently available accessories for the Model B are the integrating sphere reflectance accessory and the test tube holder. The monochromatic light beam may also be brought outside the instrument to accommodate longer cells, or for special uses requiring a high grade monochromator.

Other Beckman spectrophotometers are the well-known Model DU, for ultraviolet through near-infra-red work; and the Model IR-2 for the infra-red region.—National Technical Laboratories, *South Pasadena, California.*

F-M Generator

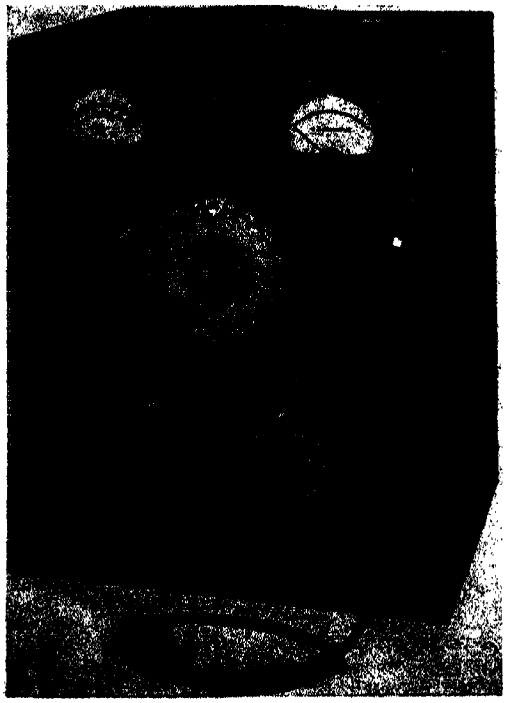
The Type 202-*D* f-m signal generator, designed for use with telemetering receiver equipment and in other associated applications, covers the frequency range from 175 to 250 mc and is provided with three continuously adjustable deviation ranges, 0–24 kc, 0–80 kc, and 0–240 kc. In addition, amplitude modulation up to 50 percent may be obtained using the internal audio oscillator, and modulation to 100 percent using an external audio oscillator.

The internal audio oscillator provides eight fixed frequencies between 50 c and 15 kc, any one of which may be conveniently selected by a rotary-type switch for frequency modulation or amplitude modulation.

The deviation sensitivity of the f-m system is within ±0.5 db from d.c. to 200 kc. The a-m system is substantially flat from 30 c to well above 100 kc.

A front panel jack permits direct connection of an external modulation voltage source to the screen element of the final stage for pulse and square-wave amplitude modulation. Under these conditions, the rise time of the modulated carrier envelope is less than 0.25 μsec. and the decay time less than 0.8 μsec.

A monitoring meter is used to standardize the output level of the signal generator in order to make the mutual inductance (piston type) r-f attenuator direct-reading over the range 0.1 μv to 0.2 v. The output impedance (with cable attached) is 26.5 ohms.

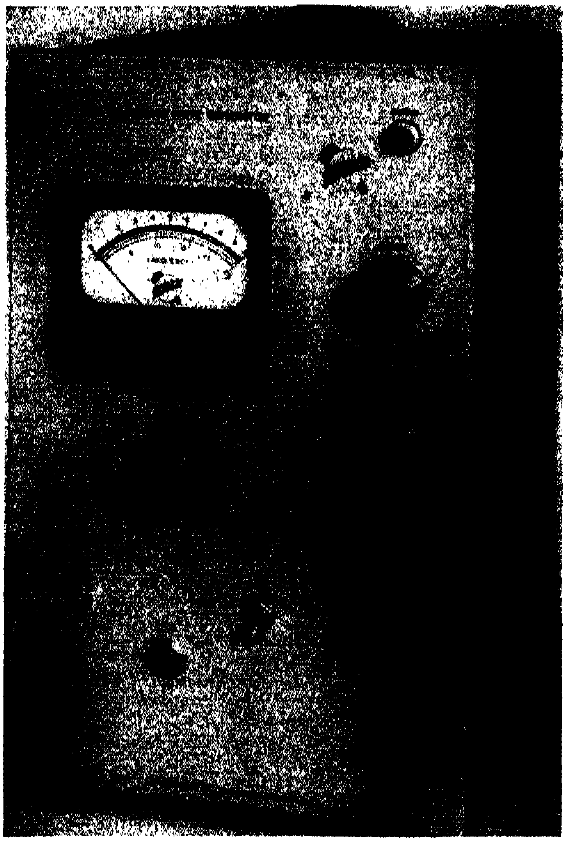


The instrument is self-contained, with power supply, and is designed for use on 115 v, 60 c.—Boonton Radio Corporation, *Boonton, New Jersey.*

Square Wave Generator

Type 105 square wave generator is continuously variable in frequency from 25 c.p.s. to 1 mc. The unusually fast rise time of approximately 0.02 μsec. (10 to 90 percent) is maintained at all frequencies without overshoot.

The Type 105 is essentially a square wave current generator with maximum current capability of 160 ma to output load. When used with the 93-ohm output cable, as furnished, approximately 15 volts are available. In the event that higher output voltages are desired, they may be had by the use of higher impedance output cables with a proportional increase in rise time.

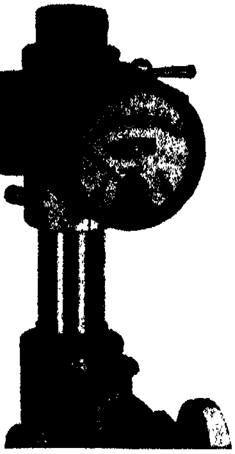


This instrument provides an ideally suitable signal for quickly and accurately testing the amplitude and phase response of amplifiers, filters, etc., having pass bands of a few c.p.s. to 20 mc.

The price of the Type 105 is $395.00 f.o.b. Portland, Oregon. Detailed specifications available upon request.—Tektronix, Inc., *712 S.E. Hawthorne Boulevard, Portland 14, Oregon.*

Microphotometer

The "Romicron C. G. Grand microphotometer" represents an instrument especially designed for use with the microscope. The photometer may be left on the microscope at all times. Readings may be obtained by operating a lever which will move the photoelectric cell into the path of rays. Indicator is a microammeter with arbitrary scale of ten divisions. A range switch mounted on the side of the housing permits a change of sensitivity and, by means of a female plug, an amplifier or galvanometer may be attached to increase scope of instrument. Also available will be a diaphragm eyepiece with observation telescope and beamsplitter



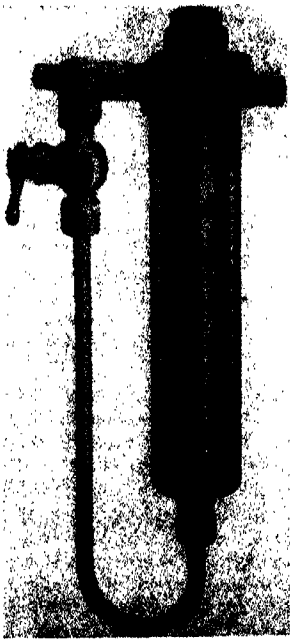
for measuring small areas and specific sections of a specimen.—Paul Rosenthal, *505 Fifth Avenue, Room 900, New York 17, New York.*

Cartesian Manostat

Designed for automatic pressure and vacuum control in the laboratory, pilot plant, and industry, the Cartesian manostat eliminates the use of complicated electrical and mechanical systems or extra equipment.

The operation is based on sealing off a given amount of gas at the control pressure desired inside a Cartesian diver floating in a pool of mercury. At equilibrium, the diver normally rests against the upper, adjustable orifice sealing it shut, but an increase in pressure in the system will cause it to sink, allowing the excess gas to escape from the system through the orifice to a source of pressure lower than the control pressure. The system pressure will then drop until the control pressure is reached, when the diver again seals the orifice. A small bleed into the system from a source of higher pressure insures that the system pressure will never go below the control point.

Model No. 5 industrial has a maximum capacity of 20 CFM for a system pressure of 100 p.s.i.a. with the largest orifice size, and a maximum sensitivity of 0.025 percent at 10 p.s.i.a. with the smallest orifice size.



Model No. 6 (illustrated) does not have the large capacity of the No. 5, but it has a feature that once a vacuum has been set in the instrument, the system may be shut down without disturbing the setting. When operated under vacuum, the quantity of gas maintaining the control pressure is sealed inside the diver even when the system is restored to atmospheric pressure, since the excess pressure forces the diver down upon an internal central tube, closing it and protecting the mercury seal.

Suggested applications include precise vacuum distillations or evaporations and physical chemical measurements such as vapor-liquid equilibrium determinations.—Emil Greiner Company, *20–26 North Moore Street, New York 13, New York.*

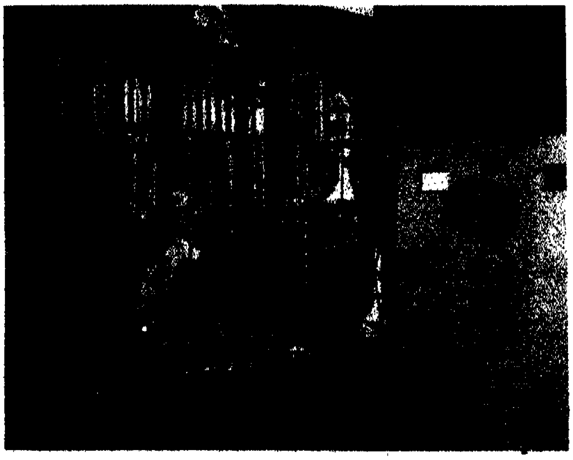
Vacuum Fusion Apparatus

In the vacuum fusion apparatus in use at National Research Corporation, Cambridge, Massachusetts, impurities in metals can be detected even when the percentage of a given element is as small as 10^{-5} (0.00001) percent or one part in ten million.

During the various stages of preparation, all metals retain or pick up small quantities of oxygen, hydrogen, nitrogen, and carbon. It has long been known that even minute amounts of these impurities may produce marked effects on the final properties of the metals. The above-mentioned elements may be contained as gaseous occlusions in structural faults, in solution or held in actual chemical combination as oxides, hydrides, nitrides, and carbides of various composition and degree of stability. Among the properties which have been found to be markedly affected by gaseous impurities are drawing characteristics, ductility at both elevated and room temperatures, tendency toward strain embrittlement, and heat-treated properties as affected by the degree of effective utilization of reactive alloy additions. As the demand for special alloys containing reactive metals and for highly purified metals is rapidly increasing, it becomes more and more important to determine the exact relationship between the amount of an impurity and its ultimate effect on the properties of a given metal or alloy.

Ordinary analytical procedures for the determination of the elements in question are impracticable in the percentage range encountered. Hence, vacuum fusion and vacuum combustion methods were developed specifically to handle this problem.

Under proper melting conditions under high vacuum, metals may be made to give up their gases quantitatively. The combined oxides react with the graphite crucible in which the melting is conducted, and the oxygen is released in the form of carbon monoxide. The hydrides and nitrides are decomposed, and the hydrogen and nitrogen are liberated directly. The choice of a correct temperature is highly important; it must be sufficiently high



to decompose the chemical compounds and at the same time not so high that the metal being analyzed will volatilize and coat the inside of the apparatus. Sometimes it is necessary to add a flux to assist in achieving these results. The mixture of hydrogen, nitrogen and carbon monoxide is pumped by means of a mercury diffusion pump into a vacuum chamber of known volume. The pressure of gas collected is measured by a McLeod gauge, which is simply a device intended to measure very low gas pressures.

After the total pressure of the gases is determined, they are circulated through a tube containing copper oxide. Here the hydrogen and carbon monoxide take oxygen from the copper oxide and are converted to water vapor and carbon dioxide, respectively. All the gases are allowed to circulate also through a cold trap cooled to −196°C by liquid nitrogen. Here the carbon dioxide and the water vapor are frozen out, while the nitrogen remains gaseous. The nitrogen is then returned to the McLeod gauge, where its pressure is determined.

The cold trap is then warmed up to about −80°C with a mixture of dry ice and acetone. At this temperature, the CO_2 is set free, and its pressure plus the pressure of the nitrogen is measured. By this means, the weight of each gas present may be determined.

The apparatus itself is necessarily complicated. It is constructed entirely of glass, and the few ground glass joints present are carefully sealed with a special high vacuum wax having an exceedingly low vapor pressure. Since the pressure in the system should be in the order of 0.01μ, the smallest leak will vitiate the results.

The main system is evacuated by the combination of a diffusion pump and an efficient mechanical pump. The gases are circulated through the system by means of two small, high speed diffusion pumps.

Since it would be impracticable to place a heater inside a high vacuum system, the metals are heated from outside the system by means of a high frequency induction coil.

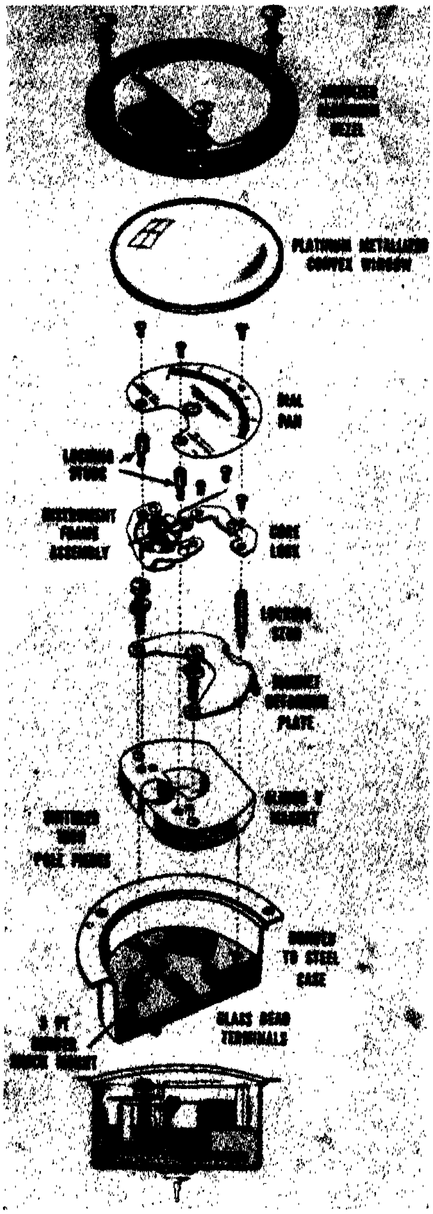
The time for a single analysis, exclusive of the preparation of the sample, is about an hour and a half. Accuracy depends a good deal on the individual system and the operator, but with care, determinations may be made with a high degree of reproducibility. The quantities detectable may be as low as 10^{-5} percent, as is the case with hydrogen in many metals.

The vacuum combustion system used to determine small amounts of carbon is similar in nature but considerably simpler. Here the sample is heated in a ceramic crucible in the presence of oxygen under about 16 cm pressure. The carbon in the sample burns in the oxygen and is converted to carbon dioxide. The mixture of carbon dioxide and the excess oxygen then pass through a freezing chamber where the carbon dioxide is frozen out. The gaseous oxygen may then be pumped from the system. After the oxygen has been removed, the carbon dioxide is allowed to warm up and its pressure measured. By applying the same principles as outlined previously, the weight of carbon dioxide may be readily determined and hence the percentage. Analyses by this method give good results, and checks are consistent to 0.001 percent C.—National Research Corporation, *70 Memorial Drive, Cambridge, Massachusetts.*

"Ruggedized" Electrical Instruments

Improved performance has been attained with a completely new, internally shock-mounted, D'Arsonval type of panel instrument. The low mass movement is carefully designed to provide improved electrical accuracy, as well as resistance to severe abuse. The rubber shock mounts, movement, frame structure, fasteners, hair springs, bearings, pointer, and panel mount have all been designed for maximum resistance to shock and vibration and electrical overloads. Hermetic sealing has also been provided for weather protection in any climate.

Ruggedization has not been at the expense of any of the electrical and other performance requirements for electrical indicating instruments. Thus the instrument user and equipment designer are granted a new freedom of application, since the use of electrical instruments is permitted in fields previously limited by the essential fragility of the conventional electrical instrument.—Marion Electrical Instrument Company, *Manchester, New Hampshire.*



TV Amplifier

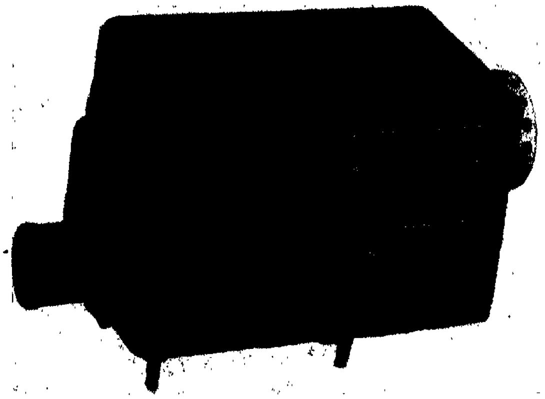
The Model 212TV amplifier, specifically designed for television use, is a single untuned amplifier having a band width of 40 to 240 Mc and a gain of 20 db into a 72-ohm unbalanced load, and 25 db

into a 300-ohm balanced line. Capable of replacing up to 12 single channel TV or f-m amplifiers, it has a transmission characteristic of ±2 db over the band width and an impedance of 200 ohms. In addition to an integral power supply, transformers can be supplied to match 52-, 72-, and 93-ohm unbalanced, and 300-ohm balanced lines.

Owing to the traveling wave circuit used, a tube failure does not mean amplifier failure, but only a loss of 0.7 db in gain. Compact and simple in construction and reliable in operation, the Model 212TV amplifier can safely be left unattended over long periods of time in television distribution systems, in hotels, apartment houses, restaurants, sales rooms, and television sets in fringe areas. —Spencer-Kennedy Laboratories, Inc., Department SI, *186 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Synchronous Camera

New 16-mm synchronous cameras (Model 111) are used for photographing events taking place at two or more remote stations with exact shutter synchronization. Model 111 is supplied with shutter speeds of 5, 10, and 20 or 4, 8, 16, and 32 frames per second. The cameras may be used with standard AN-A-6 magazines or with Syno-Pack magazines which are specially designed to eliminate film stoppages.

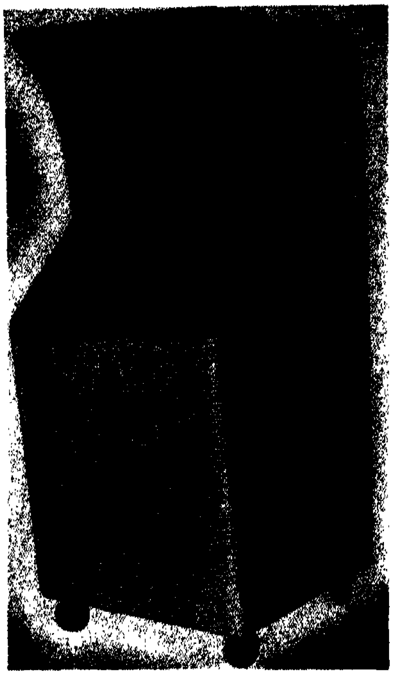


Provision is made for single exposure operation, if desired. Timing and coding lights mark film to facilitate the location of any given sequence or any marked frame without counting. External synchronization pulse circuit is provided, permitting shutter synchronization accurate to 1 msec. Any number of synchronized cameras may be used in a parallel gang.

Some of the more obvious applications of the camera include flight testing, guided missile flight records, fire control system evaluation, and the study of industrial process controls and instrumentation. If a timer is used for taking one frame per minute, 33 hr. may be recorded on one magazine load of film. Price is $950.00, with six weeks' delivery.—Flight Research Engineering Corporation, *P. O. Box 1-F, Richmond, Virginia.*

Electronic Blackboard

For a long time the efficiency of electronic training programs has been hampered by the lack of sufficiently large display of oscilloscope wave forms. The new T-602 projection oscilloscope provides an excellent solution to this problem. Called the "electronic blackboard," it delivers pictures either 18×24 in. on a built-in screen, or 8×10 ft. with an external screen for larger audiences. The great light-gathering power of its Bausch and Lomb $F/1.9$ refractive optical system provides the largest, brightest cathode-ray tube display now commercially available.



To facilitate the instructor's use, the instrument is housed in an attractive integral assembly. It meets all the performance requirements for high grade general purpose oscilloscope work. Its advanced circuit design and moderate price make it particularly attractive in any application where large screen display of electronic circuit phenomena is needed.

Particular new features such as functional centering controls, improved calibration circuit, driven and recurrent sweeps, line frequency deflection and phasing, as well as novel brightening and Z axis intensity circuits greatly increase the basic usefulness of the T-602. Although essentially a high gain, medium band width unit, it is also available on special order in a wide band version for more involved applications.—Television Equipment Corporation, *238 William Street, New York 7, New York.*

Manufacturers' Literature

Aluminum Products—Booklet contains descriptive information and illustrations of the various forms in which Revere aluminum is fabricated. Also included is a chart with comprehensive tables giving the properties and characteristics of most of the wrought aluminum alloys.—Revere Copper and Brass, Inc., *230 Park Avenue, New York 17, New York.*

Leak Detector—16-page catalog describes the Model 24-101A leak detector for the location and measurement of leaks in evacuated or pressure systems. Examples of both probe and envelope techniques are discussed, and accompanying schematic diagrams show the testing equipment necessary.—Consolidated Engineering Corporation, *620 North Lake Avenue, Pasadena 4, California.*

Leak Detector—Bulletin LD-6 describes typical applications of the Model MS-2 mass spectrometer leak detector. Principle of operation, features, and pertinent data pertaining to vacuum testing and pressure testing with explanatory illustrations are included.—Vacuum-Electronic Engineering Company, *316 37th Street, Brooklyn 32, New York.*

Sound Level Meter—Catalog leaflet describes the Type 410-A sound level meter, a lightweight, pocket-size instrument meeting ASA requirements. Included are specifications and list of accessories, with prices.—Hermon Hosmer Scott, Inc., *385 Putnam Avenue, Cambridge 39, Massachusetts.*

Cathode Press—Vol. 7, No. 1, Winter, 1949–50, 33 pp., contains articles on the first ceramic x-ray tube, a coaxial power triode for higher power at the higher frequencies, new techniques for superficial therapy with beryllium window x-ray tubes, the twenty-four million volt betatron, methods of evaluating x-ray screen quality and performance, and other articles of interest.—MACHLETT LABORATORIES, INC., *Springdale, Connecticut.*

Panalarms—Bulletin 400, 4 pp., describes Series 400 Panalarms, signals for hazardous and corrosive atmospheres. White and red lights are dim in normal operation; bright when off-normal. Sound signals may also be included.—PANALARM PRODUCTS, INC., *7216 North Clark Street, Chicago 26, Illinois.*

Selenium Rectifiers—4-page pamphlet on design, application, and servicing of selenium rectifiers, information on trouble-shooting methods for the half-wave circuit, and rectifier repair and replacement technique.—RADIO RECEPTOR COMPANY, INC., SELETRON DIVISION, *251 West 19th Street, New York 11, New York.*

Experimenter—Vol. XXIV, No. 8, January, 1950, features a simple, complete coaxial measuring equipment for the u.h.f. range, and includes description of equipment for standing-wave measurements, for power measurements, for voltage measurements; fixed-line and adjustable-line elements; terminations; attenuators; filters; external coupling elements; and foundation elements.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Optical Bench Assembly—Bulletin 174–50, 4 pp., describes and illustrates the Model L360N precision optical bench assembly, consisting of a collimating system with light source, targets and filters, a nodal slide, and a viewing microscope, all mounted on a lathe bed type bench.—THE GAERTNER SCIENTIFIC CORPORATION, *1201 Wrightwood Avenue, Chicago 14, Illinois.*

Coordinate Comparator—Bulletin 181–49 describes and illustrates the M1225–37 coordinate comparator, for measuring star photographs, spectrograms, x-ray plates, charged particle tracks, and any similar records made on $3\frac{1}{4}\times4\frac{1}{4}$-in. photographic plates.—THE GAERTNER SCIENTIFIC CORPORATION, *1201 Wrightwood Avenue, Chicago 14, Illinois.*

Tracerlab—Catalog B, 100 pp., illustrated, presents the complete line of Tracerlab instruments. Included are applications, specifications, and prices on scalers and scaler accessories, preamplifier and tube accessories, counting rate and survey meters, Geiger-Müller tubes, radioactive reference sources, general equipment, lead shields, dosage meters, industrial instruments, etc.—TRACERLAB, INC., *130 High Street, Boston 10, Massachusetts.*

Polarographic Literature—Leeds and Northrup Bibliography of Polarographic Literature [Bibliography E-90(1) 1950] is an up-to-date listing of all available literature on the polarographic method of chemical analysis. Listed are a total of 2208 references, by 1310 authors, on 903 principal subjects. Articles are listed in chronological order, from the earliest associated work in 1903 up to the middle of 1949. All references are cross-indexed alphabetically by authors and by subjects.—LEEDS AND NORTHRUP COMPANY, *4934 Stenton Avenue, Philadelphia 44, Pennsylvania.*

Pressure Transducers—4-page temporary catalog, December, 1949, describes various types of transducers, including information on ranges and resistances, and prices.—STATHAM LABORATORIES, *9328 Santa Monica Boulevard, Beverly Hills, California.*

Spectrographic Outfits—Catalog H-1, on Hilger equipment, discusses the process of spectrochemical analysis and some of the advantages of prism instruments. Complete technical data are given for each instrument. Applications for each type instrument are indicated.—JARRELL-ASH COMPANY, *165 Newbury Street, Boston 16, Massachusetts.*

Instrumentation—Vol. 4, No. 3, 32 pp., fully illustrated, contains articles concerning measurement and control of industrial processes.—MINNEAPOLIS-HONEYWELL REGULATOR COMPANY, BROWN INSTRUMENT DIVISION, *Wayne and Windrim Avenues, Philadelphia 44, Pennsylvania.*

Oscillograph—Bulletin B-641-A describes the construction and performance of a Duddell-type oscillograph employing an oil-damped bifilar suspension required to operate at frequencies up to 1000 c.p.s.—MUIRHEAD AND COMPANY, LTD., *Beckenham, Kent, England.*

Electrosensitive Recording Paper

Alfax is an electrosensitive paper for permanent, instantaneous recording at high speeds. Papers are available in three types. Type A is the most sensitive high speed paper. It records a sepia brown trace on a white background and is being used at speeds up to 18,000 in. per min. Types OO and NO record a black trace on a white background and are used at writing speeds up to 700 in. per min. Paper impedance varies from approximately 500 ohms at low writing speeds to 200 ohms at the highest writing speeds. The power required to mark the paper depends on the writing speed and the density required in the mark. At low speeds a current of a few milliamperes will produce a legible trace. At 28 sq. in. of area per min. 2–3 watts at 20–30 volts will produce dense solid areas, while at a speed of 180 sq. in. per min. 25–30 watts may be required for solid dense recording. The paper may be used with conventional recorders using a positive stylus or roller on the paper and a negative metal platen or edge under it. Inertialess recording is obtained by using a helix type of recorder. A cylindrical drum with a raised spiral turn forms the negative electrode. The paper passes between this helix and a narrow-edged strip of metal used as a positive electrode. Current passing from this strip through the paper to the helix marks the paper with a small spot. The helical drum can be driven synchronously or through a servo mechanism where scanned information is to be recorded. The system is thus available for copying or for facsimile recording as well as for the recording of any phenomenon which can be translated into an electrical impulse. Experimental rolls are available from the manufacturer for one dollar, or paper of special sizes and characteristics can be made.—ALFAX PAPER AND ENGINEERING COMPANY, *40 Riverside Avenue, Brockton, Massachusetts.*

Molybdenum Lubricant

Molybdenum has been used in recent years either in place of or supplementing regular oils and greases in the lubrication of high speed, high temperature, high pressure bearings. It is an extremely "greasy" metal, is practically indestructible at high temperatures, and in certain forms has the property of "plating out" on a friction surface to form a friction-supporting film which cannot be "squeezed out" by pressure. Thus the bearing is protected against scoring or seizing even after all the oil has been burned out.

Liqui-Moly is a molybdenum-based lubricant designed for use in any conventional lubrication system. It can be used alone or added to crank-case or other oils which carry it to the friction surface where it "plates out" forming a permanent low friction coating. Tests reported by the manufacturer show that friction surfaces running at high speed under heavy pressure will heat from 300 to 500 percent faster with ordinary lubricating oil than when running dry with Liqui-Moly, and moreover that the temperature-rise with oil is continuous until failure and seizure, whereas with Liqui-Moly it reaches a stable point and then recedes. This material has high chemical stability and is unchanged in its properties by extreme temperatures, operating effectively from sub-zero to red-heat. Typical applications, in addition to conventional uses, are the lubrication of deep-drawing dies; elimination of "run-in" time on precision bearings and slides; as a pipe-fitting compound, to insure quick disassembly regardless of age, heat, or corrosion; reduction of friction and seizure in press-fitting; to prevent sticking in tightly wound flat coil springs; as a lubricant for guns; and in the permanent factory-lubrication of products. It is available in experimental quantities direct from the manufacturer at $2 per pound.—THE LOCKREY COMPANY, LUBRICANTS DIVISION, *College Point 1, New York.*

Silver Storage Battery

Silvercel is an alkaline storage battery using silver and zinc as the active materials. The electrolyte is absorbed into active material so that there is no tendency to leak or spill. There are no plates or separators and resistance to mechanical shock is limited only by the strength of the case which can be selected to meet various requirements. The ampere-hour efficiency is nearly 100 percent and the energy efficiency nearly 85 percent. Heavy discharge does not injure the battery and no fumes are released on either charge or discharge. The battery is stated to compare favorably with all present-day storage batteries on the basis of life, size, weight, and number of recharging cycles. Five sizes are available ranging from a ½-amp.-hr., 1½-v battery in a case 1×½×1½ in. to a 40-amp.-hr., 1½-v battery in a case 4¼×1½×4 in. Larger capacity units are in the development stage.—YARDNEY ELECTRIC CORPORATION, *105 Chambers Street, New York 7, New York.*

Flexible Stainless Tubing

Carpenter No. 20 stainless steel is used in manufacturing a new line of flexible tubing in sizes from 1 to 2½ in. inside diameter, and in various gauges. It is intended for use where flexibility and corrosion resistance are major considerations. Fittings can be welded to it or the ends can be supplied in rigid standard tube sizes for use with flanges.—CARPENTER STEEL COMPANY, *131 Springfield Road, Union, New Jersey.*

Hydrophobic Starch

Dry-Flow is a hydrophobic (water-repellant) derivative of corn starch. It is a finely divided powder with a silky texture, and is free-flowing to such an extent that it behaves like a liquid in many ways. The presence of hydrophobic groups makes it extremely difficult to wet with water under ordinary conditions. It can, however, be wet with water if a wetting agent is used or if the dry material is first wetted with alcohol or other water-miscible solvents. Potential applications listed by the manufacturer include rubber dusting, flatting agent for lacquers, detackifying agent for rubber articles formed by the dip method, antihalation powder for the back of photographic films, prevention of sticking of viscous materials to container walls, lubricating agent, and cosmetic powders.—NATIONAL STARCH PRODUCTS, INCORPORATED, *New York, New York.*

Nylon Thread-Lock Plug

A service is available through which Nylon locking plugs may be fitted to threaded screw-machine parts, or the completed part will be made to specification. The threaded part is drilled through the side in which a small Nylon plug is inserted and secured by upsetting the outer end of the drilled hole. The inner end of the plug extends to the crest of the internal threads. When turned onto a stud or screw the Nylon compresses and causes the nut and stud threads to grip each other. It is not affected by oil or grease, does not age, and can be used repeatedly. A minimum length of ¾ in. is required to allow room for the plug, and the wall thickness of the part should be at least 0.1 in. Steel or aluminum parts are preferable but brass or zinc can be used.—NYLOK CORPORATION, *475 Fifth Avenue, New York 17, New York.*

Silicone Sealing Compound

G-E 81083, a silicone dielectric compound, is a smooth homogeneous mixture designed to provide a chemically stable, waterproof, dielectric seal for aircraft ignition systems and electronic equipment. As a dielectric, it is used to waterproof exposed surfaces on plastics and ceramic insulators. It will wet and adhere to both metallic and non-metallic surfaces, and is non-corrosive and relatively inert chemically. It is substantially unchanged by temperatures from −70 to +450°F, and has good resistance to steam, hot water, and hot air. In appearance and consistency it resembles medium heavy translucent grease. As a dielectric it prevents arcing due to moisture condensation on spark plugs, coils, etc. It is available in 8-oz. tubes, and in 1-, 5-, and 30-gal. containers.—GENERAL ELECTRIC COMPANY, *Pittsfield, Massachusetts.*

Sapphire Gauge Points

A line of contact points with sapphire or carbide tips is available to fit any specified dial indicator. Shapes may also be made to specification. They are characterized by resistance to wear and by a dense surface that will not charge or pick up foreign matter.—PRECISION SUPPLY AND MACHINE COMPANY, *1 East 42nd Street, New York 17, New York.*

Direct Reading Phasemeter

L. H. O'Neill and J. L. West
Department of Electrical Engineering, Columbia University, New York, New York

(Received August 29, 1949)

This paper describes a simple and accurate method for the measurement of the phase difference between two sinusoidal voltages and an instrument for making the measurement. It is shown that measurement accuracy sufficient for most ordinary purposes can be obtained through the use of very simple circuitry, and that measurement errors can be made arbitrarily small by resorting to more complex circuitry. The instrument is compact and convenient in use.

THE method described in this paper for measuring the difference in phase between two sinusoidal voltages takes advantage of the fact that the amplitude of the sum or difference of two sinusoids of equal amplitude provides a convenient and accurate measure of the magnitude of the phase difference.

Consider two sinusoids having the common amplitude E_0. The amplitudes Σ and Δ of their sum and difference, respectively, are given by:

$$\Sigma = 2E_0 \cos\theta/2 \tag{1}$$

and

$$\Delta = 2E_0 \sin\theta/2, \tag{2}$$

in which θ is the magnitude of the difference in phase between the voltages. It is evident that if the prescribed amplitude E_0 is chosen as that causing a half-scale deflection of a voltmeter used to measure Σ and Δ, an "on scale" reading corresponds to every value of θ. It is therefore possible to establish a scale or scales on the voltmeter expressing either or both of the relationships (1) and (2), and thus obtain a directly read measure of the angle θ. However, because the slopes of the sine and cosine functions are small when their arguments are in the vicinity of 90 and 0 deg., respectively, Eq. (1) yields a scale which is quite compressed when θ is near 0 deg. while Eq. (2) yields a compressed scale for values of θ near 180 deg.

Excessive scale compression can be avoided by restricting the use of the difference method to cases in which θ is between 0 and 90 deg., and the sum method to cases in which θ is between 90 and 180 deg. Since, when this is done, Σ and Δ never exceed $\sqrt{2}E_0$, it is possible, and evidently desirable, to choose E_0 as the voltage causing a meter deflection of $\sqrt{2}/2$ of full scale. Thus, "on scale" readings correspond to all values of θ, and full use of the scale is made.

ELEMENTS OF THE SYSTEM

Evidently, in order to measure phase by the previously described method, it is necessary to provide the following devices: (a) A means of adjusting the amplitudes of the two voltages to the prescribed value E_0. (b) A method of forming the sum and difference of the two sinusoids. (c) A voltmeter provided with the previously described scales and a mark at $\sqrt{2}/2$ of full scale. These devices will be described in the above order. Since it is frequently desired to measure phase difference as a function of frequency, these devices must perform their respective operations accurately over as wide a frequency range as is desired.

(a) Adjustment of Amplitudes to the Prescribed Value

Since E_0 is expressed in terms of a corresponding meter deflection, one of the voltages can be made to yield the required deflection by adjusting the sensitivity

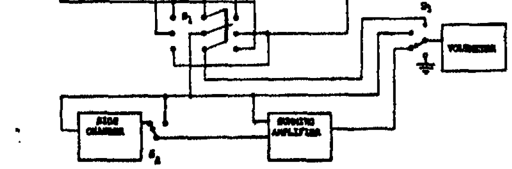

Fig. 1.

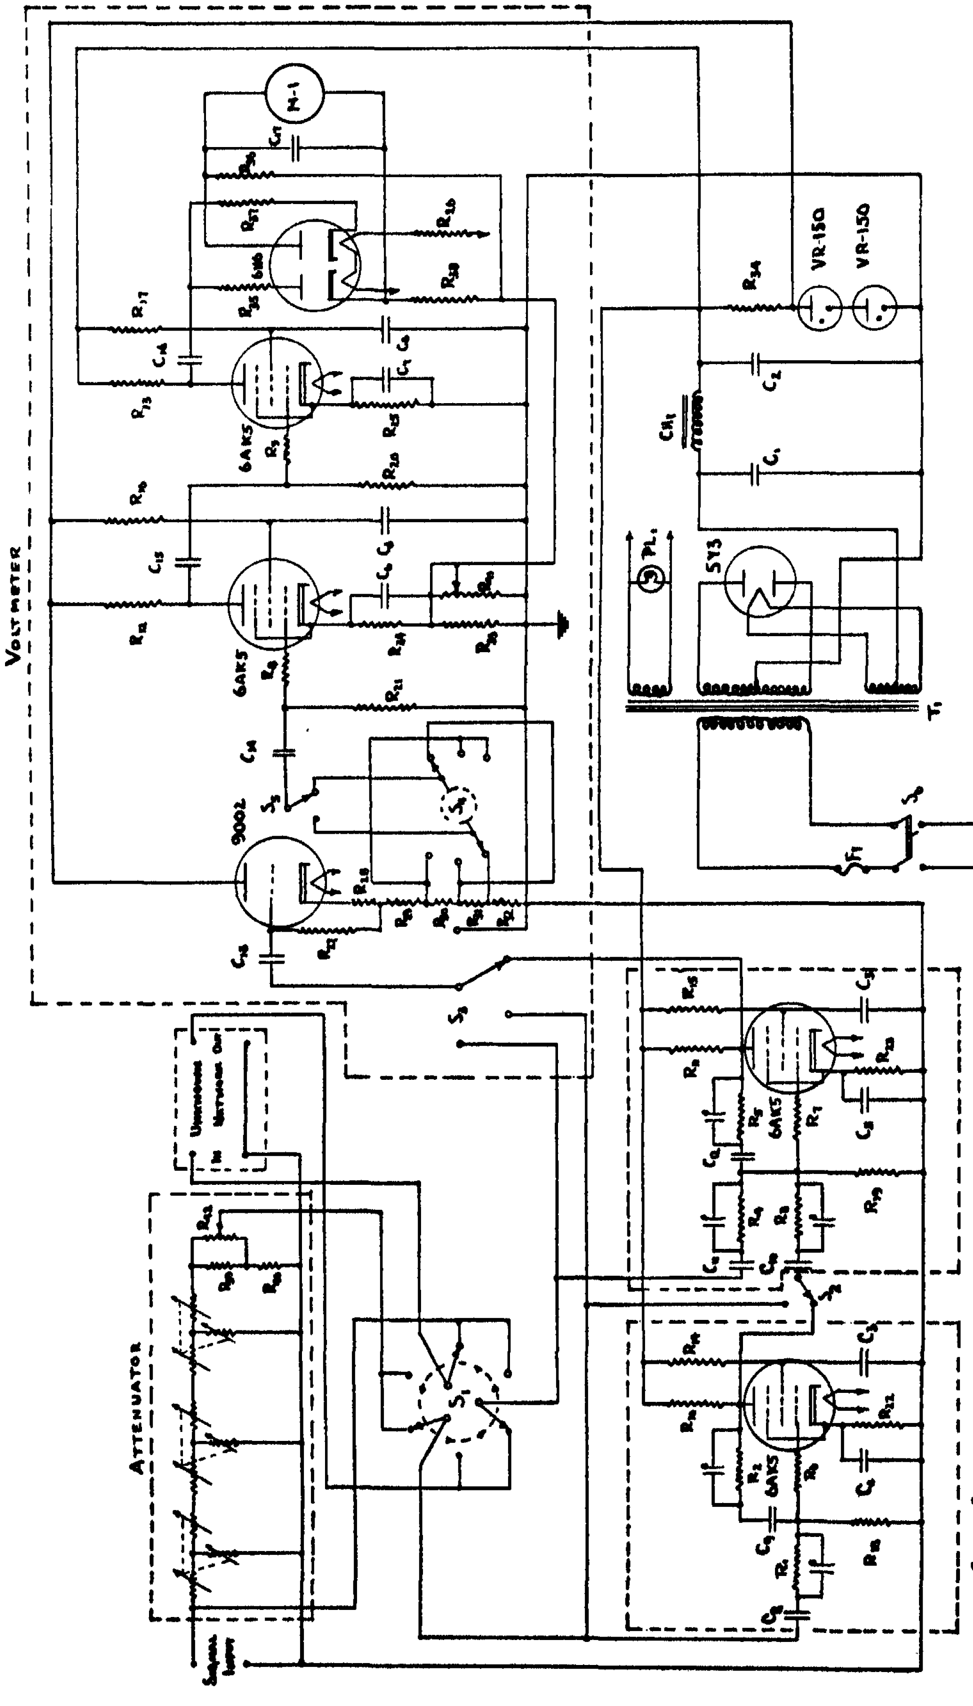

FIG. 2. Gain and Phasemeter.

of the voltmeter used to measure its amplitude. If this operation is performed with respect to the smaller of the two voltages, the larger voltage may be attenuated in a conventional attenuator until it has the required amplitude. The attenuator used for this purpose must be designed to avoid the imposition of significant phase shift upon the sinusoid transmitted through it. Appropriate attenuators for operation over frequency ranges as large as several megacycles are manufactured. The attenuator design problem is not considered here.

(b) Formation of Sum and Difference

Since the sum or difference amplitude is the measure of the phase angle, the formation of the sum or difference must be accomplished accurately in order to avoid appreciable errors in the measurement of θ. This can be accomplished through the use of a "summing amplifier" similar in principle to those used in electronic analog computers.[1] When simple, single stage amplifiers are used for this purpose, it is possible to limit phase measurement errors due to summing and subtraction errors to as little as 0.25 deg. over the frequency range from 7 c.p.s. to 100 k c.p.s. The use of multistage amplifiers makes possible the obtaining of improved accuracy. In general, the only limit on accuracy in this respect is imposed by the degree of complexity in the amplifiers which may be tolerated.

(c) Voltmeter

A voltmeter which has a deflection sensitivity essentially independent of the amplitude of the voltage applied to it has been used in the instrument which will be described. This characteristic is desirable because it avoids the compression of the scale at low amplitudes which sometimes occurs in diode probe-type meters. However, any voltmeter which has a reasonably linear scale and does not become excessively insensitive over the frequency range in which it is desired to make measurements may be used.

THE INSTRUMENT

The block and wiring diagrams of an instrument based upon this method of measuring phase difference are shown in Figs. 1 and 2, respectively. In addition to the elements previously described, the instrument includes a power supply for the purpose of providing the operating voltages for the system, and required switching systems.

The instrument shown in Figs. 1 and 2 is designed to facilitate the measurement of the phase shift through any four-terminal linear system. The instrument may be used with systems having gains greater than or less than unity. The switch *S*-1 interconnects the elements properly for these two cases.

The switch *S*-2 inserts or removes the sign changing amplifier from the system. Thus, either the sum or difference method may be used. The switch *S*-3 is used to connect the voltmeter input terminals to the input and output voltages of the system tested and to the output voltage of the summing amplifier.

The switch *S*-4 is used to adjust the voltmeter sensitivity in decade steps.

The attenuator is for the purpose of adjusting the amplitude of the larger voltage to E_0.

The instrument thus contains all the elements necessary for making the phase measurement. It is compact in form (the entire system being mounted in a 10×12-in. chassis) and has been found to be convenient in use. The over-all obtained accuracy is plus or minus one degree over the frequency range from 7 c.p.s. to 100 k c.p.s. Most of the error is imposed by the attenuator. Improved accuracy can be obtained through the use of a wider band attenuator and multistage summing and sign changing amplifiers.

As shown, the instrument measures only the magnitude of the phase difference. A simple resistance-capacitance circuit may be cascaded with the system tested to obtain an additional phase shift of known sign. The sign of the system phase shift may be determined by observing whether θ increases or decreases when such a network is inserted.

An Electron Tube Potentiometer Method for Use in Circuits Involving Very High Resistance

H. Bloom and G. W. Butler
Chemistry Department, Auckland University College, Auckland, New Zealand

(Received July 15, 1949)

The construction and use of an electron tube potentiometer designed for circuits involving high resistances to the order of 100 megohms are described.

IN the investigation of electrokinetic potentials of systems involving organic liquids, by the streaming potential method (see Briggs,[1] Bull,[2] Bull and Gortner[3]) it is necessary to measure potentials of the order of 10 to 2000 millivolts, the resistance of the streaming cell being often as high as 100 megohms. As the electrodes are easily polarized thus leading to spurious results, no d.c. must flow during the measurements. The circuit described below and shown diagrammatically in Fig. 1 was devised to replace the commonly used quadrant electrometer, and *p*H meter as null-point detecting instruments in the usual Poggendorf compensation method for measuring potential.

The principle of the method is similar to that of Kreielsheimer[4] and Macnamara[5] who used a pair of tubes (with identical grid voltage—plate current characteristics) operated in push-pull as null-point detecting instruments for a Wheatstone's bridge network used for measuring impedances. In the present circuit, the arrangement shown in the figure is utilized for the measurement of potential in a Poggendorf compensation circuit.

The tubes T_1 and T_2 have a galvanometer G connected across their load resistors $R_1-R_2-R_3$ to detect differences in the plate currents. The negative side of the potentials to be balanced (one from the streaming cell and the counter-potential from the Leeds and Northrup measuring potentiometer) are connected to the respective grids, the positive ends being earthed. If the potentials are not equal, the two grids will be at different potentials to ground with the result that the plate current is different for each tube provided that the tubes used have equal characteristics. As the potential drop across each load resistor will then be different, the galvanometer will register a deflection. When the voltage applied from the measuring potentiometer is adjusted to be equal to that of the streaming cell, both grids will be at the same potential and the galvanometer will show no deflection. The reading of the measuring potentiometer will then give the value of the potential drop across the streaming cell under the conditions of balance. The operation of the potentiometer is not affected by the introduction of large resistances into one or the other of the grid circuits, even with resistances as high as 100 megohms. On using the apparatus for the measurement of electrokinetic potentials in systems involving non-polar liquids, constant and reproducible results were obtained showing that there was no polarization of the electrodes and hence no passage of grid current during the measurements.

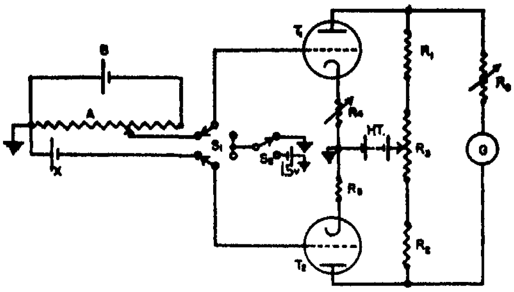

Fig. 1. S_1 = D.P.D.T. switch; S_2 = S.P.D.T. switch; $R_1=R_2$ = 10,000 ohms; R_3 = 2000-ohm radio potentiometer; R_4 = 1200 ohms (variable); R_5 = 1000 ohms; R_6 = 250,000 ohms (variable); A = Leeds and Northrup measuring potentiometer; B = accumulator (2-volt); X = streaming cell; T_1, T_2 = RCA tubes, type 955; G = medium sensitivity galvanometer.

To use this circuit as a potentiometer in measurements involving very high resistances, extremely good insulation is necessary. Hence all-glass tubes, RCA Type 955 (Acorn) triodes having the necessary high transconductance and electrical insulation were used, the circuit being built up on a paraffin-wax block. Tubes with identical grid voltage-plate current characteristics are desirable, but in practice those with closely similar characteristics can be used by adjusting cathode and load resistors (R_4 and R_3) alternatively until their characteristics coincide over the range in which the measurements are to be made (in this case 0–1500 millivolts). To enable such adjustment and streaming potential measurements to be made alternatively, use is made of the switches S_1 and S_2. The grids are disconnected from the potentiometer circuit and connected together by means of S_1. R_3 and R_4 are adjusted so that there is no deflection of the galvanometer when the two grids are connected by means of S_2 directly to earth or to the negative pole of a 1.5 volt battery, the positive pole of which is earthed. Provided that the grid voltage-plate current characteristics of the two tubes are sufficiently similar (or preferably identical), these tubes will now be operating on the same grid voltage-plate current characteristic over the desired range. This was checked experimentally by the following tests:

---

[1] D. R. Briggs, J. Phys. Chem. 32, 641 (1928).
[2] H. R. Bull, J. Am. Chem. Soc. 57, 259 (1935).
[3] H. R. Bull and R. A. Gortner, J. Phys. Chem. 35, 309 (1931).
[4] K. S. Kreielsheimer, Ann. d. Physik 5, 293 (1933).
[5] Macnamara, Rev. Sci. Inst. 2, 343 (1931).

(1) A number of stable potentials from 0 to 1.5 volts (from a Leeds and Northrup potentiometer with low internal resistance) were measured using the apparatus described.

(2) The results were compared with those obtained by using a contentional Poggendorf compensation potentiometer with a galvanometer as null-point detector. These sets of results then agree to within 0.1 millivolt over the entire range. The initial adjustment of the two tubes to be on the same plate current-grid voltage characteristic was carried out by trial and error, the process being fairly lengthy, but once a satisfactory adjustment had been made for a given pair of tubes, it was necessary only to adjust R_4 before all subsequent measurements. This could be carried out rapidly.

S_1 is then moved so as to break the connection between the grids and connect them into the potentiometer circuit. A regulated voltage power supply (250-volt) was used for the high tension. The filament supply was 5.5 volts d.c. supplied from lead accumulators (with voltage divider). This suppply was found to be perfectly satisfactory for stable operation.

The higher the transconductance of the tubes the greater will be the sensitivity of the detector. With 955 tubes (transconductance approx. 2000 micromhos), potential measurements could be made to 0.1 millivolt, but as this accuracy was not required a series variable resistance R_6 was included in the galvanometer circuit. It was adjusted to decrease sensitivity so that the potential of the streaming cell could be measured to within 0.5 millivolt.

The main advantages of this electron tube electrometer over others (e.g. quadrant electrometer, tube *p*H meter) commonly used are:.

1. Ease and rapidity of operation.
2. Much higher stability. No measurable drift of the galvanometer could be detected during 1 or 2 hours and only a slight drift during a day.
3. Higher sensitivity.

The authors wish to express their appreciation for the advice and encouragement received from Dr. K. Kreielsheimer of the Physics Department, Auckland University College.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

A Method for Increasing the Safe Power Input of X-Ray Tubes

ARTHUR I. BERMAN*
Stanford University, California

(Received September 26, 1949)

A method for cooling x-ray tubes was devised, based on the principle of relative motion between the target and focal spot. The electron beam is deflected by a rotating magnetic field so that the focal spot moves in a circle upon the target face. Simultaneously, the tube itself is gyrated (without rotation about its axis) so that any point on the target describes an equal circle. The two rotations are equal in frequency but phased 180 degrees from each other. Thus the focal spot remains stationary in laboratory space. The advantages are (1) it is adaptable to most x-ray tubes with target face perpendicular to the tube axis, and target diameter twice that of the longest focal spot dimension, without any modification of tube design; (2) it combines the benefits of a rotating target, water-cooled target, and line focus without the need for rotating joints or vacuum connections. Tubes, operating continuously for hours at a time at a gyrating frequency of 6 r.p.s. have been cooled successfully by this method without observable shifting of the focal spot in laboratory space.

I. INTRODUCTION

A. Limitation on Power Input

THE fact that only about 1 percent of the kinetic energy of the electron beam evolves as x-radiation and the remaining energy is present as heat makes it imperative that an adequate cooling mechanism be incorporated in the operation of the tube. The efficiency of this cooling device will set an upper limit to the anode voltage and current permitted.

If the temperature of the target material is allowed to exceed its melting point, not only will the target be permanently damaged but even more serious consequences may arise. The metallic vapor atoms may become ionized through collision with the electron beam and change the tube resistance inducing erratic tube behavior. In addition, the metallic vapor may deposit on the glass walls, absorb x-rays, and provide a conducting path between the cathode and target. High temperatures may drive gas from the tube wall, or even crack the glass if heated non-uniformly.

B. Cooling by Radiation and Conduction

The simplest method for removing heat from the focal spot is by direct radiation into the air from the

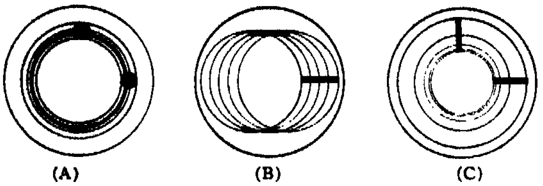

FIG. 1. (A) Path of circular focal spot on surface of gyrating or rotating target. (B) Path of rectangular focal spot on surface of gyrating target. (C) Path of rectangular focal spot on surface of rotating target. (Hottest regions shown by closest spacing of lines.)

spot and the surrounding target. Also, the heat may be conducted down the body of the anode, stored in a mass of large heat capacity, and radiated at the end of the tube.

If the tube is designed for continuous operation, the heat may be conducted from the target directly to a moving current of water. Oil is often used because of its insulating properties despite its much lower specific heat and thermal conductivity.

C. Cooling by Target Motion

By permitting an element of target material to be periodically rather than continuously irradiated, the focal spot energy is, in principle, distributed over a much larger area. This provides much more effective radiation and conduction cooling. The method was suggested as early as 1897 by Wood, and in 1914 Thomson developed a tube in which the target rotated by means of an electric motor. Coolidge and Bouwers both have built tubes of this type,[1] and they now have come into wide commercial use after difficulties in lubricating the internal bearings were surmounted. In 1931 Müller succeeded in combining water cooling with target rotation using a drive shaft passing through a special stuffing box and evacuating continuously with pumps.[2] This feat has been accomplished also by Fournier, Gondet, and Mathieu at speeds of 3 or 4 revolutions per second using a "well-greased ground conical joint."[3] Coolidge eliminated the need for internal bearings by rotating the entire tube and bending the electron beam with a constant magnetic field.[1]

A line (Benson) focus is often used to increase the effective x-ray output for a given apparent focal spot area seen by the observer. The principle is that when viewed from the side (at a grazing angle 15° or more), the projected spot will radiate about as much energy as when viewed normal to the surface. This is in direct opposition to the Lambert law of thermal radiation by which the energy would decrease by the cosine of the angle between the direction of propagation and the normal to the surface.

The rotating target tube will permit the use of this fact if the long dimension of the focal spot is set along a target radius (see Fig. 1(C)). A focal spot set in a sector of the target circle would be most efficient in minimizing local heating. The Coolidge rotating tube may use the line focus provided the target is designed in the form of a cone so that the electron beam, falling on one side, will produce an elliptical spot projected as a circle when viewed at the proper angle during rotation. This tube would require an x-ray window which extends around its girth. The filament current would be supplied by means of slip rings.

DuMond and Youtz achieved the same result as rotation by gyrating the target in a circular path (without rotation).[4] This tube, designed for continuous operation, was water-cooled. The motion was transmitted through a metal bellows. Circular symmetry is required in the focal spot for maximum cooling efficiency since a non-symmetric spot will produce local hot areas as the spot sweeps through its long dimension on the target face.

II. A NEW METHOD

A. Theory

In the writer's method the tube itself is gyrated without rotation so that a point on the target describes a small circle. Simultaneously, the electron beam is deflected by a rotating magnetic field so that the focal spot rotates in synchronism with, but phased 180 degrees from, the mechanical gyration. The strength of the field is adjusted until the circle which the focal spot traces on the target face equals the target circle. Thus the focal spot remains stationary in laboratory space while rotating on the face of the target.

It may be mentioned that the danger of tube breakage while undergoing the gyrating motion is very slight. Thin-walled glass tubes fifteen inches long have been gyrated at one end with an amplitude of one-half inch at six revolutions per second with no visible sign of strain. Actually it can easily be seen that the radial centripetal force encountered by the tube at this speed and amplitude is less than one times its weight.

It is not necessary that the x-ray window extend around the girth of the tube, but merely be somewhat larger than necessary for stationary operation. This necessity might be avoided by gyrating the tube in such a manner that the window remains in the line of sight.

B. Efficiency

The ratio of the safe power input while moving, W_m, to the power input permitted in normal stationary tube operation, W_s, is a function of the speed of rotation, the ratio of the duration of the heated part of the thermal cycle to the period of the entire cycle (approximately the focal spot diameter, for a circular spot, divided by the circumference of its path over the target face) which we call r, and specific target constants.

---

[1] W. D. Coolidge, Gen. Elec. Rev. 33, 612 (1930).

[2] A. Müller, Brit. J. Radiology 4, 127 (1931).

[3] Fournier, Gondet, and Mathieu, J. de phys. et rad. 8, 160 (1937).

[4] J. M. DuMond and J. P. Youtz, Rev. Sci. Inst. 8, 291 (1937).

These constants are: target thickness from face to fluid, d, specific heat of the target material, σ, conductivity, c, and the target density, ρ. Curves showing W_m/W_s for a circular spot, as a function of a variable called

$$\theta^2\left(=\frac{\pi d^2\rho\sigma}{c}\times\text{r.p.s.}\right)$$

for different values of r have been computed by DuMond, Watson, and Hicks and are reproduced in Fig. 2.[5] All the curves equal the value $1/r$ in the limit of infinite tube velocity.

It is obvious that the tube should be gyrated at high speed to increase the efficiency since, by decreasing the time increment during which each element is irradiated we tend, in effect, to distribute the focal spot energy in an annular ring.

C. Desirable Tube Characteristics

As in the DuMond and Youtz gyrating target tube, the focal spot should have circular symmetry to prevent local heating. A drive which permits the use of a line focus is discussed in Section IIIB.

It is desirable that the interelectrode spacing be at least 1 cm. The target diameter should be at least twice as large as the focal spot, and it should be cut perpendicular to the tube axis. To see this, the dependence of the magnetic field strength on the interelectrode distance for a desired deflection and anode voltage will be discussed below.

The following assumptions are made: (1) Space charge is absent, or at any point in interelectrode space the potential difference between the point and the filament is proportional to the axial distance to the filament. (2) The initial velocity of the electron beam is negligible. (3) The magnetic field at any moment is uniform throughout the interelectrode region. (4) The force on the electron beam by the magnetic field is perpendicular to the tube axis since the deflecting angle is small. (5) Relativistic effects are negligible.

Reference is made to Fig. 3. The equation of motion of an electron acted upon by a magnetic induction of strength B is (in m.k.s. units):

$$\ddot{y}=\frac{d}{dt}\left(\frac{dy}{dt}\right)=B\frac{e}{m}v_x,$$

where x is measured along the axial direction, y is the displacement of the beam in the direction $-(\hat{x}\times\bar{B})$, and e/m is the charge to mass ratio of an electron.

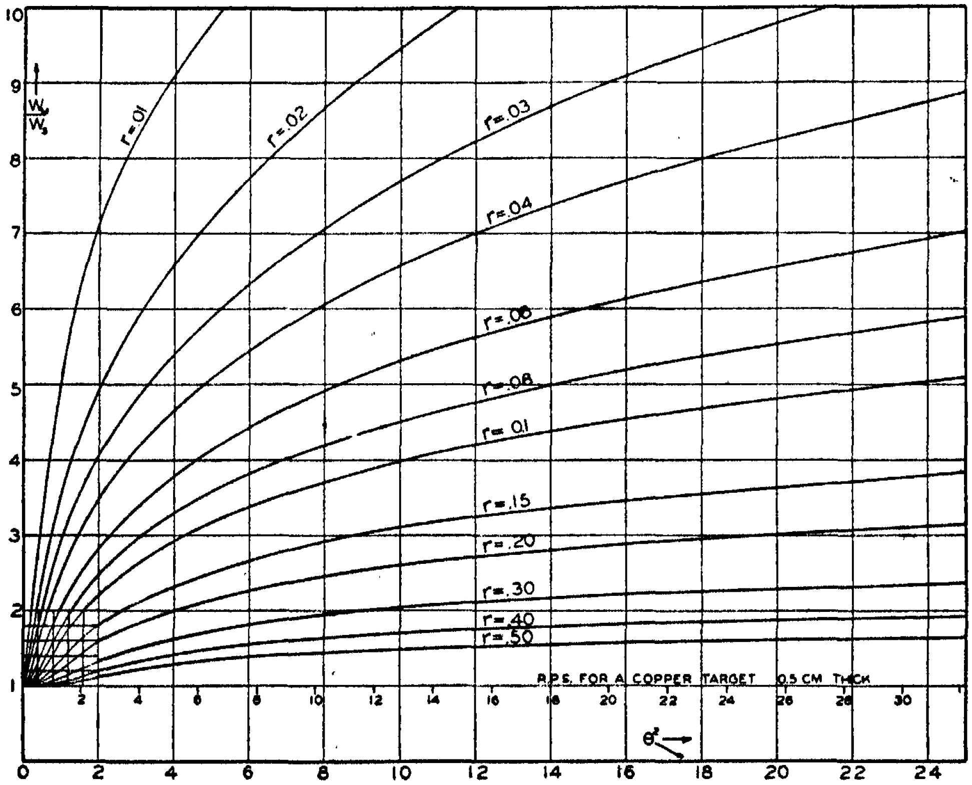

FIG. 2. Multiplication of permissible power input by virtue of tube gyration for different speeds, θ^2 = const. ×r.p.s., and for different sizes of focal spot relative to path swept out (r). (Reproduced from Rev. Sci. Inst. 6, 191 (1935).)

---

[5] DuMond, Watson, and Hicks, Rev. Sci. Inst. 6, 183 (1935).

We write:

$$\frac{d}{dt}\left\{v_x\frac{dy}{dx}\right\}=B\frac{e}{m}\frac{dx}{dt},$$

where $v_x\equiv dx/dt$ is the component of electron velocity along the x axis. The differential equation becomes

$$d\{v_x(dy/dx)\}=B(e/m)dx.$$

Since the potential difference between a point at distance x and the filament, $V=k_1x$, and since $eV=\frac{1}{2}mv_x^2$, therefore $v_x=k_2x^{\frac{1}{2}}$, where k_1 and k_2 are constants.

The solution of the differential equation is, after substituting for v_x,

$$k_2x^{\frac{1}{2}}(dy/dx)=B(e/m)x+k_3.$$

k_3, the constant of integration is found to be zero on substituting initial conditions. Solving between limits:

$$\int_0^D dy=\frac{B}{k_2}\frac{e}{m}\int_0^s x^{\frac{1}{2}}dx.$$

D, the deflection of the electron beam at the target, is therefore

$$D=\frac{2}{3}\frac{Be}{k_2m}s^{\frac{3}{2}}.$$

k_2 is found by noting:

$$v_{x=s}=\{(2e/m)V_p\}^{\frac{1}{2}}=k_2s^{\frac{1}{2}},$$

where V_p is the target to filament voltage and s is the interelectrode spacing. Therefore

$$k_2=\{(2e/sm)V_p\}^{\frac{1}{2}}.$$

Inserting this result for k_2, we obtain the magnetic induction necessary to produce the deflection D:

$$B=\frac{3}{2}\frac{D}{s^2}\left\{2\frac{m}{e}V_p\right\}^{\frac{1}{2}}$$

or

$$B=5.05(D/s^2)(V_p)^{\frac{1}{2}}\times10^{-4}\text{ weber/meter,}^2$$

where V_p is in volts and D and s are in centimeters.

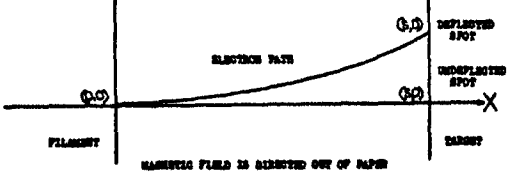

FIG. 3. Path of electron beam from filament to target under a uniform magnetic field directed out of paper.

As an example, if the tube potential is 40 kilovolts and interelectrode spacing is 3 centimeters, the magnetic induction required to deflect the beam 0.5 centimeter is 56×10^{-4} weber/meter^2 (or 56 gauss).

The relativistic derivation begins with the equation of motion

$$F_y=(d/dt)(mv_y)=Bev_x,$$

where

$$m=m_0\{1-[v_x/c]^2\}^{-\frac{1}{2}}$$

(m_0 is electron's rest mass and c is velocity of light). The result obtained differs from the non-relativistic derivation above by less than 3 percent for plate voltages as high as 100 kilovolts so the simpler expression may be accurate enough for most purposes.

Since the beam deflection is a function of the interelectrode spacing, this distance should be constant for all deflections, requiring the target face to be perpendicular to the tube axis.

To minimize the magnetic field strength required for a given deflection and tube voltage, the interelectrode spacing should be as large as possible, as indicated above.

D. Design of the Apparatus

A photograph of the experimental apparatus is shown in Fig. 4. The rotating field is supplied by a toroid surrounding the tube at the interelectrode space. The toroid, one foot in diameter, is divided into 12 segments of 250 turns each, around a core of transformer iron strips. A magnetic induction of 0.01 weber/meter^2 is produced in the center with a current of 8 amp. fed across opposite ends of the toroid (4 amp. through each half). The field is perpendicular to the axis and directed along the line connecting the points at which the current is applied. A smaller coil would, of course, produce a greater field strength at the center.

To gyrate the tube, a d.c. motor whose speed may be varied is used. A hard rubber insulating shaft is connected, through a universal joint, to a disk upon which a self-aligning ball bearing is set. A clamp connects the bearing to the anode. The filament end of the tube is held by a light socket connected to a coil spring which permits free swivel motion and allows for tube expansion. During the entire operation, the target is water-cooled through the hoses shown.

Each of the twelve toroid divisions leads to a segment of a twelve-part stationary commutator which surrounds the motor shaft. The current is fed across opposite commutator segments, and thence across opposite toroid segments, by means of two opposing carbon brushes rotating with the motor shaft and fed from the 120 volt d.c. supply by slip rings and stationary brushes. Sparking is removed with condenser-resistor circuits, not shown, connected across the segments. As successive segments receive current, the field rotates in synchronism with the gyration.

FIG. 4. Experimental model of the tube gyration apparatus.

III. RESULTS AND FUTURE POSSIBILITIES

A. Results

Figure 5 is a pinhole photograph (adjusted to show the view normal to the target face) of (A) focal spot in normal stationary operation, (B) gyrating focal spot without compensating magnetic field, (C) gyrating focal spot with compensating field. The tube is continuously operated and water-cooled. The target to filament voltage is 50 kilovolts, the magnetic induction is 16×10^{-4} weber/meter^2, the deflection of the 0.49 cm diameter focal spot is 0.36 cm, and the interelectrode spacing is 4.8 cm. The gyrating frequency is 6 revolutions per second, and the tube is an old type thin-walled molybdenum target Coolidge tube.

By extrapolating the curves of Fig. 2, it can be seen that if the target were large enough so that the deflection could be increased by a factor of say 5, and the tube designed with say a 1 mm focal spot, then the ratio of permissible power input when moving, to that when stationary is 20 to 25 times.

B. Line Focus

The line focus target may be cooled efficiently by this tube gyration method by driving the tube at an angular velocity which varies during the cycle. Thus, if the length of the focal spot is four times its width (so that at 15 degrees grazing angle the spot appears square), it should be moving four times as fast during the horizontal part of its path than during the vertical part. The path is shown in Fig. 1(B). This motion could be realized with elliptical gears. If the major axis is twice the minor axis, a constant velocity drive on one would transmit the required angular velocity to the other.

C. Slant Anode Tube

The two problems which must be solved in applying the tube gyration method to non-right angled tubes are: (1) non-symmetric deflection of the beam during the cycle, (2) defocusing of the beam as its length is varied during the cycle. The first problem could be solved by varying the toroid current and hence the magnitude of the field strength during the cycle with suitable resistors in the toroid circuit having different values when carrying current in one direction than in the other. The focusing problem may not be too serious for in general the size of the spot will not change appreciably during the cycle even though its outline may be blurred slightly.

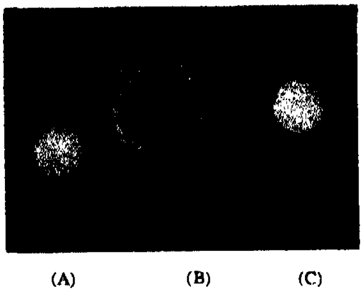

FIG. 5. Pinhole photographs of the focal spot of a water-cooled continuously operated x-ray tube. (A) Focal spot with tube in normal stationary operation. (B) Focal spot gyrating with target at 6 r.p.s. but without compensating magnetic field. (C) Focal spot gyrating with target at 6 r.p.s. and compensated with rotating magnetic field. Exposure was one minute for each picture at 50 kilovolts and 20 milliamp.

D. Application to Radiography and X-Ray Microscopy

The observation of detail in radiographs depends directly upon the minuteness of the focal spot. The concentration of energy upon a small region of the target necessitates low power input resulting in difficulties in photographic and fluoroscopic observation unless means for removing the heat rapidly are applied.

The inchoate field of x-ray microscopy begun at Stanford by P. H. Kirkpatrick requires an intense point source of x-rays at the focus of a condensing and objective lens system for high resolution microscopic analysis.[6] The tube used could be continuously operating and cooled by both water and tube gyration.

ACKNOWLEDGMENT

The writer wishes to thank Professor Paul H. Kirkpatrick for the very valuable aid given him in the successful completion of this project. His many helpful suggestions are sincerely appreciated.

RaDEF Standard Sources for Beta-Disintegration Rate Determinations

THEODORE B. NOVEY
Argonne National Laboratory, Chicago, Illinois

(Received October 17, 1949)

The preparation and use of calibrated RaDEF equilibrium sources for absolute beta-counting is described. The sources are essentially weightless and are mounted on a thin backing to reduce self-absorption and back-scattering correction problems. Calibration was done by determination of the alpha-disintegration rate of RaF in a parallel plate alpha-ionization chamber. No secondary standards are required and the sources can be recalibrated at any time.

As an example of the application of such standards, details of the calibration of a P^{32} solution distributed by the Bureau of Standards for intercalibration in February 1949 are given. The final result is 88.8 mrd/ml at 8 A.M.C.D.T. March 1, 1949. The precision of the measurement is 0.3 percent. The accuracy is estimated to be 1–2 percent.

I. INTRODUCTION

FOR most work with beta-active radioelements there is no need for an absolute measure of the number of radioactive nuclei. Relative activity measurements are sufficient. For a few fundamental measurements, however, some of the best methods depend upon a measurement of the disintegration rate of a source. Examples are the determination of neutron absorption cross sections by the activation method,[1] the determination of neutron flux by the activation of gold,[2] the determination of fission product yields,[3] and the determination of radioactive decay constants.[4]

Absolute activity measurements can be made fairly readily with an accuracy of ten or twenty percent; however, when it is desired to carry the determinations to one or two percent accuracy many difficult problems arise, mainly problems of correction for absorption and scattering of the radiation.

This paper describes the preparation and use of a RaDEF equilibrium standard which is readily recalibrated and is mounted so as to minimize the absorption and scattering correction and thus the uncertainty in the result.

II. BASIS FOR RaDEF STANDARD SOURCE

The usefulness of the RaDEF equilibrium,

$$\mathrm{RaD}\xrightarrow[22-y]{\text{soft }\beta}\mathrm{RaE}\xrightarrow[5.0-d]{\text{hard }\beta}\mathrm{RaF}\xrightarrow[138.4-d]{\alpha}\mathrm{Pb}^{206},$$

for beta-activity measurements depends upon the fact that alpha-disintegration rates can be determined quite accurately through the use of parallel plate alpha-counters which basically have a counting geometry of 2π or "fifty percent." From the alpha-activity of the source the beta-activity can be calculated. This has been done in several ways. (1) A pure RaD source is prepared and from the rate of growth of alpha-activity the beta-disintegration rate is calculated.[5] (2) A pure RaE source is prepared and the beta-disintegration rate calculated at any time from the alpha-activity growth curve.[6] (3) RaD and stable lead are electrolytically deposited from a standard pitchblende sample and the resultant equilibrium RaE activity is calculated from a knowledge of the radium content of the ore. This method was used by the Bureau of Standards in preparing beta-standards. It was subsequently found[7] that the unavoidable weight (*ca.* 1 mg) of stable lead in the source caused an eight percent error in activity determinations using the sources due to scattering.

The method chosen for this work was to prepare the sources from a solution of RaDEF in transient equilibrium decaying with the RaD half-life of 22 years. The RaF alpha- and RaE beta-activities are in the ratio of $T_1/(T_1-T_2)$ or 1.0175 and the standard sources may be checked for recalibration at any time by alpha-counting. The activity decays at a rate of 3.2 percent per year.

III. PREPARATION OF STANDARDS

For the comparison of sources of different radioactive nuclides it has been found desirable to use "weightless" sources mounted on very thin backing. In this way large back-scattering, self-scattering and self-absorption corrections are avoided.[8] This is necessary due to the uncertainties of ten or twenty percent associated with these corrections. "Weightless" in this case means a weight of material that will cause an absorption effect much less than the accuracy desired in the standards. Taking one to two percent for this accuracy it turns

out that for RaE for example, the source may weigh one hundred micrograms per square centimeter. Similarly the source backing should not contribute more than one percent backscattering effect to the counting rate. Any difference in the amount of backscattering for different energy sources will not cause an appreciable effect when all sources are mounted on identical thin supports.

The active material consisted of a solution of RaDEF in one normal nitric acid. The solution was several years old and thus was within a tenth of one percent of equilibrium. No residue could be seen on evaporating aliquots of the size used for the standards. Fractionation of the polonium in the mounting procedure could not be detected. Normal decay was observed over a period of a year.

Tygon films (*ca.* 0.7 mg/cm^2) were used as backing for the sources. These were prepared by dipping glass plates into a suitably diluted solution of clear Tygon paint. The films were stripped off when dry and were cemented with Aquadag to aluminum rings (Fig. 1c). A thin layer of Aquadag was applied to the film surface to make it slightly conducting. This avoids alpha-counting irregularities caused by charging up of the films if they are insulated from the plate on which they are placed.

The active solution was spread on the films by the use of insulin solution.[9] A drop of the insulin solution was touched to the film and spread over an area of one square centimeter. Most of the solution was then removed. The RaDEF solution (*ca.* 50 microliters) was then placed on the film and the source dried in a vacuum desiccator. The insulin solution was forty units or ten milligrams per cc. About a quarter of a drop remained spread over the source area giving a weight of about 125 μg/cm^2, well below the point where source self-absorption is appreciable.

Six standard sources were prepared with activities of about 8000 dis./min.

IV. CALIBRATION BY ALPHA-COUNTING

The standard sources were alpha-counted in a parallel plate ionization chamber filled with a 3 percent carbon dioxide-argon mixture at one atmosphere pressure. The chamber is operated at 1450 v. A fast high gain amplifier is required to provide the necessary pulse size for the scaling circuit. This counter has a very low counting loss, about 1 percent at 200,000 c/min. whereas ordinary air chamber counters have a loss of about 1.25 percent per 1000 c/min. The low loss of the A-CO$_2$ counter was useful in the calibration of the alpha-chamber. The efficiency of the chamber is very close to 50 percent when a source is mounted on a low atomic number backing as these were, but for a check an alpha-source was prepared of considerably higher activity (*ca.* 400,000 dis./min.) and was counted in the 50 percent chamber and then in a low geometry (0.2684 percent) vacuum chamber in which the beam from the source was collimated by an accurately machined circular diaphragm and passed into a carbon dioxide-argon ionization chamber through a very thin mica window.[10] The low geometry was calculated using the formula given by Kovarik and Adams.[11] The ratio of the activities—corrected for counting loss—gave the ratio of the geometries. Table I gives the results of the determination with standard errors.

V. BETA-COUNTING PROCEDURE

Mica end-windowed (*ca.* 3 mg/cm^2) G-M tubes were used with a shelf arrangement as shown in Fig. 2 for all beta-counting. The mica windows were made conducting with a thin layer of Aquadag. The apparatus fits inside a vertical lead shield with 1½-in.-thick wall. Standard commercial Higginbotham type scaling circuits were used.

All of the determinations were made in the top shelf position with the source three millimeters from the window. No attempt was made to use more distant

positions as the absorption corrections rapidly become more uncertain.

The source rings were placed in a special support (Fig. 1d). This support slid onto a shelf support (Fig. 1e) which in turn fits closely into the slots in the shelf holder of Fig. 2. The positioning was then reproducible for beta-counting and the source rings were removable for insertion into the alpha-counter chamber. The beta-geometry is very sensitive to source position at the high geometries used, a change of one millimeter being sufficient to cause about ten percent change in the counting rate.

In order to correct for absorption of the beta-particles in the air layer and in the mica window, absorption curves were taken using mica absorbers supported on a $\frac{1}{16}$-in. thick aluminum frame (Fig. 1a). The absorbers were lifted against the tube flange by inserting a wedge (Fig. 1b) between the absorber holder and the source support. It is important that the absorbers be as close to the window as possible. Reasons for this are discussed in the next section.

VI. BETA-COUNTING RATE CORRECTIONS

1. Absorption Correction

The absorption correction is the largest and most difficult correction to determine accurately. For RaDEF sources it amounts to about 25 percent due to the fact that the sources must be counted through sufficient absorber to absorb the alpha-rays of RaF. A total absorber thickness of about 11 mg/cm², is more than sufficient for this purpose as seen in Fig. 3, curve *A*. The extrapolation to zero absorber would seem to require the use of a 40.4 mg/cm² half-thickness; however, when a pure RaE source was prepared and an absorption curve taken to thinner absorber (Fig. 3, curve *B*) the curve was observed to change slope at around 15 mg/cm². The initial slope was 33.3 mg/cm². A similar absorption curve on another source yielded a slope of 34.0 mg/cm². For the standard correction the average, 33.6±0.3 mg/cm², was used requiring an absorption correction factor of 1.255±0.0028 for 11.0 mg/cm² total absorber; i.e., 3.0 mg/cm² mica G-M tube window. 0.5 mg/cm² air and 7.5 mg/cm² added mica absorber.

The absorption curves are very sensitive to the relative positions of the source and absorbers. Figure 4 shows, curves where the source is 3 mm from the tube flange and the absorbers are 1 mm from the flange (curve *A*) and against the flange (curve *B*). Even with the latter arrangement, the initial point where no absorber has been added does not fall exactly on the exponential curve due to the fact that there is still a small air space between the curved mica window and the flat mica absorbers; however, the difference is small and will partly cancel in the similar correction to be applied when another source is to be calibrated against the standard and the same absorber and source positions are used.

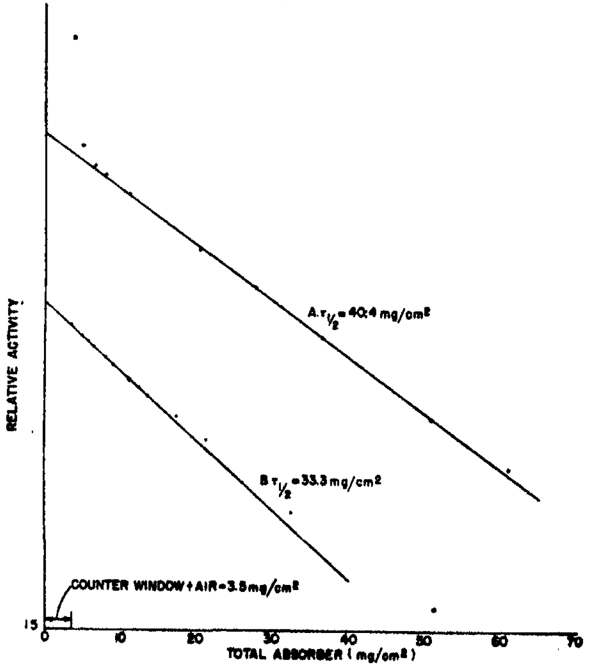

FIG. 3. Initial slope of RaE mica absorption curve as determined from RaDEF equilibrium source absorption curve, *A*, and separated RaE source absorption curve, *B*. Source is 3 mm from counter flange. Absorbers are against the counter flange.

2. Counting Loss Correction

Beta-counting rates were a few thousand counts per minute causing a counting loss of about 1 percent. This will cancel if the standard source counting rate and the unknown source counting rate are the same. For our purposes we applied a correction of 0.5 percent per 1000 c/min. of counting rate. This is an average value for our G-M tubes and will not cause a large error in the result. For the calculations of standard error in the beta-counting results we assume the counting loss correction to be 0.50±0.25 percent per 1000 c/min. of counting rate. As counting rate differences were at most 1400 c/min. between the standard sources and the unknown sources the uncertainty due to counting loss is less than 0.4 percent.

VII. APPLICATIONS TO P^{32} STANDARDIZATION

The standard sources were used to determine the specific activity of a P^{32} solution distributed by the Bureau of Standards in March, 1949.

Two 0.050-ml and two 0.100-ml samples of the P^{32} solution were mounted on Tygon films in the same manner as the standards. The absorption correction is smaller for P^{32} as there is no soft radiation to be masked out so the extrapolation to zero absorber is made from about 3.5 mg/cm². The initial half-thickness is 157 mg/cm² corresponding to an absorption correction factor of 1.016.

The four P^{32} sources and the six RaDEF sources were counted at the shelf 1 positions on two different counters designated *A* and *B*.

The RaDEF source counting rates were corrected for absorption and counting loss and divided by the previously determined beta-disintegration rate to give the "geometry." This geometry is presumably the solid angle of the source subtended by the sensitive volume of the counter excluding the small back-scattering correction. The values obtained by the six standards in the two tubes are shown in Table II with their standard errors as determined by the method of propagation of errors.

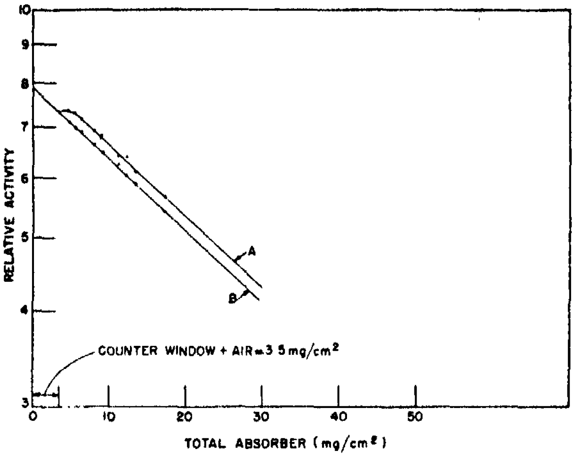

Fig. 4. RaE mica absorption curves showing curves where the mica absorbers are 1 mm from Mica counter flange, *A*, and where mica absorbers are against the counter flange, *B*. Source is 3 mm from counter flange.

The averaged geometries were then applied to the corrected counting rates of the P^{32} samples to give the disintegration rates. These are shown in Table III together with the sample volumes and the activity per milliliter of original solution corrected using a half-life of 14.30 days to the comparison time 8 A.M. E.S.T. March 1, 1949 with appropriately calculated errors.

This value is about 8 percent higher than the best value given by the Bureau of Standards for the P^{32} solution. The reason for the error in their measurements was mentioned in Section II of this paper. The value is in excellent agreement with that obtained by B. Burtt by the RaEF method.[7]

VIII. PRECISION AND ACCURACY

Tables II and III show a precision of 0.6 percent for the individual geometry determinations and 0.3 percent for the P^{32} activity determinations. The precision of the geometry determination is also indicated by the average deviations given for the average geometries. This is less than the standard error of the individual geometries.

The accuracy of the method depends upon systematic errors not shown in the corrections thus far used. These errors may be estimated as follows:

1. Possible Difference in Back-Scattering Coefficient of P^{32} and RaE from the 0.7 mg/cm^2 Tygon Films

As the total backscattering is less than 1 percent for this thickness of backing the difference due to energy difference of RaE and P^{32} is not more than a few tenths of a percent.

2. Non-Uniformity of Sources

Activity measurements on RaDEF and P^{32} sources showed some concentration of the activities at the periphery of the area. This effect if totally uncompensated by the source to be determined could cause a systematic error of several percent. For this reason it is important that the standard and unknown sources be prepared the same way.

3. Change of Geometry with Energy

If the sensitive volume of a counter depends strongly upon the energy of the incident beta-particle, then it might be expected that a geometry determined for one energy spectrum would not hold for another spectrum. The fact that geometries determined over a wide range of energies by various methods agree within a few percent,[12] i.e., within the accuracy of those determinations, sets an upper limit to the possible inaccuracy due to this factor.

A reasonable estimate of the accuracy of the method thus seems to be 1–2 percent.

IX. RANGE OF APPLICATION OF THE METHOD

The accuracy of the standardization depends upon the energy of the beta-spectrum and upon some knowledge of the decay scheme of the nuclide. Low energy beta-spectra will require the use of thinner windows on the counter tubes to avoid large absorption corrections. Atmospheric pressure flow type counters either in the proportional or Geiger region can be built with window thicknesses easily down to 50 μg/cm^2. Air absorption becomes the dominant factor here. This can be helped by substituting helium or hydrogen for the air in the counting apparatus.

If the decay involves gamma-radiation then a correction for the gamma-counting efficiency must be made. Conversion electrons are the most serious source of trouble as they are usually soft and make the absorption correction very difficult. Harder electrons such as those produced by Au^{198} amount to usually only a few percent and can be more easily accounted for.

Within these limitations this method of standardization seems at least as simple and accurate as the three other main methods of specific activity determination, "4π" counters, coincidence counters and gas counters.[4] The first method has recently been investigated by C. Borkowski and co-workers at Oak Ridge National Laboratory[13] using atmospheric proportional counters. Here gamma-rays, beta-rays, and conversion electrons only cause one count in general as they are emitted within the resolving time; however, there is a small slope to the plateau curves of ½ to 1 percent per 100 volts. As the counters have a plateau of from 300 to 1500 volts, this represents a considerable uncertainty in the disintegration rate.

Accurate activity determination by coincidence counting requires a knowledge of the decay scheme. If the scheme is simple then an accurate determination can be simply made with a source that is thin for its gamma-rays. To calibrate a counter position, however, in order to determine the disintegration rate of another source again requires an absorption correction to zero absorber. Angular correlations of emitted particles may also interfere.

[13] Private communication.

Active gas counting seems to be an accurate method and is suitable for materials which can be prepared in a gaseous form that will not impair counter action.

X. SUMMARY

A procedure has been presented for the preparation of essentially weightless RaDEF equilibrium standard sources mounted on a very light backing for use with end-windowed type counters. This type of mounting avoids the necessity of dealing with self-absorption and backscattering problems. The standards have the advantage of being relatively permanent, can be recalibrated by alpha-counting at any time, and in many cases can be used to determine the activity of other radionuclide sources with an error of <2 percent. The method loses accuracy when the beta-spectra are of low energy so that the absorption corrections are large and less reliable or when an unknown amount of conversion electrons are present.

Construction and Performance of a Multiple Gamma-Ray Counter of High Efficiency

TIBOR GRÁF
L. Meitner Laboratory, Royal Institute of Technology, Stockholm, Sweden

(Received October 18, 1949)

A multiple gamma-ray counter is described, composed of 24 counter tubes connected in parallel. The tubes have Bi-plated brass screen cathodes and are placed inside the same envelope. Relative and absolute values for the efficiency of the counter were determined experimentally in the range 0.28 to 2.62 Mev. Compared to a single brass counter of similar dimensions, the multiple counter shows for gamma-rays of, say, 0.7 Mev energy a tenfold increase in efficiency. Its starting voltage is 5–600 volts lower.

The "effective resolving time" of the multiple counter appears to be 3 to 4 μseconds.

The counting rate curve seems to follow the inverse-square law down to the shortest counter-source distances. The solid angle subtended by the multiple counter for sources, placed in its middle, is nearly 4π.

I. INTRODUCTION

THE problem of measuring the gamma-radiation of substances of very low specific activity led the author to a counter design incorporating several features, all tending to increase the efficiency of the counter for gamma-rays. The high efficiency values obtained in the energy range 0.28 to 2.62 Mev, as well as other desirable properties of the counter, revealed in the course of some investigations of the author,[1] seem to warrant publishing some details of its construction and performance.

Quite generally, the efficiency of a G-M counter for gamma-rays can be improved by increasing the absorption of the gamma-rays in the material of the counter in such a way that the greatest possible number of the resulting secondary electrons should enter into the sensitive volume of the counter. This can be achieved, in principle, by making the counter of a solid metal cylinder provided with a number of counter cavities. The walls between these cavities should be thin so that a large proportion of the secondary electrons produced in them should be able to reach the counter volumes. If the individual counters have the same threshold voltage then all the wires can be connected in parallel, so that an automatic addition of the pulses initiated in the different cavities becomes possible.

In practice it is more convenient to take, instead of a solid cylinder provided with cavities, a number of hexagonal or rectangular tubes,[2] and place them inside a single envelope, in close contact with each other. Also stacks of circular tubes, of the usual G-M counter type, can be used, though there always remains a small dead space between such tubes, reducing somewhat their efficiency.

In spite of this, the use of tubes with circular cross section seemed to be preferable in the present case. The reason was greater simplicity of construction, and the advantage procured by the cylindrical symmetry of the assembly. In fact, this symmetry makes the counter useful for quantitative measurements also in cases when the sources, on account of their low specific activity, must entirely surround it in order to give a sufficient counting rate.

A further improvement in the gamma-ray efficiency of G-M counters may be obtained by making the cathodes of a material of high atomic number and presenting a large effective surface, such as a wire gauze.[3] The absorption coefficient of gamma-rays increases with the atomic number of the absorber, and the use of wire gauze seems to increase the probability of the secondary electrons reaching the sensitive volume of the counter.

[2] The use of rectangular tubes for this purpose was first suggested by S. C. Curran and J. M. Reid, Rev. Sci. Inst. 19, 67 (1948).

Recently, counter constructions of the multicellular type, consisting of several pill-box shaped counter cells, have been applied with success to problems related to the measurement of approximately parallel gamma-ray beams of fairly large cross section. Counters specially designed for such applications were made by several workers.[4–6]

While the present work was progressing, several short papers have also appeared on the use of parallel-connected gamma-ray tubes,[7–9] showing the current interest in this type of gamma-counters.

An attempt of increasing the gamma-ray efficiency of G-M counters, though by a different method, was also made by H. Slätis.[10]

II. CONSTRUCTION

General Design

The increase of efficiency obtainable with stacks of parallel-connected tubes may be estimated by comparing the counting rates produced by a large beam of gamma-radiation, in the stack, on the one side, and in a single counter of identical size, on the other. For a cylindrical stack of 7 tubes, for instance, in which 3 tubes are on a diameter, the counting rate is about 7 times that produced in a small tube, the counting rate of the single large counter being about 3 times this counting rate. In fact, the cross section of three small tubes together equals that of the single counter. Thus, the counting rates, and the efficiencies, are, in this case, approximately in the ratio 7 to 3. For a total number of 19 or 37 tubes, easily built up in rings around a central tube, the corresponding increase of efficiency may be expressed approximately by the ratios 19/5 and 37/7, respectively.

In the present design an open passage of 1.7-cm diameter was left along the axis of the entire assembly, allowing small sources to be introduced into its center. For this reason, the disposition, shown in Fig. 1(a), of the

24 tubes used, is somewhat less compact than in the arrangements mentioned above, and the improvement due to the use of a stack of tubes alone may, in this case, hardly be expected to exceed a factor of 3. Further increase of efficiency, as was actually revealed by subsequent measurements, was probably due to the other causes mentioned in the introduction.

On the other hand, the presence of a free passage in the middle constitutes an advantage in many applications on account of the large solid angle ($\sim 4\pi$) subtended by the counter for a central source. Also a single beta-counter, to be used in coincidence with the multiple counter, may be placed together with the source in the central channel. The envelope of the counter was made of 7.0-cm brass tubing of 0.15-cm wall thickness.

The anodes consisted of 0.01-cm tungsten wire mounted as shown in Fig. 1(b). A small piece of copper wire was squeezed onto one of the ends of the tungsten wire, to prevent it from slipping through the fine hole made in the lower Plexiglas plug. At the upper end of the counter, the wire passes through a brass connector, set tightly in the Plexiglas plug. To fix the wire, it is held stretched while it is blocked in position by a tapered brass pin.

This method of fixing the counter-wire was found to facilitate the construction of the multiple counter. It has previously been used with success in assembling a number of counters of various design.

After assembly, the end plates were sealed with Apiezon *W* wax.

Cathode Tubes

Bismuth was chosen as material for the cathode tubes. Bi has the highest atomic number of all the stable elements, is free from radioactive impurities, and is much less expensive than either Pt or Au. The use of lead in the counter does not seem advisable, since lead almost invariably contains RaD, and consequently also RaE and RaF, in radioactive equilibrium with it. The presence of the beta-rays of RaE is especially disturbing as they cannot be stopped by a protective surface layer, without also absorbing many of the secondary electrons produced in the lead by the gamma-radiation to be measured.

The Bi had to be electroplated on tubes which in the present case were made of brass wire gauze. For the electroplating process, the technique described by Good, Kip, and Brown was used.[11] These authors recommend a plating solution made by dissolving 9 gram of Bi_2O_3 in 100 cc of 70 percent perchloric acid, and diluting to 1000 cc of solution. The gauze mesh was 0.2 cm, the diameter of the brass wire being 0.035 cm. The tubes made of this gauze had an inside diameter of 0.8 cm, and a length of 8.5 cm. Satisfactory results were obtained when the tubes were plated with an initial current of 40 milliamp. As a result of the gradual increase of the cathode surface during the plating process, the current had to be increased after the first 22 hours. It was then maintained at 60 milliamp. for another period of 22 hours. The corresponding value of the current density was somewhat less than 2 milliamp. per cm^2 of cathode surface.

In order to reduce the time necessary for the plating of a large number of tubes, a special plating apparatus was constructed. This device made possible the simultaneous plating of four tubes, which were rotated continuously in order to obtain a smooth surface and a Bi layer of uniform thickness.

The Bi electrodes were cast from pure Bi crystals in a graphite mould which was placed inside an evacuated Pyrex tube. Four Bi electrodes, 0.4 cm in diameter, were soft soldered to small brass rings mounted into the Bakelite base plate of the plating apparatus. Connections to the Bi electrodes were brought through the Bakelite tubes which supported the upper plate. All brass or copper parts in the solution were coated with paraffin wax. The cathode tubes were guided in their rotation around the Bi electrodes by small Plexiglas rings, of 0.7-cm diameter, embedded in the wax at the foot of each electrode. Half of the total current passed through a Bi electrode of 0.8-cm diameter which was suspended in the middle of the solution and had the purpose of furnishing metal to the outside surface of the tubes.

After electroplating, the diameter of the wire attained 0.07 cm, the weight of Bi deposited on each tube being between 5 and 6 grams. The mechanical strength of the screen tube was greatly increased by the plating procedure. One of the reasons being that the brass wire ends, which had merely been twisted, became actually soldered together with Bi.

The ends of the tubes which were not covered with Bi, were cut away after the plating process. Two cylindrical brass rings were soft soldered to the remaining 7.0-cm length. The upper ring was pressed into one of the cylindrical grooves machined into the upper Plexiglas end plate of the counter, whereas the other ring held the lower insulating plug of the tube, as shown in Fig. 1(b). In order to prevent the passage of the discharge from one tube to another, an Al foil, 8μ in thickness, was wrapped around each tube. All the cathodes were electrically connected to the wall of the inner brass tube of the multiple counter.

Only straight tungsten wire lengths and cathode tubes free from points were used. With moderate care in cleaning and in assembling the different parts of the counter, it was possible, practically straight away, to secure normal operation for all the 24 tubes. After observing that the Bi cathodes were light sensitive, the transparent end plates were covered with sealing wax.

Gas Filling

While a more permanent counter construction, containing no organic materials, is quite feasible, the present design appears to serve its purpose well. The multiple discharges which appear in the counter, usually a few months after its filling, as they do in all counters containing wax, and plugs made of organic matter, disappear as soon as the counter is filled anew. This seems to indicate, that multiple discharges in the present case are mainly due to a decrease of the amount of alcohol in the gas, caused probably by its diffusion into the sealing wax and the end plates.

---

[11] Good, Kip, and Brown, Rev. Sci. Inst. 17, 262 (1946).

Also, in order to obtain good counter characteristics, the pressure of the ethyl-alcohol quenching vapor used had to be increased to 1.8 cm of mercury, from the usual value of 1.0 cm, the total pressure of the argon-alcohol mixture being 20 cm of mercury. The quenching of the counter discharge appeared to be insufficient with a lower alcohol pressure, probably owing to the small cathode diameter.

It was found that the useful life of the counter could be increased by allowing alcohol vapor, at a relatively high pressure (3–4 cm of mercury), to stay a few hours inside the counter, and diffuse into its different parts, before the definitive filling of the counter. This treatment reduced at the same time the large initial variation of the threshold voltage which was previously often observed with newly filled counters.

III. PERFORMANCE

General Characteristics

The characteristic curve of the multiple counter was found to be essentially similar to that of one of the small tubes. The plateau had a slope of 5–6 percent per hundred volts. Though the slope increased somewhat with use, as it always does with counters which cannot be outgassed properly, yet several times 10^7 pulses could be counted with the same filling. The starting voltage of the multiple counter was less than 900 volts, as compared to 1500 volts for a single counter of the same overall size filled to a pressure of only 10 cm of mercury. The starting voltage of the individual tubes was the same within 2–3 volts.

Background

The background of the unshielded counter was about 1400 counts/min. It was mainly due to gamma-radiation from the ground and the walls of the building. Indeed, a cylindrical lead shield of 10-cm wall thickness, with 10 cm of lead on the top, and 7.8 cm under the counter, reduced it to only 63 counts/min. Since the sum of the background pulses in the 24 individual counters, surrounded by the same lead shielding, was $24\times4.8=115$ counts/min., most of the background pulses with 10 cm lead must have been due to particles which each produced ions in more than one tube. Thus, whereas the connection in parallel of a number of tubes greatly improves the gamma-ray efficiency of the counter, its background due to cosmic rays will not increase in the same proportion.

TABLE I.

Energy in Mev	Ratio of the efficiency of the multiple counter to that of a conventional brass counter
0.28	21.0±0.6
0.51	13.7±0.8
0.68	10.2±0.2
1.25	6.6±0.5
2.62	5.8±0.5

Furthermore, owing to the ionizing nature of these particles, many of the pulses produced by them may be eliminated by the use of anticoincidence counters. A very simple and effective anticoincidence arrangement, especially for sources placed at the center of the counter, would consist in using the 8 central tubes of the multiple counter for the measurement, the other 16 tubes being connected in anticoincidence. The background of the 8 central tubes with 10 cm of lead was found to be 26 counts/min., whereas a determination of the number of coincidences between the central group and the group of 16 counters of the outer rings yielded 19 coincidences/min. Thus, an effective anticoincidence circuit should reduce the background of this arrangement to only 7 counts/min. This is 9 times less than the value of the background found with all the 24 tubes connected in parallel. Since for an internal source the central group of 8 counters has about half the efficiency of the whole assembly, an improvement by about a factor of five in the ratio (source activity)/(background counts) may be expected. This improvement would be especially important in the case of weak gamma-emitters giving a counting rate of the same order as the background. Experiments are being planned in order to obtain a very low background with the help of a suitable anticoincidence amplifier.

Resolving Time*

Attempts were made to determine the resolving time of the multiple counter by investigating the form and the distribution of the counter pulses. This investigation was made with an oscilloscope, the horizontal sweep of which was triggered by the counter-pulse itself.

The pulse heights observed on the oscilloscope screen were in the ratio 1:2:3:4:5, much like in the case reported by Lind.[6] The larger pulses, which were less numerous, were obviously due to discharges produced simultaneously in several individual tubes, either by secondary electrons which passed through the screen-openings of the tubes, or by cosmic-ray particles, or even by scattered gamma-quanta which became absorbed or scattered once more. The pulses due to one of the parallel-connected tubes were about 8 times smaller than those observed with a single tube disconnected from the others. This reduction of pulse height results obviously from the large capacitance of the counter wires ($=60$ $\mu\mu f$). While pulses of this magnitude are quite sufficient to operate the usual G-M tube amplifiers, they are so small that the anode voltage of the multiple counter will practically never be lowered to a value near the threshold.

---

* The author is indebted to Mr. G. von Dardel, Mr. C. Taylor, and Mr. N. Voghera for discussions on the subject of this section.

Consequently, after a discharge in one of the tubes, the other 23 tubes, in which no positive ion sheath has been formed, remain fully sensitive to radiation. Since the probability that two subsequent discharges of the multiple counter occur in the same individual tube is quite small ($\cong 1/24$), the multiple counter will almost always count an ionizing particle, even when this particle follows the previous ionizing event in an interval much shorter than the deadtime of a single tube. Hence, no deadtime, in the accepted sense of this expression can be associated with the multiple counter. In fact, intervals as short as 4 μsec. between successive pulses were observed on the oscilloscope screen. However, an "effective resolving time" τ_0 may be considered, at least when the number of pulses n per second in the different individual tubes may be assumed to be approximately the same. τ_0 may be defined as being equal to the resolving time of a single counter which at a counting rate $N=24n$ would suffer the same relative loss as the multiple counter. This latter loss is approximately the same as the relative counting loss $n\tau$ in one of the individual tubes, for the counting rates, and hence also the losses, are supposed to be the same in all the tubes. Since, for $N\tau_0 \ll 1$ the relative loss in the single counter is $N\tau_0$, and by definition $N\tau_0=n\tau$, it follows that $\tau_0=(n/N)\cdot\tau$. Thus, for not too high counting rates, the effective resolving time of the multiple counter should be about 24 times shorter than that of an individual tube. For unequal distribution of the counting rates between the individual tubes, this time would obviously be somewhat longer.

A measurement of the resolving time of the multiple counter was kindly made, at the author's request, by Mr. G. von Dardel, with a 20-channel time interval analyzer constructed by him. For this measurement the pulses generated by the multiple counter across a 500 ohms load were amplified by a fast linear amplifier of gain 10^4. Although the smallest interval between pulses that could be measured with this arrangement was of the order of 4 μseconds, no minimum interval between successive pulses of the multiple counter could be detected. For intervals shorter than about 60 μseconds the number registered by each channel of the analyzer was 3 or 4 percent less than for intervals exceeding this value. This decrease in the number of intervals is attributed to the fact that two subsequent discharges separated by an interval smaller than the deadtime of an individual tube,—though they may occur in two different tubes of the multiple counter,—may not take place in one and the same tube. Hence, the probability that the second of two such discharges will actually take place is reduced in the ratio 23/24. This interpretation is confirmed by a measurement made with the interval analyzer which for the deadtime of the individual tubes of the multiple counter gave a value of 60 μseconds.

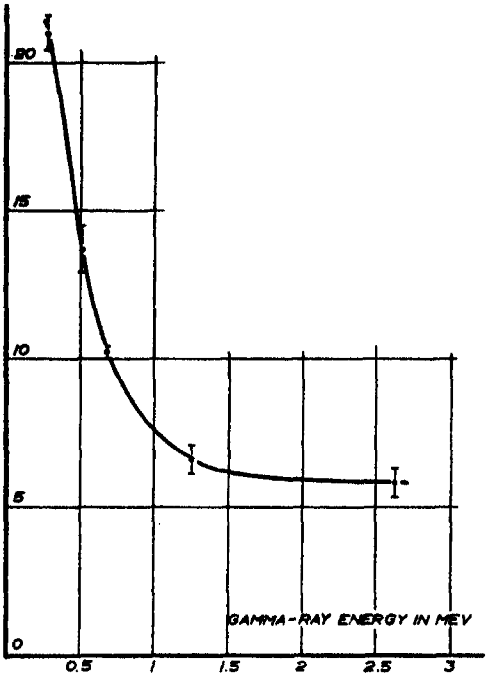

FIG. 2. Experimentally determined ratio for the efficiency of the multiple counter to that of a single brass counter of the same size, as a function of quantum energy.

According to what was said previously the effective resolving time of the multiple counter should be about 24 times smaller than this value, i.e., about 2.5 μseconds. To this should be added the time of spread of the discharge along the wire,[12] estimated at 0.5 to 1 μsecond.

Thus, compared to a conventional counter of the same over-all size as the multiple counter, for the deadtime of which a value of 760 μseconds was obtained, the multiple counter exhibits an about 200 times smaller resolving time.

Relative Efficiency

The efficiency of a G-M counter for a beam of monoenergetic gamma-rays is defined as the ratio of the quanta counted to the number of quanta passing through the counter. Consequently, the efficiency of two counters of identical size may be compared, by comparing, under the same geometrical conditions, the counting rates produced in each counter by a distant source emitting a single gamma-ray.

The counting rate of the multiple counter was compared to that of a conventional brass counter which had the same diameter and the same wire length (7.0 cm). For these measurements the counter was placed on a wooden table, with its axis vertical. A small size source was disposed in the median plane of the counter, at a

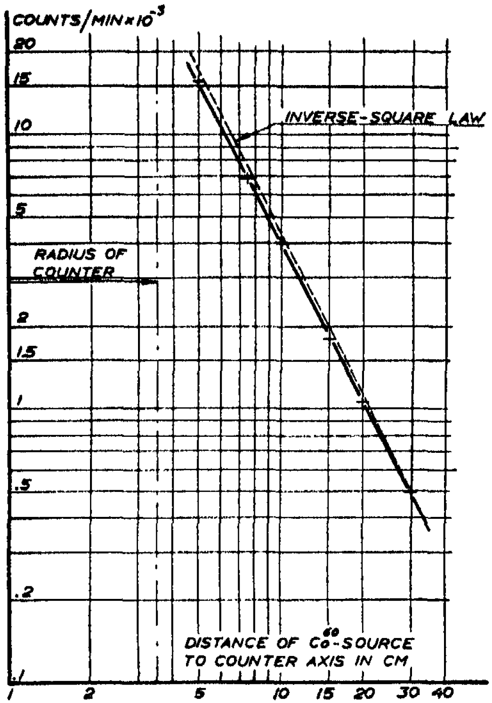

FIG. 3. Double logarithmic plot of counting rate *vs.* distance of source from counter axis. For comparison, a dashed straight line, representing the inverse-square law, was drawn through the experimental point at 30 cm.

distance of 20 to 100 cm from the counter axis, depending on the intensity of the sample. The amount of scattered radiation reaching the counter was kept at a negligible value.

The following gamma-ray sources were used:† Hg^{203} (0.28 Mev[13]), Cu^{64} (0.51 Mev), Cs^{134} (0.68 Mev[14]), Co^{60} (1.25 Mev[15]), and ThB+C+C″ (2.62 Mev).

Co^{60} and Cs^{134} emit several gamma-rays, of not very different energy. The energies quoted for these two sources are weighted mean values.

For Cu^{64} the contribution of the 1.35 Mev weak gamma-radiation[16] was determined through absorption measurements and was corrected for in the results. Similar corrections were made for the low energy gamma-quanta emitted by ThB+C+C″.

The final results of the comparison, given in Table I, show that the efficiency of the multiple counter for 0.28 Mev quantum energy is 21 times larger than that of the brass counter. This ratio diminishes for larger energies, as can be expected, and, above about 1.5 Mev becomes approximately equal to 6. The experimental points lie on a continuous curve, shown in Fig. 2, representing the efficiency ratios for all quantum energies between 0.28 and 2.62 Mev.

In order to determine the influence of the source-counter distance in measurements made with comparatively thick sources placed near the counter, the counting rate produced by the gamma-rays of Co^{60} was measured for distances between 5 and 30 cm. The results of these measurements are plotted on double logarithmic scale on the graph of Fig. 3. Following calculations of F. Norling,[17] the solid angle subtended by a counter of conventional design varies much less rapidly at short distances than would be indicated by the inverse-square law. According to the experimental points of Fig. 3, however, this law seems to apply rather closely for the multiple counter, even for distances comparable to its radius.

This behavior may partly be due to the fact that the length of the multiple counter is approximately equal to its diameter. Another possible cause is the fact that the secondary electrons are ejected from points more evenly distributed throughout the volume of the multiple counter than in a counter of the usual design.

The influence of the relative position of the source around the counter was investigated by measuring the counting rate produced by a sample of Cu^{64} placed directly on the surface of the counter, at different points of its "equatorial circle." No deviation exceeding the limits of the experimental error (±0.5 percent) was found, although any asymmetry should have the greatest effect for the shortest distance between source and counter. Hence, this result may be taken as an indica-

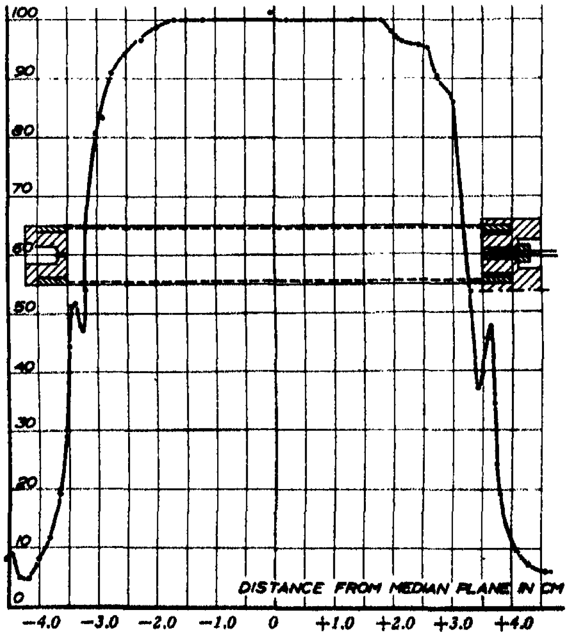

FIG. 4. Relative efficiency values along the axis of the multiple counter. The relative position of one of the counting tubes is indicated.

tion of the good cylindrical symmetry of the multiple counter.

The counting rate for a Cu^{64} source placed at the center of the counter was found to be about twice that obtained when the same sample was applied directly against the outer envelope of the counter. This increase is mostly due to the much larger solid angle (nearly 4π) subtended by the counter. However, for a central source, the losses due to the absorption in the counter walls are also smaller. On the other hand, a gamma-quantum coming from the center of the counter may only pass through three tubes, at the most, instead of six, and its probability of being counted is correspondingly smaller.

The variation of efficiency over the cross section of the counter was investigated by using the gamma-radiation from a Co^{60} source placed at 40 cm from the counter. A horizontal fan-shaped beam of gamma-radiation was employed, the position of which remained unaltered during the measurements. Its vertical dimension was limited to 0.15 cm. Its horizontal extension was greater than the length of the counter.

In a first series of measurements the counter was placed vertically at different heights above the table. The counting rates obtained furnished, after correction for the background and for scattered radiation, a relative measure of the efficiency along the counter wire. These relative values are plotted in Fig. 4, against the distance of the beam from the median plane of the counter. There appears to be a fairly large region of constant efficiency.

In a second series of measurements the counter was disposed horizontally. The direction of incidence of the beam was perpendicular to the counter axis and parallel to a diameter of the counter passing through two tubes only (see Fig. 1(a)). The counting rates obtained with the counter at different levels above the table were plotted, after corrections, in Fig. 5, against the distance of the beam from the counter axis.

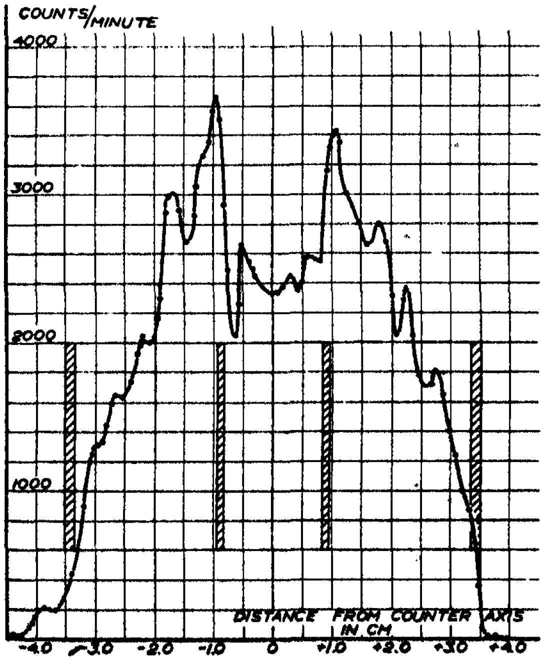

FIG. 5. Counting rate *vs.* distance of beam from the axis of the multiple counter. Incident beam normal to the schematic cross section shown.

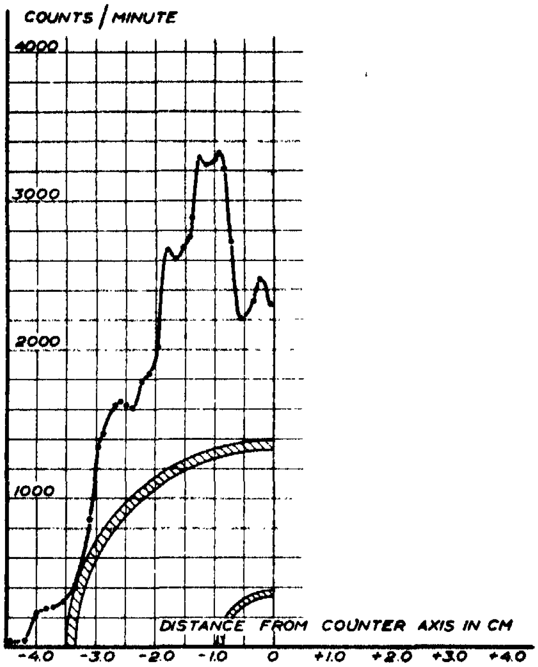

FIG. 6. Counting rate due to a beam parallel to the counter axis, as a function of its distance from the axis. Area encountered by the beam can be deduced from the diagram.

The peaks of the curve obtained indicate the increase in the number of secondary electrons produced in the walls of the individual tubes on the point of entering the beam. The depression in the middle of the curve is, of course, due to the presence of the open channel along the counter axis. The corresponding loss of efficiency may be estimated from the curve at about 10 percent.

Finally, the counter was placed with its axis parallel to the direction of the beam, its center being at the same distance from the source as for the previous measurements. The net counting rates, obtained with the counter at various heights, are plotted in Fig. 6 against the distance of the beam from the counter axis. The curve drawn through the experimental points corresponds to only half the cross section of the multiple counter. It is interesting to note that the area under the entire curve, which was assumed to be symmetrical with respect to the counter axis, is nearly equal to the area of the curve in Fig. 5. This means that a parallel beam of gamma-radiation from Co^{60} (1.25 Mev), irradiating the whole counter, would produce the same counting rate, whether the counter axis is parallel or perpendicular to the beam. Since the circular cross section of the counter is smaller than its rectangular cross section, the efficiency of the counter for an axial beam is about $(4/\pi)$ times greater. Also, in order to reduce the counting rates observed to the same solid angle, the ordinates of the curve in Fig. 6 should be multiplied by the ratio of the counter diameter and the chord length corresponding to each ordinate. It may be seen then that for a beam of sufficiently large cross section (a few cm^2), the efficiency over the annular face of the counter is much more uniform than the curve of Fig. 6 would indicate it.

Clearly, a more uniform response would be obtained by disposing the tubes in parallel rows, instead of in concentric rings.

However, as was mentioned in the introduction, for measurements with nearly parallel gamma-rays, where uniform efficiency over a large counter area is desirable, counter designs of the multicellular type, such as those described by DuMond,[4] Lind,[6] and Beyster and Wiedenbeck,[5] appear to be more appropriate.

Absolute Efficiency

The absolute efficiency of the multiple counter for different quantum energies was obtained by multiplying the experimentally determined efficiency ratios, read on the curve of Fig. 2, with the efficiency of the brass counter used for the calibration.

The curve connecting the experimental points, which in Fig. 7 are indicated by crosses, represents the efficiency curve of the multiple counter in the range 0.28 to 2.62 Mev. For the efficiency of the brass counter, the values measured by Bradt *et al.*[18] were assumed. The lower curve of Fig. 7 shows the one obtained by these authors, after correction for the absorption of the gamma-rays in the 0.15-cm thick counter wall.

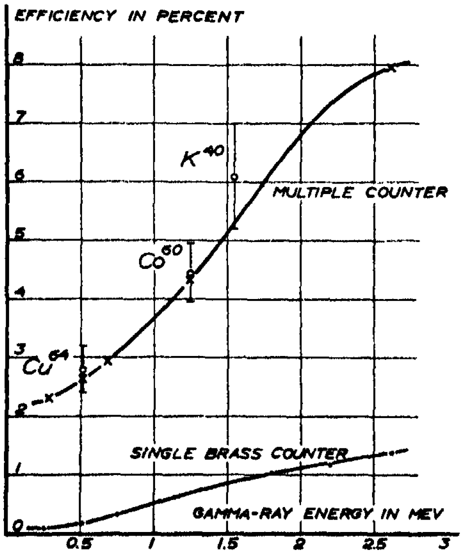

FIG. 7. Absolute efficiency of multiple counter *vs.* gamma-ray energy. Beam normal to counter axis. Lower curve: Absolute efficiency of single brass counter, following Bradt *et al.*, corrected for absorption in the counter wall.

The efficiency of the multiple counter varies, as is seen, from 2.3 percent at 0.28 Mev to about 8 percent at 2.62 Mev. The uncertainty in the determination of the individual points is estimated at about 10 percent.

In order to provide a check on the efficiency curve obtained in this way, the absolute efficiency of the multiple counter was also measured directly for three different quantum energies.

In the case of the 0.51 Mev annihilation radiation, from Cu^{64}, the coincidence method was used. For 1.25 Mev quantum energy the gamma-radiation from Co^{60}, and for 1.55 Mev the radiation from K^{40} was employed, the counting rates produced by known source intensities being measured under well determined geometrical conditions.

The coincidence method allows a determination of the efficiency of the counter for the annihilation radiation without the necessity of knowing exactly the source intensity or the solid angle subtended by the counter. The reason for this is that the two annihilation quanta are emitted in opposite directions. The efficiency of one of two coincidence counters, placed symmetrically with respect to the source, will simply be given by the ratio of the coincidence rate to the counting rate of the other counter. Corrections must, of course, be made for chance coincidences, for the background, for the absorption of the radiation in the source, and for the possible presence of other gamma-rays.

A Cu^{64} source, in the form of a 0.5-cm long activated Cu wire of 0.16-cm diameter, was placed between the multiple counter, and a conventional brass counter of the same wire length and of 3.5-cm inside diameter. The counters were placed vertically, at 20 cm from each other, with the source in the middle of their center line.

The value furnished by this method for the efficiency of the multiple counter, 2.8±0.4 percent, appears to be in good agreement with the corresponding value of 2.6 percent taken from the curve of Fig. 7. However, the value yielded by the coincidence method does not represent the average efficiency over the entire counter cross section, as do the values obtained by calibration with the brass counter. It corresponds to a smaller sectional area subtending a solid angle equal to that subtended by the brass counter. When the distance of the brass counter to the source was increased to 20 cm, that of the multiple counter remaining 10 cm, the somewhat higher value of 3.2±0.3 percent was obtained for the efficiency. The reason for this increase is clear from the curve of Fig. 4, since the quanta giving rise to coincidences in this second arrangement are passing through a region of the multiple counter which extends only about halfway between its median plane and the ends of the wires, and in which the efficiency has its maximum value. As a matter of fact, this increase of efficiency was partially compensated by the fact that in the second arrangement the lateral extension of the effective solid angle was limited to a region situated within less than one cm from the axis of the multiple counter. As shown by the curve of Fig. 5, the average value of the efficiency is somewhat less in this region than in the twice wider region corresponding to the first arrangement.

---

[18] Bradt, Gugelot, Huber, Medicus, Preiswerk, and Scherrer, Helv. Phys. Acta 19, 77 (1946).

An attempt was also made to justify experimentally the use in the present investigation of the results obtained for the efficiency of a brass counter by Bradt *et al.*, by measuring the efficiency of the brass counter for the annihilation radiation. The solid angle for coincidences was defined by the multiple counter. It covered the diameter of the brass counter exactly, but only the middle half of its wire length. After correction for absorption in the counter wall a value of 0.23±0.03 percent was obtained for the efficiency of the brass counter. This result agrees well with the value of 0.215±0.007 percent obtained by Bradt *et al.*

The determination of the efficiency at 1.25 Mev was made with a Co^{60} standard, the intensity of which at the time of the measurements was 0.62±0.06 microcuries, as deduced from data furnished with the standard by Tracerlab, Inc. With the source in the median plane of the multiple counter, at 30 cm from its axis, a net rate of 490±14 counts/min. was found. The corresponding value of 4.45±0.5 percent, obtained for the efficiency of the multiple counter at 1.25 Mev, is seen to fit well the efficiency curve of Fig. 7.

With counters of high efficiency even a substance of as low specific gamma-activity as natural potassium may conveniently be used as a standard.

Potassium is readily available, its activity suffers practically no decay, and its gamma-radiation is composed of a single gamma-ray. This gamma-ray has an energy of 1.55 Mev[19,20] and is emitted at a rate for which a new computation of the author yielded the value of 3.4±0.5 quanta per second per gram of potassium. This value is thought to be somewhat more precise than the value published previously.[20]

About 315 g of K_2SO_4 was placed around the counter, in an annular box which was in its turn surrounded by 7.0 cm of lead. The mean distance of the source from the counter axis was 6.0 cm. Minor corrections had to be applied to account for self-absorption and for a certain reduction in the counting rate caused by the axial extension of the source (7.0 cm). A net counting rate of 139 counts/min. was obtained, corresponding to a value of 6.1±0.9 percent for the efficiency of the multiple counter at 1.55 Mev. This value agrees, within the limits of the error, with the value which was determined by calibration. A more precise determination of the gamma-emission rate of potassium seems, however, to be desirable before potassium may become a useful gamma-ray standard in connection with detectors of high efficiency.

A comparison of the efficiency values obtained for the present counter with those of the multicellular counter reported by Lind[6] and by Lind *et al.*[21] seems to indicate that the values published by these authors are overestimated.*

IV. CONCLUSIONS

The multiple counter described combines the advantage of high gamma-ray efficiency and of short resolving time with the simplicity and reproducibility of operation of the conventional G-M counter. In measurements with large beams of extremely weak gamma-radiation, or in coincidence measurements, when large solid angles are desirable (as in connection with beta-spectrometer work, for example), the multiple counter may prove to be more advantageous even than a scintillation counter.

At low energies, in the range 0.2 to 1 Mev, it may prove difficult to attain an efficiency comparable to that of a good scintillation counter. At an energy of 2.6 Mev, however, the average efficiency of the present construction for a large *axial* beam of gamma-rays is already about 10 percent. It appears comparatively easy to improve this value by a factor of 2 or 3, by increasing the length and the number of the tubes.

For still higher gamma-ray energies, it should be possible to attain an efficiency of 40–50 percent in this way.

V. ACKNOWLEDGMENTS

The author is greatly indebted to Professor Lise Meitner for her continued interest in this work and for stimulating discussions. Thanks are also due Mr. H. Johansson for his excellent machine work in the construction of the multiple counter.

The loan by Dr. S. Eklund and Mr. G. von Dardel of part of the equipment used in this investigation is gratefully acknowledged.

Calcium and Cadmium Tungstate as Scintillation Counter Crystals for Gamma-Ray Detection

R. H. GILLETTE
Laboratory of the Linde Air Products Company, Tonawanda, New York

(Received November 17, 1949)

The high density, transparency, and chemical inertness of calcium and cadmium tungstates, together with their reasonable luminescent efficiencies when stimulated with high energy radiation, strongly suggest their use as phosphors in scintillation counters for gamma-ray detection. Some of the properties of these crystals are reported and compared with anthracene. It is shown that with proper design, the total anode current produced by a given source is several times greater with the tungstates than with anthracene, although the latter has a more favorable pulse size distribution. Cadmium tungstate has a zero temperature coefficient of luminescence up to 40°C and shows no afterglow after exposure to intense radiation.

SHORTLY after the announcement by Moon[1] that a single crystal of natural Scheelite ($CaWO_4$) gave a considerable response as a scintillation counter phosphor for gamma-ray detection, experiments were started in this Laboratory to synthesize and test crystals of this material for scintillation counter applications. Subsequently it was found that cadmium tungstate has certain advantages for this application and consequently both crystals have been prepared and studied. It is the purpose of the present communication to summarize the results of these tests and to compare the performance of these tungstates in gamma-ray detection with some of the other currently interesting materials.

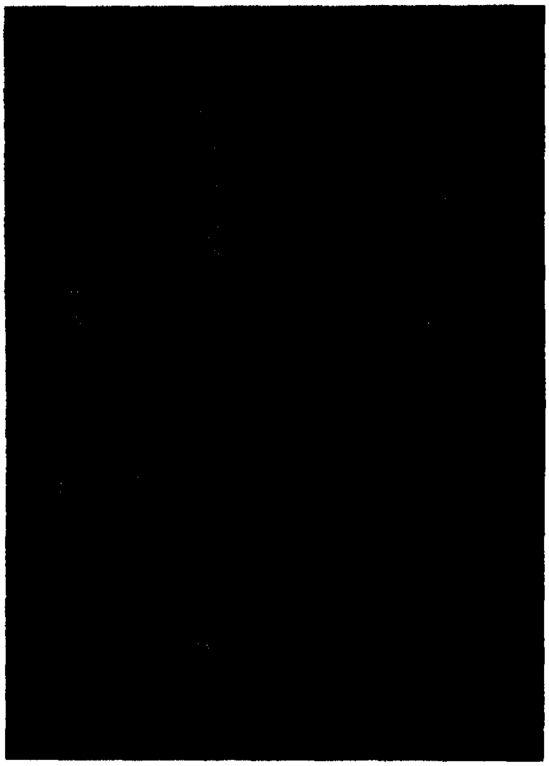

FIG. 1. Some "as grown" and fabricated forms of $CaWO_4$ (right half) and $CdWO_4$ (upper left). Rods of both materials are seen and a boule and a boule section of $CdWO_4$. The last named shows a cloudy region. Polished rods and a mosaic of $CaWO_4$ are presented.

NATURE AND PROPERTIES OF THE CRYSTALS

The crystals used in this investigation were prepared by the Verneuil technique and have been grown mainly as rods about one-eighth inch in transverse dimension and up to five inches in length, although some other shapes and sizes have also been prepared experimentally and tested. Calcium tungstate is obtained as a water-clear crystal of tetragonal structure usually with the crystallographic C axis oriented along the growth axis of the rod. Some of the earlier crystals showed clouds of precipitated CaO but it was found possible to eliminate this completely. Cadmium tungstate grows as a clear, yellowish green monoclinic crystal showing very marked (010) cleavage, although cloudy crystals have also been prepared. In fact, unless special precautions are taken to prevent it, the material cleaves much like mica. The crystal structure does not vary much from tetragonal and generally the "unique" (b) axis is oriented perpendicular to the growth axis of the rod; in this way cleavage occurs along the rod. The exact color is very sensitive to trace impurities. The physical and chemical properties of the two materials are summarized in Table I, and Fig. 1 displays a photograph of typical as grown and fabricated forms. Optical transmission curves throughout the visible, near ultraviolet, and infra-red are shown for calcium and cadmium tungstate, respectively, in Figs. 2 and 3. These were obtained with a Beckman DU spectrophotometer and a Perkin-Elmer Model 12C infra-red spectrometer. The transmission of a slab of natural Scheelite, kindly loaned us by Professor Moon, is also shown in Fig. 2. This material had a considerable number of opaque inclusions so that it was not possible to find a field entirely free of them for the transmission measurements, although they constituted not more than 5 percent of the irradiated area.

The fluorescent emission peaks listed in Table I were obtained by direct visual observation of the fluores-

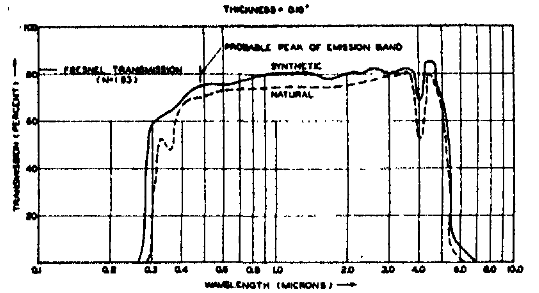

FIG. 2. Transmission curves of synthetic and natural calcium tungstate. The latter contained a number of opaque inclusions. The Fresnel transmission of a slab and the probable peak of the emission band when stimulated with gamma-rays are indicated.

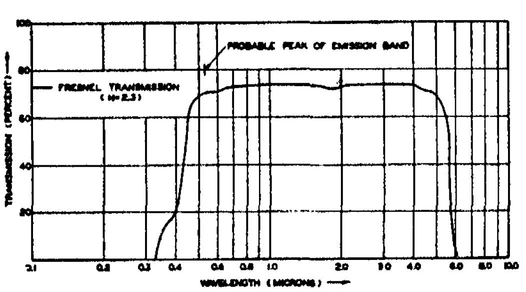

FIG. 3. Transmission curve for pale yellow-green cadmium tungstate. Coloring by trace impurities can change this curve very appreciably and may introduce serious absorption of the luminescent radiation.

cing crystal using a Bausch and Lomb spectroscope. The hardness measurements, specific gravity determinations, and the data on chemical resistivity were obtained in this Laboratory as were also the crystal parameters of $CdWO_4$; the remaining data are taken from the literature.

Because of the high density of the crystals and the presence of a high concentration of tungsten ($Z=74$) very considerable absorption of gamma- and x-rays is to be expected. The absorption coefficients have been calculated on the assumption that the different ions present in the crystal absorb independently of one another. In the gamma-ray region the absorption coefficients due to photo-electron production (τ_{PE}), Compton scattering (τ_C) and a pair production (τ_{PP}) were calculated from the corresponding values[2] for Pb by use of the formulas:

$$\begin{aligned}(\tau_{PE})&=4.07\times10^{-7}(\rho Z^4/A)(\tau_{PE})_{Pb}\\(\tau_c)&=0.224(\rho Z/A)(\tau_c)_{Pb}\\(\tau_{PP})&=2.72\times10^{-3}(\rho Z^2/A)(\tau_{PP})_{Pb},\end{aligned}\qquad(1)$$

where ρ is the density of the material in question in the crystal, A is its atomic weight, and Z its atomic number. The results of these calculations are shown in Table II where the contributions from the three processes are listed separately. It is interesting to note in this connection that the contribution of oxygen atoms to the Compton coefficient is not negligible, a typical value being 0.086 cm^{-1} for 1-Mev gammas. For comparison, the values of τ_c for anthracene calculated on the assumption that only the carbon absorbs are also presented in Table II; τ_{PE} and τ_{PP} are negligible for this substance over the range covered. The data are plotted in Fig. 4. In the x-ray region standard mass absorption coefficient data[3] were used in the usual way. The data are presented in Table III where both the mass and linear absorption coefficients at a number of useful wavelengths are given. The thickness of crystal necessary to reduce the incident beam to 0.1 of its initial intensity, ($2.303/\mu$), is also given.

A quantity of considerable interest in the design of scintillation counters is the refractive index of the phosphor crystal since this governs the amount of luminescent radiation which escapes from the crystal. This arises from the fact that the light is generated in a medium of refractive index $\eta>1$ but, at least in the 931A type photo-multiplier tube, it must traverse a region of refractive index $\eta=1$ in getting to the photosensitive cathode. It is well known that light traveling from an optically dense medium to a less dense one suffers partial reflection; the fraction reflected varies with angle of incidence on the surface and becomes 100 percent at angles equal to or greater than the critical angle α which is given by $\alpha=\sin^{-1}(1/\eta)$. In order to make these results more nearly quantitative, let us consider the somewhat idealized case of a com-

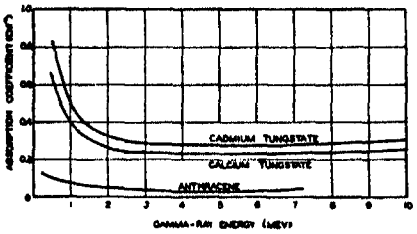

FIG. 4. Gamma-ray absorption coefficients.

pletely transparent, isotropic crystal in the form of a rectangular parallelepiped which is free from scattering material and which has optically polished faces. (Actual crystals of scintillation counter interest are not isotropic, but the indices are so close together that no serious error is introduced by neglecting the anisotropy.) Consider any volume element in the crystal in which light is being isotropically generated and drop perpendiculars from it to the six faces. If now the index of refraction be $\geqslant\sqrt{2}$, and this covers all crystals of scintillation counter interest, the only light which can escape from the volume element will be that emitted into the six cones of half-angle α which have the above perpendiculars as axes. The solid angle subtended by a whole sphere is 4π while that subtended by a cone of half-angle α is $2\pi(1-\cos\alpha)$, hence the fraction of the light from the volume element emitted into each cone is $\frac{1}{2}(1-\cos\alpha)$. It follows that a fraction of the light given by $1-3(1-\cos\alpha)=3\cos\alpha-2$ is permanently entrapped in the crystal. In Table IV the percentage of light escaping from each face and the percentage entrapped under the above assumptions is listed for a number of crystals of scintillation counter interest. It is evident that very serious losses may occur with the higher index materials. Similar results hold for other geometric forms although the quantitative calculation may become extremely difficult in some cases. For example, it is not difficult to show that the fraction of light permanently entrapped in a sphere with an optically smooth surface is $(\cos\alpha)^3$. This quantity is also listed in Table IV and shows a sphere to be a somewhat less favorable shape than a rectangular prism of comparable volume.

Some of the light emitted into the favorable cones above will also be reflected in accord with Fresnel's laws. The fraction of the incident light transmitted may be computed as a function of angle of incidence by use of well-known formulas,[4] and is given by $(T_{\parallel}+T_{\perp})/2$ where $T_{\parallel}$ is the transmission coefficient for light the electric vector of which is in the plane of incidence and $T_{\perp}$ is that for light having its electric vector perpendicular to the plane of incidence. This function is plotted in Fig. 5 for materials which span the range of refractive indices of scintillation counter interest. Consider, however, a ray of light emitted into that favorable cone which has its axis perpendicular to the "front" face. A fraction of it, given by the above function, will be transmitted; the remainder will be reflected and strike the back face at the same angle of incidence either directly or after total reflection from a side face. The same fraction will be transmitted and the remainder will hit the front face again, still at the same angle of incidence. Because of the assumption of complete transparency, all the light will eventually emerge as this process is repeated. Furthermore, the amount lost through the back face will be exactly compensated by a corresponding fraction of the light originally directed into the favorable cone based on the back face. Hence all the light in the favorable cones escapes in the case considered; none of that not emitted into these cones. It is also of interest that light directed toward the "front" face can never escape from a side face. In practice, of course, there is always some scattering material present which changes the direction of a portion of the light allowing it to escape and there is always some absorption which degrades the remainder into heat.

It is possible, by suitable design, to avoid the above losses to a considerable extent. When using the 5819 photo-multiplier tube this can be done by cementing

the crystal to the tube envelope so that the light never passes through air (or vacuum). Under these circumstances the refractive index of the crystal in the formulas for trapped radiation is replaced by the ratio of this index to that of the tube envelope. This is a smaller number than η and hence a larger fraction of the light can escape. In fact, it can be shown that if this ratio becomes less than 1.225 all the light escapes. Under these circumstances the light from a rectangular prismatic crystal cemented to the 5819 tube and silvered on the other five sides would be almost completely funneled to the photo-cathode. If, however, the ratio were still 1.414 or greater not more than one-third of the total light would strike the photo-cathode—i.e., that directed toward the front and back faces.

The methods of the last paragraph are not applicable to the 931A type tube because the light must traverse a region of refractive index $\eta=1$ in reaching the photo-cathode. It may be shown that attaching a film or a plate of different refractive index between the crystal and air (or vacuum) would not change the over-all critical angle and hence the amount of light entrapped. Under these circumstances it is probably best to introduce a non-absorbing, scattering medium into the crystal or to roughen one or more of its surfaces to produce diffusion. In this way the direction of the light rays is changed and, in the absence of absorption, all the light can eventually escape since it will ultimately reach a surface at an angle less than the critical angle. Precipitation of a cloud of transparent particles of different refractive index in the body of the crystal, controlled introduction of many very fine bubbles, and rough grinding of the surfaces have all been found to be very efficient for this purpose. A mosaic made up of several crystal bars, the adjacent surfaces of which have been rough ground before cementing together with a transparent cement of different refractive index, makes a particularly favorable arrangement for a coincidence device in which two photo-cells look at the same crystal.

When working with a 931A type photo-multiplier tube some care must be taken in the selection of the mirror arrangement to be used if the maximum gain is to be obtained. Marshall, Coltman, and Bennett[5] have shown that the photo-cathode in this tube is effectively 12 mm×5 mm in linear dimensions and it is situated behind a focusing grid at some distance inside the envelope. This fact limits the solid angle of radiation which can be accepted by the photo-cathode to a rather small fraction of that of a hemisphere. The light emitted by each face of the phosphor, on the other hand, is spread into a whole hemisphere but that emerging near grazing refraction is somewhat decreased in intensity due to the falling off of the curves of Fig. 5 as the critical angle is approached and hence the longer path of these rays in the crystal. If the crystal is much larger than the photo-cathode, the light from the four side faces is inevitably lost (for $\eta \gtrsim 1.414$) and hence not more than one-third of the total light can be used even if the crystal be silvered. If the crystal is smaller than the photo-cathode, there will be a small loss attendant upon silvering the side faces because a portion of this light would, in the absence of the silvering, reach the photo-cathode. Evidently silvering the back face would about double the light reaching the photo-cathode. However, the most favorable mirror arrangement for a small crystal is probably similar to that of Marshall, Coltman, and Bennett who use a hemispherical mirror the diameter of which is large relative to the crystal. In this way, instead of the approximately two-fold gain realized by the silvered crystal, a gain approaching sixfold is possible. Crude experiments with aluminum foil have indicated the essential soundness of this approach.

TABLE IV. Percentage of generated light emitted from each face of a rectangular prism$^{(A)}$ and percentage entrapped in such a prism$^{(B)}$ and in a sphere$^{(C)}$ on the assumption of polished, optically smooth faces, no scattering, and no absorption. $\alpha=\sin^{-1}(1/\eta)$ where η is the refractive index.

Crystal	η	(A) $100(1-\cos\alpha)/2$	(B) $100(3\cos\alpha-2)$	(C) $100(\cos^3\alpha)$

TOTAL ANODE CURRENT MEASUREMENTS

In most of the experiments to be reported a single 1.67-mg radium source was used. It was shielded with steel and, after shielding, gave 1.4 mr per hour at 1 meter with a standard survey-meter. The photo-multiplier tube was a selected 1P21 type operated at

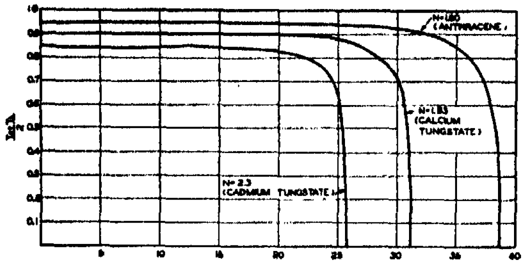

FIG. 5. Fresnel transmission function.

115 volts per dynode obtained from Eveready Mini-Max Batteries (No. 493) by means of a suitable voltage divider. The voltage drop in the load resistor in the anode circuit of the photo-multiplier tube was bucked out as indicated by a Leeds and Northrup Model 2420C galvanometer having a sensitivity of 0.019 μA/mm, and the potential across the bucking network was read. The photo-multiplier tube, attached crystal and voltage divider were mounted in an aluminum box which had a very thin aluminum cover which could be removed to change crystals and so arranged that the crystal was irradiated through the cover. As a matter of practice the response was measured with the source at a series of distances from the phosphor and the data were plotted on log—log paper. Because of the finite size of the source compared to the distances of separation the inverse square law was replaced with an inverse 1.7 power law. Typical plots are shown in Fig. 6.

A number of preliminary experiments were carried out with crystals of different size to find the permissible range of positions with respect to the photo-cathode over which no significant variation in response could be detected. When these had been found great care was taken in centering the crystals studied to insure comparable results. Finally to correct for changes in response due to aging of the photo-multiplier tube, temperature variations, and drift of the voltage supply batteries, and thereby secure day to day reproducibility, a number of crystals were selected and maintained as standards so that they could be checked from time to time and slight adjustment of circuit elements made to secure a constant response. The variation in response to the standards was always less than 7 percent over any experiment. Whenever possible crystals being compared were ground and polished to the same shape and size. If this was not possible the relative responses were corrected to the same volume basis, although in most cases the correction was a minor one.

A series of nine identically shaped $CaWO_4$ pieces fabricated at different times and under different conditions were carefully intercompared. The anode currents with the source at 5.5 cm from the phosphor crystal ranged from 16.6 to 23.8×10^{-8} amp. with an average of 17.7×10^{-8} amp. Inspection of the samples, however, showed excellent correlation between response and the degree of cloudiness of the crystals—probably from precipitated CaO. These particles serve as diffusing media and permit escape of a larger portion of the generated light. The completely clear crystals all showed responses close to 17×10^{-8} amp. Comparison of a clear $CaWO_4$ crystal with a high quality anthracene crystal of the same shape and size prepared at the University of Rochester showed that the tungstate gave a response 3.15 times as great as the anthracene. When a clear $CdWO_4$ crystal was tested under the same circumstances, the response was 4.28 times that of anthracene. A similar comparison between crystals of $CaWO_4$ and KI(T1) showed about equal response, but it was not possible in this case to make the conditions exactly comparable.

The data of the last paragraph can be used to make a very rough comparison between the number of visible quanta emitted by the tungstates and by anthracene under identical conditions of gamma-ray stimulation. This is done by correcting for differences in gamma-ray absorption ($[1-e^{-\tau d}]$ where τ is taken from Table II and d is the crystal thickness), the amount of entrapped light $\frac{1}{2}(1-\cos\alpha)$, and the differences in response of the photo-multiplier tube to the fluorescent radiation.[6] When these corrections are applied and the above data substituted, it is found that the same number of fluorescent quanta are generated in $CaWO_4$ as in anthracene and twice the number in $CdWO_4$. However, these results may be uncertain by perhaps a factor of two because of failure of the crystal to stop the recoil electrons, etc.

The expected increase in response of $CdWO_4$ when a diffusing medium is added has also been observed. Three crystals of this material of the same color but respectively clear, partially cloudy, and entirely cloudy were compared with an anthracene crystal of identical size and shape. The relative responses to the gamma-ray source as measured by the total anode current were 4.28, 5.00, and 6.25, respectively. Use of an aluminum foil reflector somewhat more than doubled the anode current from each but left the relative response substantially unchanged. The composition of the material producing the clouds in the crystals is not known with certainty.

It has been shown in considerable detail by Kröger[7] that the tungstate phosphors show a considerable temperature dependence of luminescent output when stimulated with ultraviolet light. As may be seen from Fig. 27 of reference 7 each of these phosphors tends to approach a limiting low temperature efficiency which is maintained over a considerable range. On heating, however, a characteristic temperature of the phosphor is reached at which the response begins to decrease and this decrease continues gradually and non-linearly toward zero with further heating. The same behavior is observed when the crystals are used for gamma-ray counting as is seen in Fig. 7 where the fraction of the response at 30°C is plotted against temperature. These data were collected by placing the crystals in an oven at some distance from the photo-multiplier tube and "piping" the light to it through a Pyrex rod. In this way only the temperature of the crystal was varied. The data agree quite closely with those of reference 7. The temperature of half-response is 86° for $CaWO_4$ and 118°C for $CdWO_4$. Below 40°C the temperature coefficient of the latter is seen to be zero.

A further significant difference between calcium and cadmium tungstate is associated with the afterglow following exposure to intense radiation. A sample of the former was placed near a 20 millicurie Sr^{90} beta-ray source for a period of sixty hours after which it was quickly removed and placed in front of the photo-multiplier tube in the device for measuring anode current. Strong phosphorescence was observed which decayed as shown in Fig. 8. At the two breaks in the curve the crystal was removed from the container and exposed to the room light for the indicated period of time. In each case the emission was considerably enhanced in this way but this extra luminescence rapidly decreased to the slower rate of decay characteristic of the darkened crystal. The light storage properties are rather remarkable in that the above sample still showed appreciable phosphorescence (in the form of a considerably enhanced "background" count) more than nine months after exposure to the Sr^{90} source.

When the above experiment was repeated with samples of cadmium tungstate no phosphorescence was observed after the few seconds necessary to transfer the crystals from the Sr^{90} source to the photo-multiplier tube compartment. The same relative behavior of calcium and cadmium tungstate has been observed after exposure to an intense x-ray beam ($\approx 10^6$ roentgens). So far as the writer is aware, cadmium tungstate is the only useful scintillation counter crystal which shows this complete absence of afterglow following exposure to intense radiation.

A few preliminary experiments were performed to test the response of the tungstates to x-rays. The Geiger counter on a North American Philips x-ray Spectrometer was replaced with the crystal and a 1P21 photo-multiplier tube the output of which was fed into a counting rate meter and the counts per second recorded with a Brown Recorder. The spectrum from the copper target x-ray tube was scanned by placing a cleaved single crystal of rock salt in the specimen holder. Both tungstate phosphors showed very similar behavior and both showed increased sensitivity at the shorter wave-lengths. The minimum intensity detectable at 1.54A gave 10,000 counts per minute with the Geiger tube, while the minimum detectable intensity at 0.5A gave 600 counts per minute with the Geiger tube; but part of this difference is the result of decreased efficiency of the Geiger counter at the shorter wave-lengths.

PULSES FROM THE TUNGSTATES

For some purposes the total anode current measurements are inadequate and it is necessary to count individual pulses. The electron released by the gamma-ray probably excites the phosphor in a very short time and the decay following excitation is probably exponential, although there are few enough luminescent quanta involved so that considerable statistical fluctuations are to be expected. If it be further assumed that a constant fraction of the light emitted each instant reaches the photo-cathode, the current pulse in the load resistor will be of the same form. This seems to be confirmed by the few studies that have been made with very fast oscillographs. The only amplifiers available for the present work, however, had rise times of about 0.15 microseconds which is of the same order of magnitude as the probable time constant of the exponential phosphor decay. Investigation of the transient response of broad-band amplifiers to such pulses indicates that the pulse observed will have a characteristic shape which will allow the time constant for phosphor decay to be estimated if the rise time of the amplier is known.

Many pulses from the tungstates have been photographed using an Atomic Instrument Company Model 204B Linear Amplifier and a DuMont Model 248A Oscillograph. The traces observed using a triggered sweep of 2.5 microseconds duration are consistent with a time constant of phosphor decay of about 0.5 microseconds. In addition, calcium tungstate tended to show one or more smaller peaks on the same trace. In general, these had less than one-third the amplitude of the triggering pulse and were observed much less frequently with cadmium tungstate and with anthracene. In view of the long afterglow of the calcium compound mentioned earlier, these subsidiary peaks may represent energy stored in the phosphor and released compara-

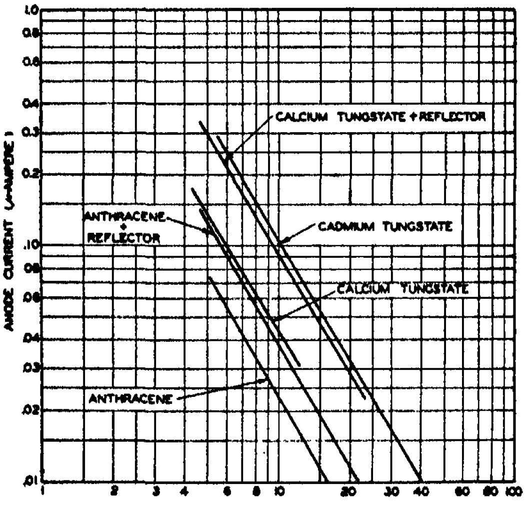

FIG. 6. Total anode current at various crystal to source distances.

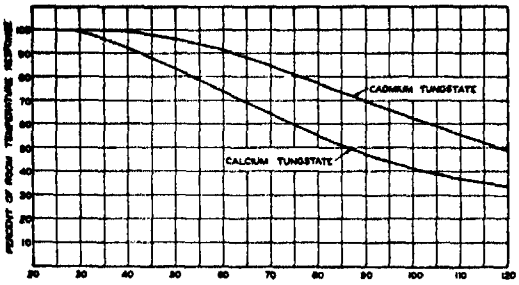

FIG. 7. Temperature dependence of luminescent output.

tively slowly, perhaps by some phosphorescent mechanism distinct from that for the main luminescence. In effect, the pulses have long, low tails. In cadmium tungstate and anthracene the small peaks observed can probably be accounted for by noise and by direct response of the photo-multiplier tube to gamma-rays which is by no means negligible. Possibly this "tail" of phosphorescent emission would account for the observation by Bell[8] that the decay time of scheelite is about 10 microseconds. It is hoped that data with more suitable recording equipment can be obtained soon which will settle this question.

Anthracene, in common with NaI(Tl), has an especially favorable pulse height distribution curve showing a considerable fraction of large pulses.[9] In order to compare the pulse height distribution from this material with that from the tungstate phosphors, the discriminator circuit of the Model 204B Amplifier was used in connection with a scale of 64 scaler and impulse register to count the pulses at various discriminator settings. It proved to be desirable for this purpose to cool the photo-multiplier tube to dry ice temperatures. In one set of experiments the crystals were also cooled while in another the crystal was kept at room temperature and the light "piped" to the cooled photo-multiplier tube through a Pyrex rod. The results are shown in Figs. 9 and 10 where counts per minute above background are plotted against the grid bias of the discriminator. Previous experiments had proved that these grid bias values were accurately proportional to the height of the pulses in volts which triggered the multivibrator of the discriminator; although the actual height, of course, depends on amplifier gain. It is evident from these curves that the behavior of these phosphors is only slightly affected by the decrease in temperature and that the anthracene shows a considerably greater proportion of large pulses. However, extrapolation to zero pulse height would give a decidedly larger count rate for the tungstates than for anthracene in agreement with the total anode current measurements reported above.

CONCLUSIONS

Calcium and cadmium tungstate crystals show some very interesting properties as scintillation counter phosphors. They are high melting materials, chemically inert toward most of the reagents with which they are likely to come in contact, and in general they are not difficult to fabricate. The pronounced cleavage of $CdWO_4$ may be advantageous in some applications. Because of their high density and because of the presence of elements of relatively high atomic number they show strong absorption of gamma-radiation. This has a corollary that they show a considerable energy dependence as gamma-ray detectors, but this can probably be minimized by suitable methods.

Although the pulse height distribution of the tungstates is seen to be less favorable than that of anthracene, the total response to the gamma-rays of radium as measured by the anode current of the photo-multiplier tube is greater than that of anthracene by factors of 2 to 6 and undoubtedly could be made even greater by proper design. The light yield of the tungstates is probably not greatly different from that of anthracene. The total anode current from the tungstates is about the same as that from thallium activated potassium iodide. Cadmium tungstate shows a zero temperature coefficient of luminescent output in the vicinity of room temperature, and is probably unique in showing no afterglow after exposure to extremely intense radiation.

The pulses from the tungstates while well under a microsecond in duration are undoubtedly considerably

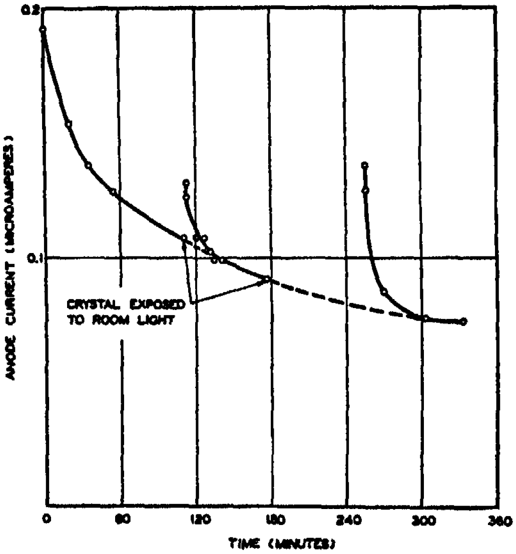

FIG. 8. Decay of calcium tungstate phosphorescence after 60 hours' exposure to a 20 mc SR^{90} source. At the two points indicated by the beginning of the broken line the crystal was removed from the photo-multiplier tube chamber and exposed to room light. When replaced in front of the photo-multiplier tube and measurements resumed the points on the solid line following the break were obtained. Note especially the greatly enhanced emission produced by the exposure to light. A portion of the initial slope may have been caused by the brief exposure of the crystal to room light during transfer to the photo-cell chamber.

longer than those from the organic phosphors. Kröger[7] has shown that the characteristic emission of the tunstates is associated with the $WO_4^=$ ion and probably approximates an atomic emission line broadened by lattice vibrations. It seems reasonable that this is the only effect observable in $CdWO_4$ where the pulse appears to be less than 0.8 μsec. in duration. In Scheelite, however, the long phosphorescence following exposure to intense radiation and the photo-sensitivity during this phosphorescence, together with the delayed peaks seen on the oscillograph traces of the pulses, suggest that a typical phosphor mechanism associated with lattice imperfections and electron traps may also be operative. Randall and Wilkins[10] have reported photoconductivity in pressed $CaWO_4$ powders, but this result was not confirmed by the single crystal measurements of Klick and Schulman.[11] However, it appears that the lattice effect, if present, represents a rather small part of the total luminescence and hence may not have been detectable in these measurements.

In conclusion the writer wishes to acknowledge the very competent assistance of Mr. Ontario H. Nestor of this Laboratory who carried out many of the measurements reported, and to thank Dr. W. G. Eversole and his co-workers for supplying the crystals. To Dr. L. I. Dana and Dr. J. M. Gaines he is deeply indebted for many very helpful discussions of the problem and for permission to publish this work. Professor Brian O'Brien has given much valuable advice on the optical problems.

A Low Frequency Sinusoidal Voltage Source

LOUIS A. ROSENTHAL
Rutgers University, New Brunswick, New Jersey

(Received December 1, 1949)

The low frequency range of an audio oscillator can be extended to d.c. by means of a heterodyning circuit using power line frequencies as a reference. The voltage wave forms are essentially sinusoidal and can be used for certain novel tests. A theoretical discussion of the beating phenomenon is included with particular applications and observed results.

A NUMBER of interesting applications exist for a low frequency sinusoidal voltage source. Frequencies extending from 20 c.p.s. to near d.c. can be obtained with the circuit described and the range of the normal audio oscillator is thus extended. The method is essentially a beating method in which an audio oscillator is heterodyned with a stable frequency source. The 60-cycle power line is excellent for the reference frequency and a Hewlett-Packard oscillator (200 B), after a sufficient warm-up period, is a very stable variable frequency source.

Wave forms can be observed on a recording-type meter such as an Esterline-Angus or Brush recorder and the period can be ascertained by knowing the chart speed. Figure 1 is a recording of some wave forms that can be obtained. Since the recorder used* has a -3-db response at approximately 1 cycle per second, the range of usable frequencies was limited. Any variable frequency test must take into account the response of the recorder.

It is worth while to mathematically describe the behavior of the modulator.[1, 2] The circuit is shown in Fig. 2. A voltage of frequency "ω_1" feeds the two peak rectifiers 180° out of phase. In addition, another signal "ω_2" is fed in phase to both rectifiers. If either signal goes to zero, the output will likewise be zero. Figure 3 shows the vector voltage addition that takes place. The locus of the vector voltage "ω_2" is a circle and its relative angular velocity is "$\omega_2-\omega_1$." Since the detectors are essentially peak detectors, the actual output voltage should be the difference between the amplitudes E_1 and E_2.

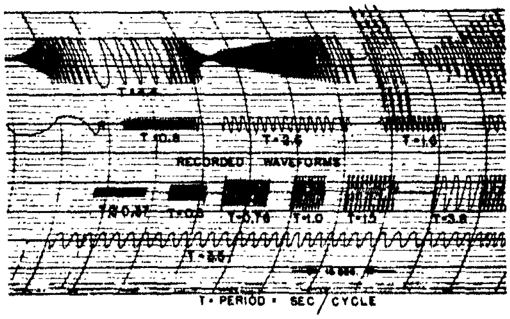

FIG. 1. Some typical recorded voltage wave forms. The frequency and amplitude can be controlled independently.

The magnitude of the voltage applied to the upper diode is

$$|E_1|=(A^2+B^2+2AB\cos\theta)^{\frac{1}{2}},$$

and that of the lower diode,

$$|E_2|=(A^2+B^2-2AB\cos\theta)^{\frac{1}{2}},$$

where $\theta=(\omega_2-\omega_1)t$. If a modulation factor is intro-

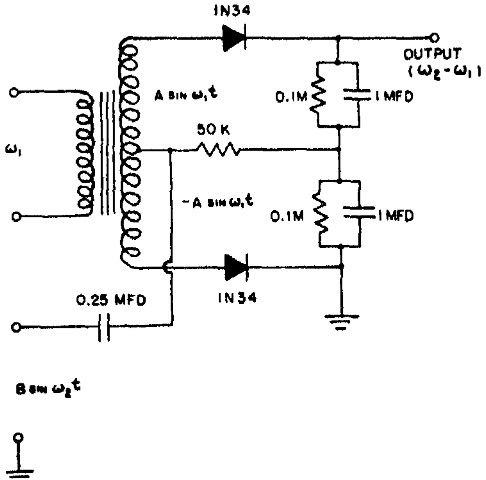

FIG. 2. The modulator circuit. The transformer is a center-tapped filament transformer; 4 volts r.m.s. on each side of center-tap.

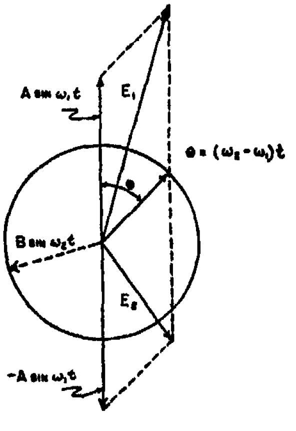

FIG. 3. The vector addition of the two voltages of different amplitude and frequency. The voltages E_1 and E_2 are the amplitudes to be detected.

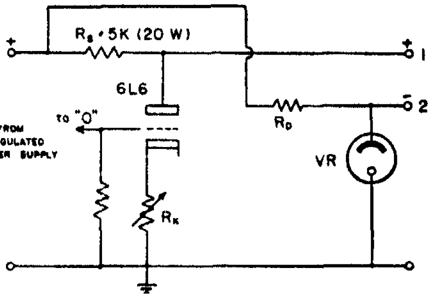

FIG. 4. The power stage driven by the modulator (see text).

duced as

$$m=\frac{2AB}{A^2+B^2},$$

then

$$|E_1|=(A^2+B^2)^{\frac{1}{2}}(1+m\cos\theta)^{\frac{1}{2}}$$
$$|E_2|=(A^2+B^2)^{\frac{1}{2}}(1-m\cos\theta)^{\frac{1}{2}}.$$

The RC filter and peak rectifier can produce a voltage that follows the magnitude, provided the modulation factor is not its maximum of 1 and the RC time constant is properly chosen.

The voltage across the two filter networks is

$$\begin{aligned}E_0&=|E_1|-|E_2|\\&=(A^2+B^2)^{\frac{1}{2}}[(1+m\cos\theta)^{\frac{1}{2}}-(1-m\cos\theta)^{\frac{1}{2}}].\end{aligned}$$

Expanding the result in a series there results

$$\begin{aligned}E_0=(A^2+B^2)^{\frac{1}{2}}\bigg[1&+\frac{m\cos\theta}{2}-\frac{(m\cos\theta)^2}{8}\\&+\frac{3}{48}(m\cos\theta)^3\cdots-1+\frac{m\cos\theta}{2}\\&+\frac{(m\cos\theta)^2}{8}+\frac{3}{48}(m\cos\theta)^3\cdots\bigg].\end{aligned}$$

Collecting terms there results

$$E_0=(A^2+B^2)^{\frac{1}{2}}[m\cos\theta+1/8(m\cos\theta)^3\cdots].$$

Thus, there is some distortion present which decreases rapidly for small values of "m." The maximum possible value for "m" is 1 where $A=B$. If one of the injected voltages is twice the other then $m=0.8$, while for a three to one ratio, $m=0.6$. The output amplitude to be expected is

$$|E_0|=m(A^2+B^2)^{\frac{1}{2}}=\frac{2AB}{(A^2+B^2)^{\frac{1}{2}}}$$

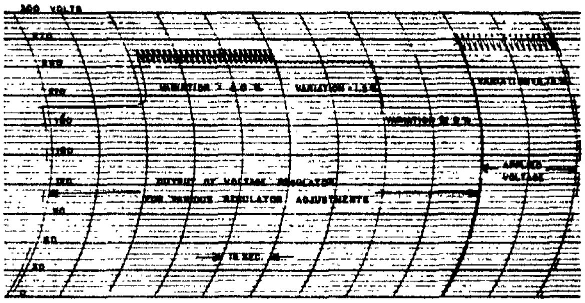

FIG. 5. The low frequency ripple before and after the regulator is observed for various regulator adjustments.

and the frequency is essentially the difference frequency "$\omega_2-\omega_1$."

The modulator, being of high internal impedance, can drive a power tube and the low frequency output can be obtained with or without a d.c. component. Figure 4 is such an arrangement. A well-regulated power supply is shunt modulated by the 6L6 as a triode. The output of the low frequency modulator is applied to the grid, and an adjustable R_k allows various d.c. voltages to appear between terminal 1 and ground. If a signal "e_g" is applied at "0," a voltage variation of

$$\frac{uR_se_g}{(1+u)R_k+R_p+R_s},$$

where u, R_p = tube parameters, will appear at terminal 1. The d.c. component can be altered by adjusting "R_k." To cancel out the d.c. component a voltage reference tube or battery can be used. Thus the amplitude of oscillation, frequency, and average value can be controlled independently. Other circuits might suggest themselves depending upon the particular application in mind.

As a typical application, consider the testing of a voltage regulator circuit. The recording milliammeter is converted to a recording voltmeter by a proper series resistance. A d.c. voltage with a superimposed alternating component is applied to the regulator, and the voltage before and after the regulator is recorded (see Fig. 5). A quantitative evaluation of the regulation properties can be made.

My thanks are extended to Mr. W. Kurylo and Mr. H. Borkan of the Department of Electrical Engineering, who assisted in the preparation of this report.

A Photo-Multiplier Gamma-Ray Detector

J. D. Graves and G. E. Koch
Naval Radiological Defense Laboratory, San Francisco, California

(Received December 1, 1949)

The sensitivity of the RCA 1P21 photo-multiplier to gamma-radiation has led to the investigation of the characteristics of this tube as a gamma-ray detector. The range, linearity, directional dependence, temperature dependence, applied voltage regulation requirements, and radiation energy dependence were determined for several tubes. Preliminary results concerning the ability of the tube to maintain a calibration are given. A basic circuit for such a detector is given.

In many high intensity measurements (order of 10 r per hr.), where the scintillating phosphor must necessarily be diminished in size or efficiency to limit the total current from the photo-multiplier, the main contribution to this current proved to be due to the action of the gammas directly upon the tube. This led to the investigation of the RCA 1P21 photo-multiplier tube without a phosphor as a possible detector of high intensity gamma-radiation. For high gamma-radiation fields such a detector would incorporate many of the desirable features of an integrating-type scintillation counter without the difficulties usually accompanying the use of a phosphor.

To determine the extent to which such a device could be applied as a gamma-radiation detector, the following characteristics of the 1P21 photo-multiplier were studied:

(a) the extent of the detectable range of gamma-radiation intensity from a radium source;
(b) the linearity of response as a function of radiation intensity;
(c) the response of the tube as a function of the direction of the impinging gamma-radiation;
(d) the temperature effect on the sensitivity from −196°C to +70°C using a fixed radiation intensity;
(e) the signal current output as a function of the total voltage applied to the tube;
(f) the response of the tube to equal roentgen intensities in the energy range from 40 to 180 kv as compared to 1.2 Mev.

APPARATUS AND EXPERIMENTAL METHODS

The detector is shown schematically in Fig. 1. The "probe" consists of a blacked-out 1P21 photo-multiplier in a metallic container to eliminate non-penetrating radiations and to provide electrical shielding and protection from shock. A negative battery supply was used to operate the photo-multiplier. Two stages of direct coupled amplification were used. To insure operation in a region where the amplifier tube characteristics are linear, and to obtain greater sensitivity, it was desirable to use a sensitive meter (0–20 μa) in the plate circuit. Metering the output of the photo-multiplier was achieved by initially shunting the meter, adjusting the grid bias for linearity of the plate current over the 20-μa range, and finally balancing out this plate current by adjusting the current flow from the meter battery. In this manner any negative voltage developed across the anode load resistor of the photo-multiplier gives a positive indication on the meter. In the most sensitive position a radium gamma-flux of 1.2 mr per hr. gave full-scale deflection at room temperature.

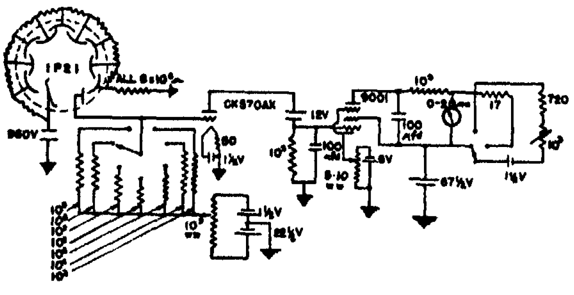

Fig. 1. Schematic diagram of the circuit used in the determination of the gamma-radiation detection characteristics of the 1P21 photo-multiplier.

The linearity of response and intensity range of the detector were determined by placing a 100-mg radium pill at various distances from the photo-multiplier, observing the plate current, and calculating the gamma-intensity at the photo-multiplier.

The response of the detector as a function of the direction of the impinging radiation was measured by moving a 1-mg radium pill around a circular path 40 cm in radius in planes perpendicular to and containing the axis of the tube.

The effect of temperature on the response of the photo-multiplier was measured with the photo-multiplier mounted in a special container designed to allow operation throughout the temperature range from −190°C to +70°C. This container was first heated to 70°C and kept at this temperature until temperature equilibrium was established as indicated by a constant output. The temperature of the container was then rapidly lowered approximately 5°C, and temperature equilibrium was again established. This procedure was repeated until liquid-nitrogen temperature was reached. After reaching liquid-nitrogen temperature equilibrium, the container was allowed to warm to room temperature at a rate which required about 8 hr. By a similar gradual process the container was then heated to 70°C. The entire temperature cycle required about 18 hr.

The energy dependence of the photo-multiplier or the response of the tube to equal roentgen intensities of varying energy was determined in the region from

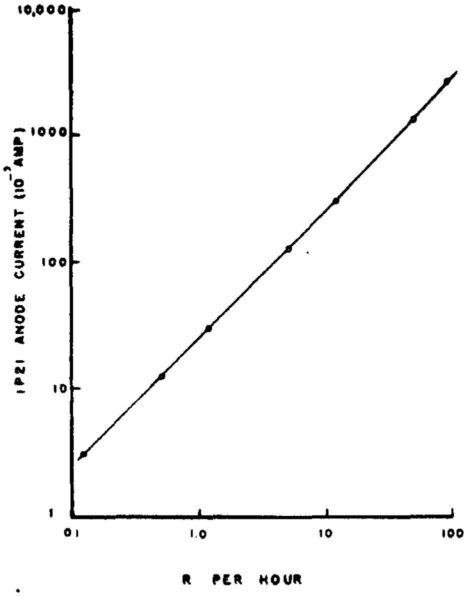

FIG. 2. 1P21 anode current as a function of gamma-radiation rate from a radium gamma-source.

40 kv effective to 180 kv effective and at 1.2 Mev by exposing the photo-multiplier to the radiations from a commercial 250-K.V.P. x-ray machine and a 200-mC cobalt 60 gamma-source. The K.V.E. output of the x-ray tube was varied by variation of the peak voltage applied and filtration, and was determined by the conventional measurement of the half-value layer of copper. Intensities were measured in the x-ray region by observing the discharge rate in thimble chambers exposed at the actual time of photo-multiplier exposure. The intensity of the cobalt 60 gamma-radiation incident upon the photo-multiplier was calculated. A total of five tubes were tested. The results presented are for one of these tubes.

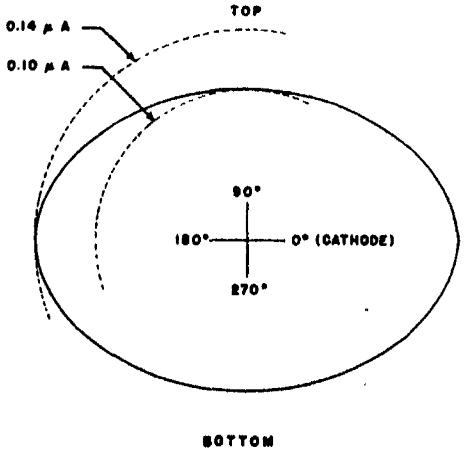

FIG. 3. Directional response of the 1P21 to a point source of radium gamma-radiation 40 cm from the center of the tube and in a plane containing the axis and intersecting the cathode of the tube.

DISCUSSION OF RESULTS

Detectable Range of Radiation Intensities

With the fixed voltage supply used, the detectable range of gamma-radiation was from 0.12 mr per hr. to 100 r per hr. The lower limit of this range is a function of the total amplification available and could theoretically be extended. When that portion of the total current from the photo-multiplier contributed by the action of the gamma-radiation is comparable to the fluctuations in the dark current, the meter time constant must be increased to minimize the effect of these fluctuations as observed on the meter. This time constant is the factor determining the lower practical limit of the detector. With the 0.1-sec. time constant used here, 0.12 mr per hr. was the lowest gamma-flux detectable. This lower limit varies by a factor of about two for the five tubes tested due to the variations in the dark current fluctuations from tube to tube.

The upper limit of this instrument, 100 r per hr., is not the true upper limit of the instrument but is determined by the fixed circuit parameters used. At this gamma-radiation intensity, the current output from the photo-multiplier was comparable to the maximum current available, as limited by the 8-megohm voltage-dropping resistors used in the photo-multiplier power supply. By reducing the values of these resistors and reducing the voltage applied to the photo-multiplier, it would be possible to extend the upper limit of this instrument manifold.

Linearity of Response

The current output of the photo-multiplier as a function of radiation intensity is shown in Fig. 2 for the range of intensities from 0.1 to 100 r/hr. The response of the photo-multiplier is seen to be linear throughout this range. The output of the amplifier was linear on every range with the same slope, so that only a single scale multiplier was required for each range. As a matter of convenience the photo-multiplier anode load

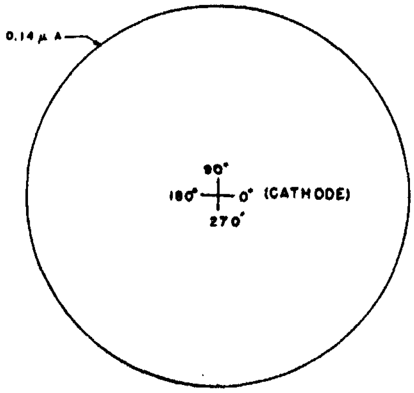

FIG. 4. Directional response of the 1P21 to a point source of radium gamma-radiation 40 cm distant from the center of the tube and in a plane perpendicular to the axis and bisecting the cathode of the tube.

resistors were adjusted so that the multiplier increased by a factor of ten with successively increasing ranges. All tubes tested exhibit a linearity in response; however, a slight shift in applied voltage is necessary to maintain a calibration between tubes.

Directional Response

The directional properties obtained are shown in Figs. 3 and 4. For all five tubes, a 40 percent change in current is observed when the source is moved from a point on the axis of the tube 40 cm above or below the center of the cathode to a point equally distant in a plane perpendicular to the axis and through the center of the cathode (Fig. 3). There is no observable difference in the response of the tube to equal radiation flux from the top or the bottom of the tube. It may be seen from Fig. 4 that the response of the tube is independent of the direction of the impinging radiation in a plane perpendicular to the axis of the tube and passing through the center of the cathode.

Effect of Temperature

The temperature dependence of the current output of the tube is indicated in Fig. 5 for increasing temperatures and for decreasing temperatures. The slight difference in appearance of the two sets of data may be due either to a difference in the physical position of the dynodes, because of expansion and contraction, or to a lag in the emission properties of the surfaces. Figure 5 shows these temperature characteristics to be independent of applied photo-multiplier voltage. It may be seen that the contribution of the dark current to the total current from the photo-multiplier increases rapidly with increasing temperature above 25°C. Above about 70°C the dark current is still rising rapidly, but the contribution due to the signal remains essentially constant. The effect of applied voltage upon these two contributing factors at 70°C is shown in Fig. 6. The temperature dependence curves were found to maintain a similarity of shape from tube to tube, but the temperature at which the decrease in sensitivity with increasing temperature began (in this case −10°C) shifted as much as 20°C in either direction. The general shape of the dark current curve with temperature was also similar, but its value at a given temperature showed 100-fold variations in magnitude from tube to tube. The choice of a photo-multiplier for maximum signal to dark current ratio throughout a temperature range should be made through consideration of the temperature at which the sensitivity of the tube begins to decrease as well as the initial signal-to-noise ratio.

Sensitivity as a Function of Voltage

The output of the tube as a function of voltage is shown for two constant temperatures in Fig. 6. In both cases the percentage change in current output is greater at the low voltage portion of the curve than it is at the high. The actual magnitude of the change, however, is greater at high voltage than at low voltage. It is significant to note that the percentage increase in dark current at the higher temperature is far greater than the corresponding increase in signal current. For example, at 1040 v, dark current is less than 50 percent of the total current, while at 1140 v, the dark current represents more than 80 percent of the total current. There is no measurable dark current present in the output at −80°C. In both cases a one percent increase in applied voltage causes a 10 percent increase in current output. Although the signal-to-noise ratio, and therefore the relative sensitivity of the signal and dark current to voltage, varies greatly from tube to tube, the sensitivity of the total current output to the applied voltage is essentially the same for all five tubes.

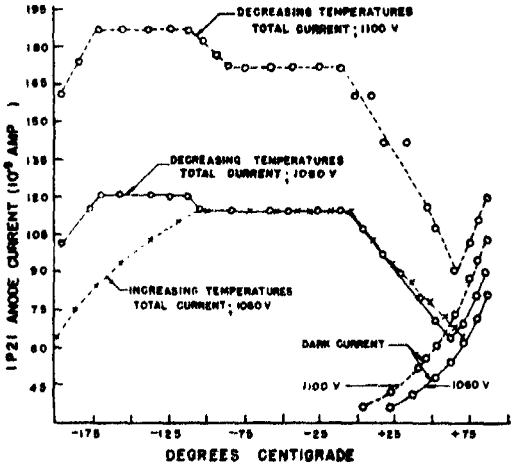

FIG. 5. The effect of temperature on the signal current and dark current output of the 1P21 for 1060 and 1100 total tube voltage. The response of the tube with increasing and decreasing temperatures is shown at 1060 v. A constant intensity of gamma-radiation was used.

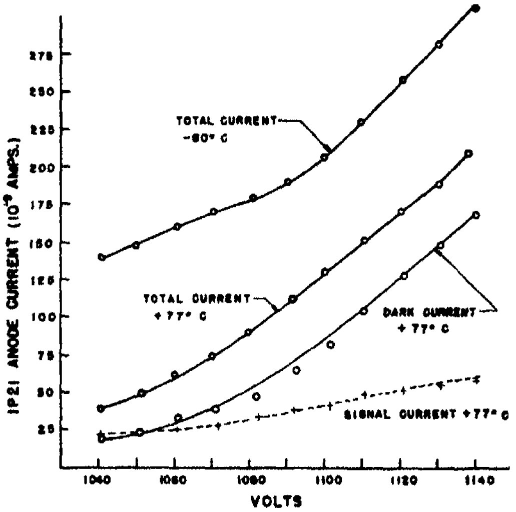

FIG. 6. The effect of applied voltage upon the total 1P21 anode current at −80°C, and the total current and dark current at 77°C.

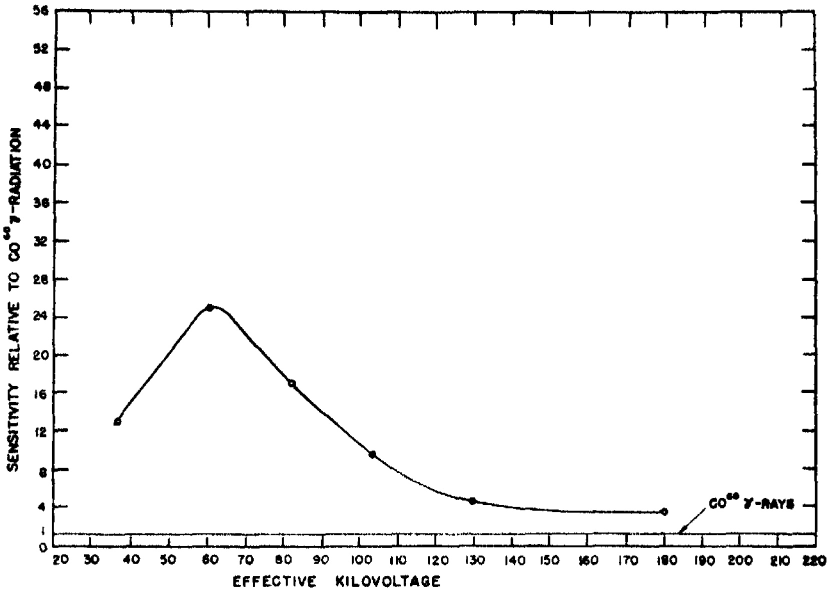

FIG. 7. The sensitivity of the 1P21 photo-multiplier to x-radiation relative to Co^{60} gamma-radiation as a function of the x-ray energies expressed in effective kilovolts.

Energy Dependence

The sensitivity of the photo-multiplier to x-radiation in the range from 40 to 180 K.V.E., relative to cobalt 60 gamma-radiation, is shown in Fig. 7. This curve is for constant roentgen radiation intensity and is therefore the ratio of current output of the tube to the ionization in air, as a function of energy.

The sensitivity of the tube to 60-K.V.E. x-radiation is seen to be 24 times its sensitivity to the 1.2-Mev gamma-radiation. At 130 K.V.E. the sensitivity is only five times that at 1.2 Mev. Although this dependence upon energy appears rather extreme, it is similar to that of other heavy-walled counters and less than that of some of the inorganic scintillation counters.

The ability of the photo-multiplier to maintain a constant anode current over long periods of time when irradiated by a constant source is being investigated at the present time. The detailed results of this investigation will be presented at some future date. It has been observed, however, that some photo-multipliers operated at a constant temperature of 0°C, a constant applied voltage, and exposed to a constant radium gamma-flux exhibit an initial decay in output current varying in time from several hours to several days and in magnitude from a few percent to 50 percent. Several of the tubes showed a constant current output for two months after the initial decay. With a few of the tubes the initial rapid decay was followed by a continued linear decay. Removal of the constant temperature conditions produced extreme variations in the output current, presumably due to the variation in room temperature.

CONCLUSIONS

The wide range, linearity of response, and directional properties of the photo-multiplier appear to make it a suitable gamma-radiation detector. The pronounced energy dependence below 0.5 Mev can introduce serious errors in measurement of radiation fields unless the energy distribution of the radiation is known and the detector calibrated for it. The use of shielding around the photo-multiplier can reduce this energy dependence considerably over wide ranges of gamma-energy. Although the use of shielding accentuates the energy dependence in the low energy region below the peak (60 K.V.E.) and tends to move the peak to higher energies, the energy dependence in the high energy region above the peak will be diminished.

In applications where the temperature range of expected use is in the region of changing sensitivity of the tube, it is necessary to provide some compensation for this effect in order to obtain a quantitative measure of the radiation field. Compensating thermistors in the metering circuit and the dark current bucking-out circuit can be used successfully over given temperature regions to minimize this temperature dependence.

The effect of applied voltage on the response of this detector presents a similar disadvantage. As a one percent change in total applied voltage causes a ten percent change in response, some degree of regulation would be required for quantitative results.

The extreme speed possible with this type of detector is of value in measurements of rapidly changing high gamma-flux.

A Dust Electricity Analyzer*

W. B. Kunkel and J. W. Hansen
Department of Physics, University of California, Berkeley, California

(Received November 15, 1949)

An apparatus is described by means of which the size and the charge of large numbers of microscopic particles can be simultaneously determined. The method is based on Hopper and Laby's work on the determination of the electronic charge, i.e., horizontal deflection of particles settling under gravity recorded photographically. The procedures involved are given in some detail, and the nature and limitations of the general results are discussed. Simplicity of operation and design are emphasized to render the instrument a workable tool in industrial research.

THE electric charges of the particles in dust clouds and aerosols are of increasing interest, both practically and theoretically. In the first place, all industrial processes in which materials in powder form are used are affected by the electrical behavior of the particles; occasionally direct use is made of the charges acquired by them.[1] On the other hand, it is obvious that the analysis of the electric charges generated at the surfaces of microscopic particles by contact and friction represents a powerful method in the study of surface phenomena because the areas involved are large compared to the volumes and because the charges that can be measured are extremely small. For these reasons, it was considered desirable to describe here a relatively simple arrangement by means of which the charges and sizes of the individual particles of a sample of a dust cloud can be determined in a single experiment.

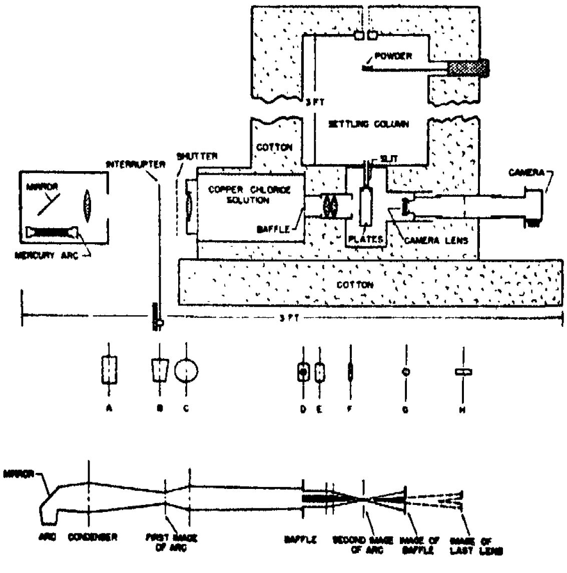

FIG. 1. Sketch of apparatus, drawn to scale in most details. Specifications of the optical elements used in our arrangement were (from left to right): mirror $d=57$ mm, $f=\infty$, first and second lens $d=56$ mm, $f=52$ mm, third and fourth lens (coated) $d=39$ mm, $f=63$ mm, fifth lens Leica objective $f=50$ mm set at $d=f/4.5$. Note: The third and fourth lens are considerably closer to the deflecting plates than shown in the diagram. All lenses are double convex.

THE APPARATUS

The apparatus is basically that designed by V. D. Hopper and T. H. Laby[2] for use in their determination of the value of the electron. Since these authors, however, did not describe their arrangement in sufficient detail for duplication, and since for the dispersion of dust clouds a large volume was needed, the system had to be redesigned and adapted to the proposed use. The apparatus required was built and put into operation in 1947.[3] As the measurements achieved by it were, however, still fairly crude and not accurate for particles below 3 microns in diameter, it was found necessary further to develop and refine the arrangement. The final successful design and operation of the device is the topic of the present article.

PRINCIPLE

The main feature of this method is to record photographically successive positions of the particles as they settle under the influence of gravity in a horizontal electric field. From the observed rate of fall, it is simple to calculate the Stokes' law diameter,[4] and from the simultaneous horizontal deflection one can thus calculate the approximate charge of the particles. Such an arrangement, however, calls for a rather special optical system to obtain a strong dark field illumination. Clearly the light cannot be introduced at right angles to the direction of observation since the plates needed to set up the field have to be vertical and solid. Illumination at acute angles introduces great difficulties of construction. Thus, observation in the direction of propagation of the light is the only practical solution. The dark field is obtained by cutting out the central cone of the highly divergent light beam so that no direct light strikes the lens of the camera. Only light scattered into this dark cone will be caught by the camera lens and thus reach the film. The complete arrangement is perhaps best explained by a simplified sketch (Fig. 1).

The optical system was designed to yield optimal contrast, i.e., maximum intensity with minimum scattered background, using the lenses at our disposal at the time of construction. It should be noted, however, that it seems possible to improve the performance of the instrument by proper changes in the dimensions indicated in Fig. 1. The following description, therefore, emphasizes the important features of the arrangement, rather than the exact dimensions. In this description items will be referred to by their letter designations in Fig. 1.

DESCRIPTION

A high pressure mercury arc, water cooled, G. E. Type A-H6, serves as light source. It has to be operated in a horizontal position, so that a prism or a front silvered mirror is needed to tilt the virtual source into an upright position. The beam is first focused at a short distance by a large lens of short focal length. Near this first image of the source, a rotating disk interrupter which is driven by a synchronous motor is introduced. The interrupter, 12 inches in radius, was geared to run at 450 r.p.m. by a motor running at 1800 r.p.m. It carried four openings of 6° (*B*), two or three of which could be closed according to the time intervals to be observed. Since the intensity emitted by the arc fluctuates with 120 maxima per second, it is essential to line the shutter disk up so that maxima occur whenever an opening crosses the optical axis. Behind the disk a hand operated shutter is mounted. It is opened only during an actual observation. This shutter keeps all light and heat out of the system when no illumination is needed. A second large lens, similar to the first, condenses the light into a slightly converging beam which passes through a large volume of aqueous solution of $CuCl_2$, reducing the infra-red intensity by about 95 percent without appreciably affecting the strong green and blue light. Directly behind this heat filter, an opaque circular baffle (*D*) of $\frac{1}{2}$-inch diameter is interposed at the center of the beam. The light that passes, mainly above and below the baffle, is admitted by an oblong aperture (*E*) to the actual analyzing chamber. At the entrance of the analyzing chamber, a system of two lenses serves to focus the beam at the center between the vertical plates to form a second and reduced image of the source. The dimensions are so chosen that the image of the opaque spot has the size of and falls on the iris diaphragm (*G*) of the camera lens (set at *f* 4.5) which is detached from the camera body and brought close to the vertical plates. The position of the camera body should be adjustable in order to make it possible to bring into focus particles that are displaced along the optical axis. It is desirable although not essential that the camera operate with a focal plane shutter. We have been using a Leica camera. If no focal plane shutter is available, the exposures can be timed by hand by means of the flange shutter between the first and second lens. A copying attachment by means of which the camera can be replaced by a ground glass plate enables visual observations to be made. Particles reaching the region of the second image which is very bright scatter much light in the forward direction, i.e., into the dark cone subtended by the camera diaphragm. However, light scattered from the last lens surfaces also reaches the camera lens and appears as background on the film. In order to reduce this disturbance, a baffle (*H*) is introduced between the camera and its iris diaphragm at the image plane of the last lens. Although it is true that this additional limitation of the solid angle reduces the intensity received by the film in some parts of the focal plane, the gain in contrast is appreciable, since most of the background is caused by the last lens (despite its being coated).

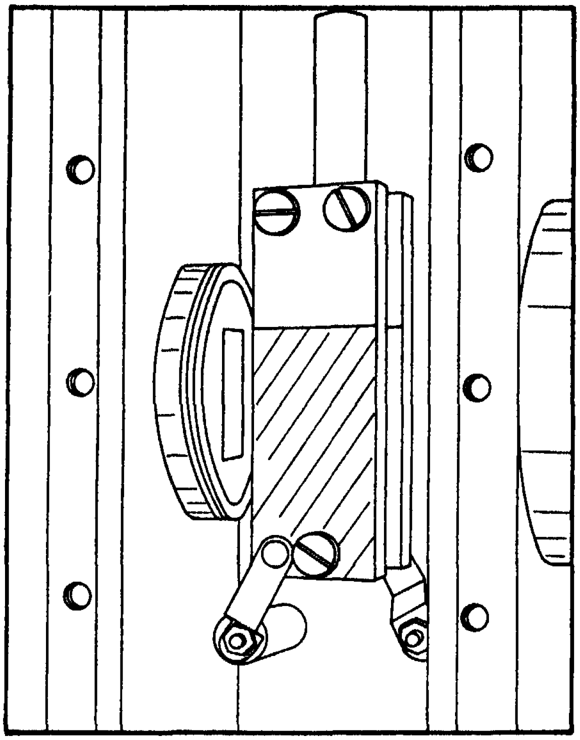

FIG. 2. View of vertical plates inside analyzing chamber. Note that the graphite coating does not reach far above the optical axis because of Eq. (5) in spite of loss of accuracy of field strength.

The sketch is drawn to scale and so are the apertures and the outline of the beam indicated under it. The dust is introduced at the top of the settling column either by blowing it through a tube or by mounting a small thimble-like container, as shown in Fig. 1, and applying a measured short blast of air from above. In either case, the volume of air blown in should be small compared to the volume of the tower in order not to cause a violent disturbance in the system. The cloud thus produced will settle under gravity and partly enter the analyzing chamber through the slit right above the region of the second arc image. The slits used were made mostly of microscope cover glass edges

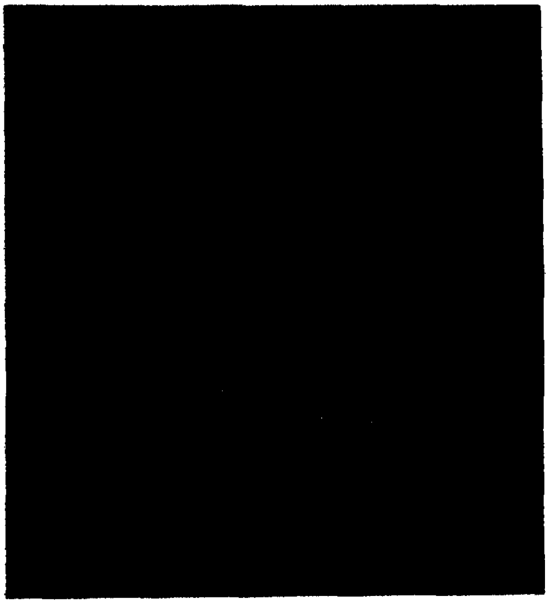

FIG. 3. Quartz particles of various sizes (2 to 9μ) settling without horizontal field. 30 flashes/sec.

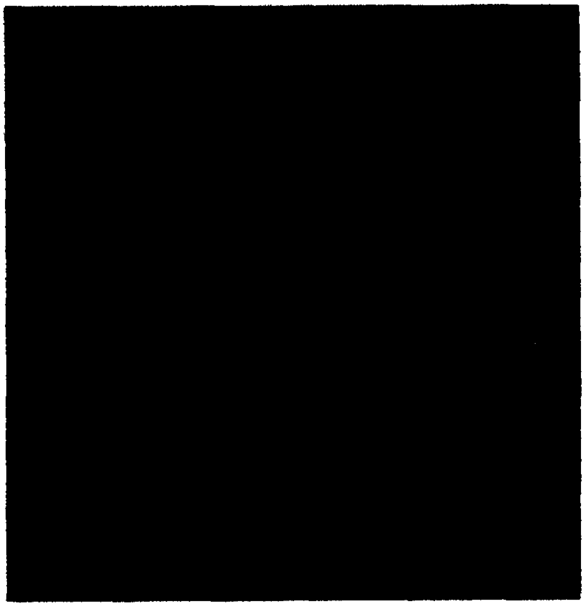

FIG. 4. Quartz smoke (mostly less than 1μ diameter) settling without field. Note how many are out of focus and how many deviate from the vertical. 7.5 flashes/sec.

which were 0.2 mm thick, 5 mm long and spaced approximately 1 mm apart. The dimensions and material of the slit are important as will be shown later.

For the observation of fine dusts, it proved advantageous to lower the slit as far down as possible to reduce the loss of particles by diffusion. The vertical plates are made of glass and coated with colloidal graphite. They are held very accurately 8 mm apart by three carefully ground quartz spacers and mounted electrically insulated parallel to the vertical walls of the chamber. Thin wire leads connect the plates through insulators to a reversing and grounding switch outside the apparatus near the camera. Ordinarily both plates are grounded, the voltage supplied by B-batteries, chiefly 180 volts, being turned on only during the actual exposures. The chamber itself is made of heavy brass mounted on a bottom plate carrying set screws and a level indicator. All surfaces inside are coated with a highly absorbing flat black paint, and all parts touched by light at grazing incidence are covered with black velvet. Since in this arrangement it is impossible to avoid light striking certain areas inside the chamber, the total time of exposure to radiation has to be limited to the utmost minimum. Only during an actual observation is filtered light admitted at the rate of at most 30 flashes, of 1/450 second each for an exposure of 1 second duration, i.e., a total illumination of not more than 1/15 second. If this illumination is not repeated after too short intervals, the absorbed energy will spread rapidly over the whole metal chamber so as not to cause any noticeable heating. After prolonged exposures, however, heating of the metal parts will result, followed by convection, rising at the walls and funneling down between the plates, increasing the apparent rate of fall of the particles. The apparatus without an elaborate thermostated heating system to maintain constant temperatures, therefore, has its limitations. If great accuracy and easy operation with long exposures are required it will be necessary to surround the entire settling tower and analyzing chamber by a thermostatic heat bath. In general, however, as in our case, wrapping the whole structure in two to three inches of cotton and keeping the room temperature constant to within a degree centigrade is all that is necessary. Under these conditions the temperature inside the system usually stayed constant within 1/100 of a degree centigrade for several hours, and the convection setting in near the end of the observation, at most, falsified the measurements on particles smaller than 1 micron in diameter. Great care should be taken to see that the camera is not shifted or tilted during a measurement. Since vibrations and shocks should be prevented from reaching the apparatus, the motor driving the rotating shutter is mounted on rubber supports resting on lead bricks, which in turn are imbedded in a large box of dry sand. No vibrations made themselves felt through this filter. A sketch of the analyzing chamber is shown in Fig. 2.

PROCEDURE

Before the actual experiments begin, the vertical as well as the correct position of the camera and the associated magnification are determined by photographing first a weighted hair hanging freely through the slit and then a small calibrated scale held in the plane of observation. To accomplish this, the apparatus has to be opened. If the same slit is used repeatedly, and if neither the camera lens nor the camera holder are moved, these operations, of course, need not be repeated. After reassembling the apparatus, sufficient time must be allowed to let the system come to complete thermal equilibrium. We actually let at least one night pass before runs were made. A long stem thermometer graded in 1/20 of degrees, the bulb of which touched the metal of the chamber, served as a check on the inside temperature.

After equilibrium is reached and all convection presumably has died down, the cloud is generated in the manner desired inside the tower near the top or it is introduced through a hole at the top of the settling column. If rapidly falling particles are expected to be present, the arc is turned on and pictures are taken at once at short intervals of, say, 10 seconds. The polarity of the horizontal *field is reversed between successive exposures to reduce the loss of particles by a steady drift toward one of the sides* caused by the bulging of the field beyond the ends of the plates. After about two minutes, when the largest particles have settled out, the intervals between pictures are gradually increased, roughly in inverse proportion to the average velocity of the particles. When after 10 to 30 minutes, the sizes and thus the rates of fall get very small, the time of exposure is increased to two, three, and finally four seconds, and the number of flashes per second is reduced by closing some of the shutter openings. This enables the measurement of particle sizes down to below two microns in diameter (depending on the density of the material). The tracks of the smallest particles of about one micron diameter and less cannot be resolved at this shutter speed. In this case the presence of completely resolved traces in the same picture are relied on to serve as a time scale. If no such traces are visible, then the scale is taken from the timing of the complete camera exposure. It would, of course, also be possible to arrange for a slower interrupter speed when these fine smoke particles are to be observed. Test runs must be made in order to determine and adjust the cloud density if possible, or to adjust the slit width so that the number of particles reaching the analyzer is neither too large nor too small for a good evaluation of the cloud properties.

Examples of tracks obtained are shown in Figs. 3 to 7. All of them are due to quartz particles. The first two pictures are taken without a field. They show that the trajectories of these particles are neither necessarily vertical nor straight. If they are very small, Brownian motion and unequal radiative heating causing photophoresis may interfere. If the particles are too heavy, their shape may cause them to skid sideways.† Figures 5 to 7 show particles of various sizes and charges. The vertical dimension of the field of view is approximately 5 mm. Since we are using the camera lens, which is corrected for distant objects, as a projector lens, particles slightly too far away will appear as circles, the diameter of which is proportional to the displacement out of focus. Similarly, point objects too close to the camera appear as blurred stars or hexagons caused by the hexagonal iris diaphragm of the camera lens.

In order to calculate the sizes and charges of the particles photographed, the negatives of the pictures

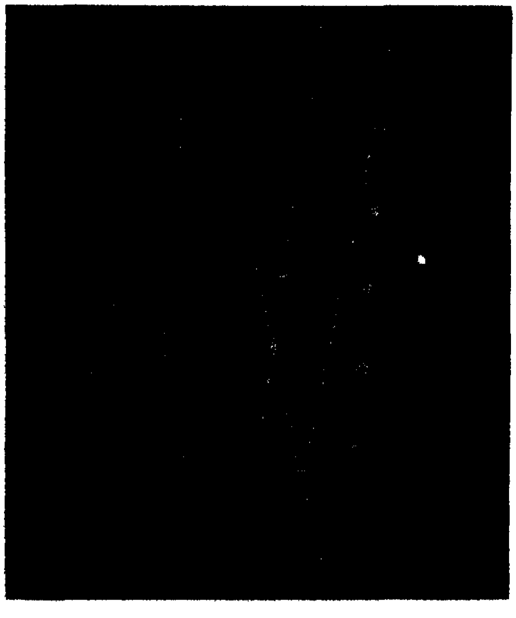

FIG. 5. Tracks of fairly large quartz particles (5 to 16μ) in a field of 225 volts/cm. 30 flashes/sec. Note the stars and circles due to particles too close and too far from the lens. Also note how the images are partially eclipsed near the upper and lower edges of the picture due to the aperture *H* in Fig. 1.

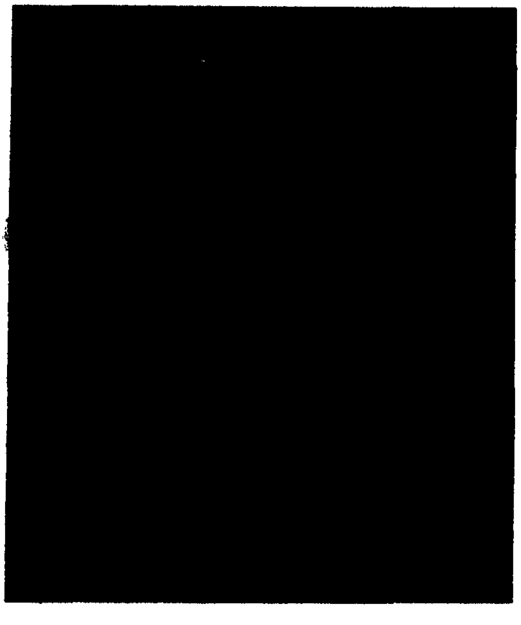

FIG. 6. Tracks of highly charged quartz particles of medium size in a field of 225 volts/cm. 7.5 flashes/sec.

---

† In a previous article it was shown that wedge-shaped platelets will appear to drift laterally as if charged. This is owing to a short time observation of the well-known helical paths of such platelets under viscous free fall.

are projected to a standard total magnification of, say, 50 onto a screen on which the vertical and horizontal displacements are easily measured. If the vertical length of a certain trace is denoted by Y and the horizontal displacement by X, the corresponding velocities are given by

$$V_x = \nu X/MN \quad \text{and} \quad V_y = \nu Y/MN,$$

where M is the magnification, ν the number of flashes per second, and N the number of intervals between dots of the trace. Using Stokes' law to estimate the particle size, we have for the diameter:

$$d = \left[\frac{18\eta V_y}{(\rho_1 - \rho_2)g}\right]^{\frac{1}{2}} = \left[\frac{18\eta\nu}{(\rho_1 - \rho_2)gM}\right]^{\frac{1}{2}} \times \left[\frac{Y}{N}\right]^{\frac{1}{2}} = A\left(\frac{Y}{N}\right)^{\frac{1}{2}}; \quad (1)$$

similarly for the charge

$$q/d = \frac{3\pi\eta V_x}{E} = \frac{900\pi\eta l\nu}{VM} \cdot \frac{X}{N} = B\frac{X}{N}, \quad (2)$$

where η is the coefficient of viscosity of the medium (air), $g = 981$, ρ_1 and ρ_2 the densities of the material and the medium respectively, and V and l the voltage (in volts) and the distance between the plates respectively. All quantities are expressed in c.g.s. units. It should be kept in mind, however, that for solid particles these formulas in general are only very approximate, since mostly we are not dealing with spheres. Both values will, at least as long as the analogy with the viscous flow holds, appear smaller than they actually are.[4] The magnitude of the error will depend on the shape and may easily exceed 10 percent, but it will hardly ever falsify the order of magnitude. This is also the reason why it is in general not necessary or justified to apply the Cunningham correction. Only for particles smaller than 1 micron, which often do not deviate appreciably from the spherical shape, will any such correction have to be considered. It should also be pointed out that the Cunningham correction opposes the shape correction, the first letting the particles fall faster than Stokes' law predicts, and the latter slowing them down again. For the same reason, the density of air can, in general, be neglected relative to the density of the material as can the temperature variation and uncertainty in the coefficient of viscosity. There is little sense in attempting to use accuracies better than 1 percent in any of the constants involved. For the objectives of these applications greater accuracy is usually not required.

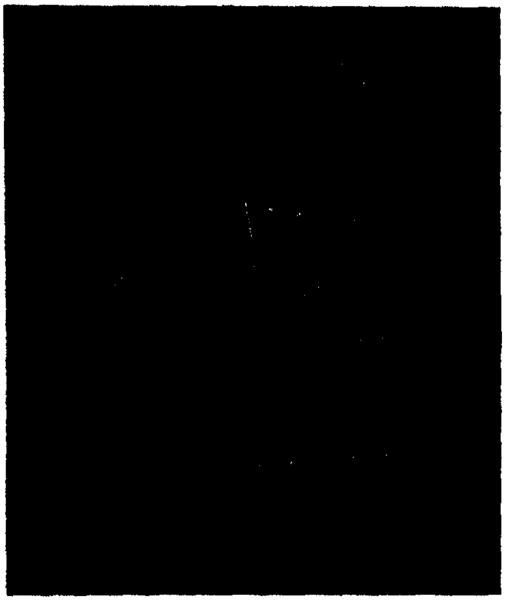

FIG. 7. Tracks of highly charged small quartz particles in a field of 225 volts/cm. 7.5 flashes/sec.

The constant B in Eq. (2) depends on the experimental conditions only, while A in Eq. (1) also varies with the density of the material involved. Both, however, will usually not change in the course of one experiment, except, perhaps, for the factor ν, the flash frequency, which might be intentionally decreased (preferably by a factor of 4) when the fast particles have settled out and only the slow small ones are being observed. The evaluation of the quantities q/d and d will then simply consist in multiplying the velocities and, respectively, the square root of the velocities, as given by X/N, and by $(Y/N)^{\frac{1}{2}}$, into these constants. This can be done by slide rule if N is counted and X and Y are measured in centimeters, but it is usually faster to employ a combined multiplying nomogram measuring tool. It is easy to see how such a device should be constructed. It should give the same reading for constant ratios Y/N etc.; e.g., by plotting N at right angles to the displacement and drawing in lines of constant slope each carrying the appropriate value of d. Taking into account the polarity on the plates and the sense of the deflection, a complete analysis of the charge and size distribution of the sample observed is obtained.

LIMITATIONS

It is essential to investigate some of the numerous instrumental limitations of the method. The most serious shortcoming of the arrangement described here is the tendency to develop convection currents inside the analyzer. If the convection has a horizontal component, it is easily detected and the experiment can be declared invalid. But it so happens that the convection currents most often are vertically upward or downward in the region that is photographed because the walls of the chamber are either cooler or warmer than the plates. In the former, the small particles whose settling rate is less than the air velocity are swept out, while those larger particles that reach the field of vision are slowed down and appear smaller than they really are. Usually this difficulty quickly becomes apparent by the general dearth and rather sudden cut-off of particles of small size. The vertically downward convection however, is not only the most likely convection, as pointed out before, but also the one most easily overlooked. All that happens is that the particles settle faster than in still air, thus appearing too large, an effect counteracting the shape correction. When the average velocities of the particles seem to increase with time, increasing downward convection is the most probable cause.

The most definite check on the reliability of the size measurement and thus indirectly on the charge estimates is a comparison of the observed size distribution with a microscopically determined one.[5] Especially convincing is a check against the dust that is collected on a cover glass placed below the region observed in the measurement. This should be done in every crucial experiment. When the size frequency curves for the photographed and collected samples show great similarity, the effect of convection can be considered negligible. Figure 8 shows an example of good agreement.

Another critical factor is the width of the slit. It will be desirable to make the slit as narrow as possible in order to admit the particles that are falling very close to the focal plane only. On the other hand, it is clear that highly charged small particles will have less chance of passing through a narrow slit than those with lower charge or larger diameter because of the attraction by the induced charges in the slit material. In order to keep this disturbing variation of the effective slit width below 10 percent for a reasonable upper limit of charge on the smallest particles to be studied, the slit will have to have a minimum width. A crude calculation giving a first approximation appears to be very simple. Consider a particle of charge q approaching the slit very much closer to one edge than to the other. Assume now that the slit material is not only conducting but that the total image charge $-q$ is concentrated on the very edge at the point of closest approach of the particle trajectory. Then the effective collision radius of the charged particle provided q is large is given by:[6]

$$a' = 2(C/V)^{\frac{1}{2}}, \tag{3}$$

where $C = q^2/3\pi\eta d$ is due to Coulomb's and Stokes' laws and $V = g\rho d^2/18\eta$ is the settling rate of the particle. Thus

$$a' = \left(\frac{24}{\pi g}\cdot\frac{q^2}{\rho d^3}\right)^{\frac{1}{2}}.$$

If this is required to be less than 5 percent of the slit width S, we have

$$S > 20a' \cong 0.001\frac{q}{\rho^{\frac{1}{2}}d^{\frac{3}{2}}}, \tag{3}$$

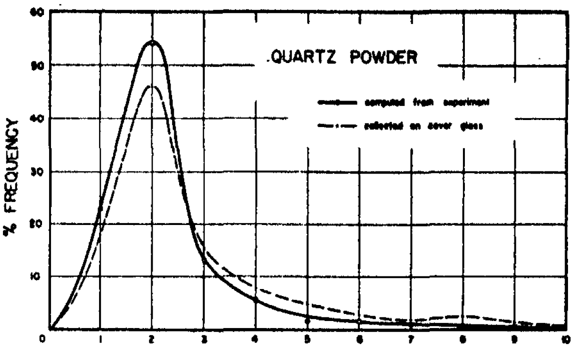

FIG. 8. Size distribution of quartz dust. Case of negligible convection; particles appear smaller in the experiment than they actually are. Sample photographed: 2500 approx., sample counted by microscope. 500 approx.

where q is now to be expressed in electrons and d in microns. For $q = 200$ and $d = 1$

$$S > (0.2/\rho^{\frac{1}{2}})\ \text{cm},$$

i.e., in general of the order of 1 mm. From this it is also clear how important it is to use a material of low dielectric constant to form the slit, since in that case the attraction will be much smaller than here calculated. In addition, it sets an upper limit for the density of the clouds to be studied. Since it would not be desirable to obtain more than N tracks per picture and since the volume visible at any time is AS where A is the area of the field of vision, we must require a density

$$n \leq N/(AS). \tag{4}$$

In our case, $A = 0.2$ cm², $S = 0.1$ cm, and taking $n = 50$, we find $N \leq 2500$ cm^{-2}, a number which is at the same time small enough to make any agglomeration during settling highly improbable.[6]

The third limitation to be considered is due to the effect of the electric field which makes itself felt at some distance above the plates. In order not to lose small highly charged particles which will drift sideways under influence of the field above the plates during an exposure, the polarity is reversed for successive observations and the time between pictures is chosen long enough to select the particles coming from a region relatively unaffected. This minimum interval T will depend on the charge q and the size of the particles, i.e., their settling rate V_0, the duration of the previous exposure τ, and the dimensions involved. As a first approximation, we find for large q and a permitted displacement $l/4$ of particles of diameter d

$$T = \frac{l_0}{V_0} + \frac{l}{2V_0}\cot\frac{3\pi^2\eta l^2 d}{2V\tau q}, \tag{5}$$

where l_0 is the distance between the observed region and the upper edges of the conducting plates. l is again the distance between plates and V their potential difference.

[5] For microscopic size determinations, see J. M. Dalla Valle, *Micromeritics* (Pitman Publishing Corporation, New York, 1943).
[6] W. B. Kunkel, J. App. Phys. 19, 1053 (1948).

As an example for one of our cases, we give $l=0.8$ cm, $l_0=0.5$ cm, $V=180$ volts, $\tau=4$ sec., $q=200$ electrons, $d=1$ micron, and for quartz, $V_0=0.008$ cm/sec., which yield $T=110$ sec. This means that 4-sec. exposures at 2-min. intervals will include all particles with $d\geq 1$ micron and $q\leq 200$ electrons, but may lose particles exceeding one of the limits. The relation between the critical values of q and d that will be just admitted is implied in (5) but is rather complicated as V_0 is proportional to d^2.

CONCLUSION

The apparatus described here has been used with considerable success in the study of the electrification of dusts in general and under different conditions of dispersion. It has proved to be a very workable instrument, efficient, reliable and easy to operate. The results have been reproducible, quantitative, and unambiguous, which is rare in the literature on tribo-electricity. The great advantage of the method lies in the fact that large samples can be measured, permitting reliable statistics and significant conclusions. In general it proved amply sufficient to make measurements on random samples ranging from 300 to 2000 particles, depending on how pronounced the effects were and on the accuracy required. The labor involved is not prohibitive once a method of measurement and tabulation is worked out. These features may very well make the apparatus a tool that could be employed to advantage in various branches of industrial research, and it is hoped that this description will be of some help to whoever has to investigate the charges on small particles.

We wish to express our gratitude to Professor L. B. Loeb who started us on this method of study and whose active support and helpful suggestions were essential to the development of this work.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

Spectral Sensitivity of Two Commercial X-Ray Films between 0.2 and 2.5 Angstroms*

Herman E. Seemann
Kodak Research Laboratories, Rochester, New York

(Received December 12, 1949)

The spectral sensitivities of Kodak No-Screen and Kodak Industrial Type K X-Ray Films were determined in the region between 0.2 and 2.5A using the filtered K fluorescence of several irradiated elements as approximately homogeneous radiation. Exposures in roentgens were obtained with an air ionization chamber designed especially for the purpose. Curves are given showing the number of roentgens incident on the film which will give a developed photographic density of 1.0 above fog for the various wave-lengths. The K limits of silver and bromine are prominent. The maximum sensitivity in terms of roentgens occurs at about 0.4A, but the marked decrease found by other observers at shorter wave-lengths is probably obscured by inaccuracies. From the energy value of the roentgen, the sensitivity of the films is expressed as the incident ergs per square centimeter required to produce a density of 1.0 above fog. Computations from these results show that as the wave-length increases the films utilize the *absorbed energy* more efficiently. On the other hand, high energy *quanta* are more efficient than low energy quanta but not in proportion to their energy. In addition to the more or less gradual change with wave-length of efficiency of utilization of absorbed energy, there is evidence for sudden jumps at the K limits of Ag and Br. Qualitative explanations are given for the observed changes in efficiency.

INTRODUCTION

Most diffractionists are familiar with the general appearance of a photographic film which has been used to record the continuous x-ray spectrum diffracted by a crystal. In general, there is an increase in photographic response in going toward longer wave-lengths until the K absorption edge of the silver in the silver bromide emulsion introduces a sudden drop. The film density again increases to the K limit of bromine, at which another drop in density occurs. When compared with the absorption curve, such a record indicates that there is a connection between the x-ray energy absorbed and the amount of silver in the developed image. Figure 1 illustrates this point, but is subject to qualitative interpretation only since the intensity distribution in the diffracted spectrum was not known. For such a record to yield quantitative information, the energy distribution incident on the film must be known, as well as the characteristic curve (density-exposure relation) of the film and whether or not the latter relation is independent of wave-length. If separate monochromatic beams are obtained by diffraction from a crystal, the exposed areas are small and this may introduce errors due to development effects, to inaccurate densitometry or to difficulties inherent in silver analysis.[1] Thus, the experimental difficulties probably account for the scarcity of information in the literature† on the x-ray spectral response of photographic emulsions.

† Since the completion of this manuscript, a paper on the same general subject by H. Hoerlin has been noted: J. Opt. Soc. Am. 39, 891 (1949).

In preparing data sheets on properties of Kodak x-ray films for industrial radiography,[2] it was noticed that these films did not have the same relative spectral response in the radiation quality range commonly used. The explanation for this variation was not obvious and there was little hope of obtaining adequate information by merely using the filtered continuous spectrum from a tungsten target tube.

In view of the difficulties associated with spectral-sensitivity determinations with x-rays monochromatized with a crystal, the possibility of using the *K* fluorescence from several elements was considered. Irradiating an element with continuous spectrum x-rays excited at a suitable potential and utilizing the *K* fluorescence for various experiments is an old expedient dating back to the early history of x-rays. The use of fluorescence radiation was particularly popular before the discovery of crystal diffraction since it was then the only method for obtaining a reasonably pure spectrum. Preliminary filtration-curve data supported the fact[3] that there is indeed very little continuous background associated with the *K* fluorescence. Later absorption tests comparing the radiation from a molybdenum target x-ray tube with that from a molybdenum secondary radiator showed that electron bombardment of molybdenum resulted in much more background than did x-irradiation. Both x-ray tubes were supplied with 30 kv electrically filtered to give essentially constant potential.[4] The additional facts that the fluorescence can be further purified by reducing the proportion of $K\beta$-radiation with a suitable filter and that by proper disposition of the apparatus the intensity was sufficient for exposures to be made on "fast" x-ray films in a reasonable time lent encouragement to the practicability of utilizing the $K\alpha$-fluorescence of several elements to determine spectral sensitivity of x-ray films.

Determination of spectral sensitivity required the use of some instrument with which the intensity of the x-rays could be measured. The increasingly wide use of the international roentgen‡ caused us to investigate the possibilities of instruments which would give indications in roentgens. Commercial instruments available, however, were deficient in two important respects: They were not suited for measuring in the long-wavelength region, and their construction made them unsuitable for use with our "x-ray fluorescence sensitometer," a device of special construction designed primarily for film exposures. After some experimental work, an air ionization chamber was developed[5] which had a sufficiently transparent window for the longer wavelengths, was mechanically suited for use with the sensitometer, and could be conveniently used in conjunction with the electrometer of a sturdy commercial instrument. This instrumentation made it possible to expose films to known amounts of radiation expressed in roentgens and, since the roentgen represents a certain amount of energy absorbed in air,[6] the results could also be expressed in terms of energy.

Occasional inquiries from diffractionists about the properties of x-ray films prompted us to delay work on the main problem in order to obtain information which might be of immediate practical value. Accordingly, *relative* "speeds" of several x-ray films were determined using the unfiltered *K* fluorescence from chromium, copper, and molybdenum. The work was restricted to these elements since they represent commonly used targets in diffraction tubes. No attempt was made to obtain absolute measurements, but instead, one of the films was chosen as a standard of reference for the others. *The results showed clearly that films which are quite similar in atomic composition and therefore absorb x-rays similarly do not maintain the same relative speeds at different wave-lengths.*[7]

APPARATUS AND METHOD

The low intensity of fluorescence x-rays compared with the exciting radiation necessitates careful planning and disposition of the apparatus as well as operation of the x-ray tube near its load or current limit. The schematic diagram in Fig. 2 illustrates the arrangement

of the fluorescence sensitometer and x-ray source as used in this study.

The x-ray tube was especially designed by the Dunlee Corporation, of Chicago, to operate at the high currents and low voltages necessary for this work. It had a projected focal spot about 4.5 mm square. Condensers were connected across the rectified high voltage supply to give nearly ripple-free power. This was found to furnish a steadier output of fluorescence radiation than when pulsating potential was used. It is well known that the intensity of fluorescence varies rapidly with the potential applied to the exciting x-ray tube when this potential is above the critical value required for excitation. Consequently, changes in high voltage wave form due to heating of the transformer, for example, might change the quality of the exciting x-rays enough to alter the fluorescence output. There was evidence in favor of this explanation but it was not tested to the point of conclusive proof.

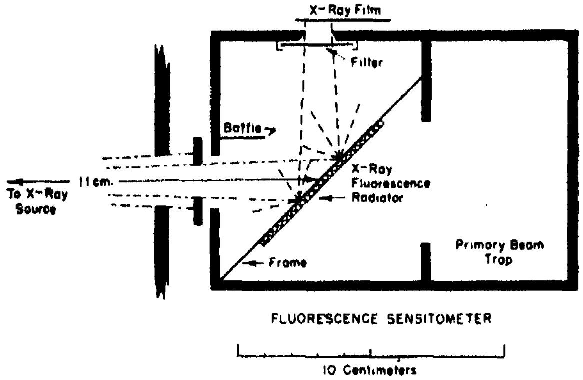

FIG. 2. Schematic diagram of x-ray fluorescence sensitometer. Heavy lines represent lead protection.

Several elements were chosen as x-ray fluorescence radiators whose $K\alpha$-emissions would permit sensitivity determinations to be made on both sides of the K absorption limits of silver and bromine. For each radiating element, another element of lower atomic number was used as a filter to isolate the $K\alpha$-doublet by absorbing the $K\beta$-doublet preferentially. A sheet of each radiating element or a suitable compound was supported by a light aluminum frame which could be placed in a compartment of the sensitometer, resting at an angle of about 45 degrees to the central ray of incident x-rays. Thus, the "fluorescence focal spot" as "seen" by the film was a disk about 2 cm in diameter. The baffle was arranged to prevent lead fluorescence emitted by the limiting diaphragm from reaching the film. The primary beam trap served a similar purpose (see Fig. 2).

For exposure, the x-ray film was placed in a cassette having a window made of a No. 87 Wratten filter. This is an infra-red gelatin filter which furnished adequate protection for the film in subdued room light but, unlike black paper, does not have a fibrous structure which would be recorded radiographically with soft radiation. The cassette was moved in a series of automatically timed steps in a direction perpendicular to the plane of the diagram. Times of exposure were $\frac{1}{16}$, $\frac{2}{16}$, $\frac{3}{16}\cdots\frac{7}{16}$ min., and the intensities were sufficient to give an adequate range of densities on Eastman No-Screen X-Ray Film, Code No. 5133, and on Kodak Industrial X-Ray Film, Type K, Code No. 5135. Both of these films are "fast" direct x-ray types. One film strip of both types exposed to each radiation, and the ionization readings taken before and after, made one run. A total of three runs was made several days apart. Considerable preliminary work was done to establish the reliability of the method. Exposed areas on the film strips consisted of a row of 1-cm squares separated by about 1 mm of unexposed film. No systematic variation in density in a square could be detected, thus proving that the fluorescent beam was sufficiently uniform in section.

Good uniformity of development was assured by developing in a machine which is a small modification of one designed for routine sensitometric testing.[8] All of the film strips for a single run were developed together for 4 min. at 68°F in Kodak Rapid X-Ray Developer. They were then rinsed in an acetic acid stop bath for a few seconds, fixed, washed, rinsed in Kodak Photo-Flo (a water-spot preventive), and dried. Densities were read on a densitometer calibrated in diffuse density.

Exposure of films in a timed series of steps made it possible to plot a density-exposure curve for each radiation and thus to interpolate to find the exposure required to produce an arbitrarily chosen density of 1.0 above fog. These data, as well as some obtained in preliminary work, have shown no systematic difference in the shape of the density-log exposure curve in the wave-length range covered[*][9] except for some uncertainty at the longest wave-length (Cr $K\alpha$) where the absorption in the "front" emulsion and film base materially affected the intensity of x-rays reaching the "back" emulsion. Thus, it would have been reasonable to have determined the characteristic curve with one radiation and to have used this as a calibration curve for *single* exposures made with the other radiations. This method would certainly save time in the exposing of films of low sensitivity, but for accuracy in the present work on films of high sensitivity there was little to choose between interpolation from single sensitometric runs and the arithmetical average of several equal exposures to each radiation, with subsequent reference of this value to one calibration curve.

For each sensitometric series, an ionization measure-

ment[5] was made so that the x-ray intensity in the plane of the film could be expressed in roentgens per minute. Therefore, film sensitivity could be expressed in incident roentgens or in incident ergs[6] required to produce a chosen density. A No. 87 Wratten filter was placed over the ionization chamber diaphragm so that the chamber truly measured what the film received through a similar window in the cassette. The back of the cassette consisted of a plate of aluminum 0.3 cm thick covered with black felt. The scattering from the back was considered negligible compared with the incident radiation.

Table I is a summary of the conditions used in these experiments. Most of the previously published data were taken from the tables in Sproull's book.[10] Impurities or unwanted elements in the radiators and filters were deemed to be insignificant for the purpose intended.

If it is assumed that the ratio of fluorescence intensities $K\alpha/K\beta$ is the same as when these lines are emitted by a tube target,[11] i.e., about 6, it is easy to calculate what amount of filtering element will change the ratio to some chosen value, say, 20. This proposed reduction of the $K\beta$-intensity to about five percent of the intensity of the $K\alpha$ was a compromise between having a really negligible proportion of $K\beta$ and too low an intensity of $K\alpha$ for practical exposing conditions. The filtering elements used in the form of foils were a little greater in thickness than necessary to obtain this reduction of $K\beta$, but for those made up from powders and powdered compounds which were bonded together, only the crudest estimate of their efficiency was possible. The amount of filtration was necessarily an integral number of layers of the particular filter stock at hand. Final tests of spectral purity were made by absorption measurements. When it was found that the *log intensity versus mass per unit area* curve was a straight line and gave the same absorption coefficient that the $K\alpha$-radiation should give, within experimental limits, the selective filtration was considered adequate. Sufficient analyzing filtration was used to reduce the intensity to the order of one tenth of its original value, thus providing a range sufficient to give a reasonable sensitivity to departure from linearity. The radiation from 74 W and 78 Pt were found to be inhomogeneous according to the linearity criterion, but this point will be discussed later.

RESULTS

The graphs in Fig. 3 show the relation between the incident number of roentgens required to produce a density of 1.0 above fog, and the wave-length. The vertical lines at 0.485 and 0.918A represent the silver and bromine K absorption edges. Since breaks are to be expected at absorption discontinuities, it seemed proper to draw them in and to extrapolate the curves to these limits. The existence of a maximum in sensitivity (minimum incident roentgens) at about 0.4A is in general agreement with the findings of other observers[12] but no detailed comparison is justified, inasmuch as they used other kinds of film and different degrees of homogeneity of radiation. In the present work there is considerable uncertainty about the sensitivity values for the two points at the shortest wave-lengths, *viz.*, 0.19A (Pt $K\alpha$) and 0.21A (W $K\alpha$), since these radiations were definitely not as homogeneous as assumed and, what is probably more significant in the present case, the calibration of the ionization chamber was most doubtful in this region.[5] Judging by the earlier work,[12] these points should be higher.

Since the roentgen represents a certain amount of energy absorbed in air, it is also possible to calculate film response in terms of incident ergs or in terms of ergs absorbed per square centimeter. From the exponential absorption law, $E=E_0\exp[-(\mu/\rho)\rho x]$, it follows that $E_a = E_0[1-\exp(-(\mu/\rho)\rho x)]$, where E_a is the energy absorbed in a layer of air x units thick, E_0 is the incident energy, and μ/ρ is the mass absorption coefficient. But μ/ρ is an absorption coefficient which includes photoelectric or true absorption and absorption by scattering. In evaluating the roentgen, absorption by scattering must be excluded because it does not contribute appreciably to the ionization, but since the Compton recoil electrons which are associated with scattering do cause ionization, their contribution is significant for short wave-lengths. The equation is therefore rewritten,

$$E_a = E_0\left(1-\exp\left[-\left(\frac{\tau}{\rho}+\frac{\sigma_a}{\rho}\right)\rho x\right]\right),$$

where τ/ρ is the coefficient for photoelectric absorption, and σ_a/ρ is the coefficient for true absorption associated with Compton scattering.

Figure 4 shows the results of this computation in terms of incident energy in ergs per square centimeter per roentgen as a function of wave-length. The value of 33 ev was taken as the approximate average energy required to produce one pair of ions in air leading to a value of 0.110 erg absorbed in 0.00129 gram of air, the energy equivalent of a roentgen.[6] Since, for 1 roentgen, $E_a = 0.110$ erg,

$$E_0 = \frac{0.110}{1-\exp[-(\tau/\rho+\sigma_a/\rho)0.00129]}$$

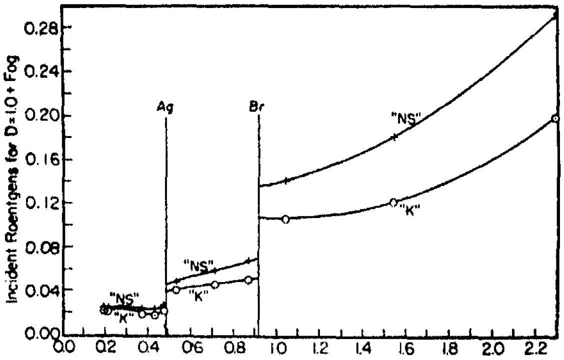

FIG. 3. Spectral sensitivities of No-Screen and Type K X-Ray Films in terms of incident roentgens required to produce a developed density of 1.0 above fog.

for wave-lengths greater than about 1A; or

$$E_0 = \frac{0.110}{0.00129[(\tau/\rho)+(\sigma_a/\rho)]} \text{ approximately,}$$

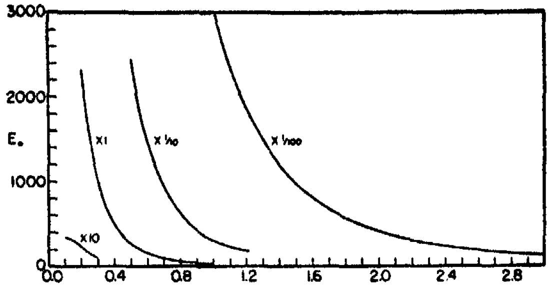

FIG. 4. The energy, E_0, per square centimeter cross section of an x-ray beam per roentgen as a function of wave-length.

for shorter wave-lengths, where the total absorption is quite small. Equation (3.185) in Compton and Allison's book[13] gives the true absorption per electron caused by scattering. From this we find that

$$\sigma_a/\rho = \sigma_{e0}N_0(Z/A)\frac{\alpha}{(1+2\alpha)^2},$$

where σ_{e0} is the classical scattering per electron, $N_0(Z/A)$ is the number of electrons per gram of air, and $\alpha = h\nu/mc^2$. The numerical values necessary to compute E_0 for different wave-lengths were taken from Victoreen's paper on mass absorption coefficients.[14] The results shown in Fig. 4 are from 10 to 20 percent higher than Mayneord's.[6] Mayneord does not give any details of his computation. Figures 5 and 6 show sensitivities in terms of the incident energy per square centimeter required to produce a density of 1.0 above fog. The single-coated films are the same exposed strips but the "back" emulsion was removed after the total densities were read. It is interesting to note that these two films, with almost identical chemical composition and amount of silver bromide per unit area but different grain characteristics, have the same sensitivity only at the shorter wave-lengths.

The results of Fig. 7 were obtained by computing the energy absorbed per square centimeter in the "front" emulsion. The mass absorption coefficients for silver bromide were calculated from the absorption data for silver and bromine in the Compton and Allison tables.[15] Because of the high absorption of silver bromide and the heavy coating on these x-ray films, the exponential absorption law rather than its linear approximation was used to calculate the absorbed energy, but no correction was applied for scattering within the film.

Although it is obvious that the data in Fig. 7 do not justify the drawing of a smooth curve through the short-wave-length region, it is also quite apparent that there is a large change in efficiency of utilization of the absorbed x-ray energy—a factor of about three times. Bouwers[16] found a trend in the same direction. It is to be expected that the photographic effect of x-rays is due largely to the ionization caused by photo- and

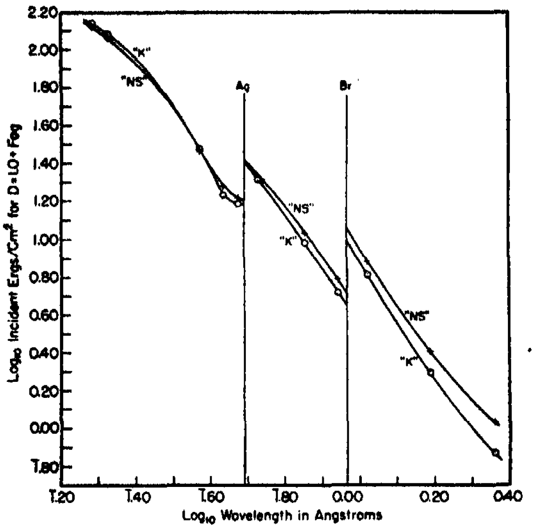

FIG. 6. Same as Fig. 5 but for the "front" emulsion only.

Compton electrons.[17–20] At long wave-lengths, the photo-electrons do not have much energy and therefore ionize primarily within the grain where they originate and render it developable. Some, of course, lose their energy in the gelatin of the emulsion if they happen to originate at the surface of a grain and travel outward. While it cannot be assumed that high energy electrons are more likely to lose a greater proportion of their energy in the gelatin than in the silver bromide, such might be the case.

From studies of nuclear emulsions,[19] however, it is known that high velocity particles expose (ionize) grains much more efficiently near the end of their paths than at the beginning. Presumably, the same principle operates for other emulsions. This means that as the wave-length decreases and the photo-electrons acquire greater and greater energies, they are less efficient in producing latent image. Although a high energy electron may have sufficient energy to expose several grains, it will lose much of its energy at such low concentration per unit length of path that it is not very effective, i.e., at high velocity there will be insufficient ions per grain to expose it. In the recent work of Bromley and Herz,[18] it was found that a water-swollen emulsion was less sensitive to hard x-rays than it was in the dry state. Thus, for the same x-ray absorption in the silver halide of the swollen emulsion, the same number of photo-electrons could not, on the average, reach and expose as many grains, because of their absorption in the increased amount of matter separating the grains. While this picture of the initiation of latent image by x-rays accounts qualitatively for the trend shown in Fig. 7, another idea which has been accepted for some years also points in the same direction.

It is generally considered that one x-ray quantum is sufficient to render a silver bromide grain developable.[21] A large number of silver atoms are liberated by one x-ray quantum but the number is much smaller than would be expected, considering the energy of the quantum. It has been estimated that only five to six percent of the absorbed x-rays which are converted to electron energy are utilized in liberating silver atoms.[22]

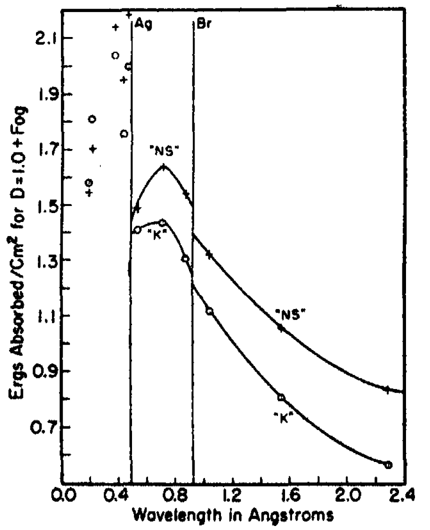

FIG. 7. Spectral sensitivities in terms of ergs absorbed per square centimeter required to produce a developed density of 1.0 above fog in the front emulsion of No-Screen and Type K X-Ray Films.

[22] P. Günther and H. Tittel, Zeits. f. Elektrochemie 39, 646 (1933).

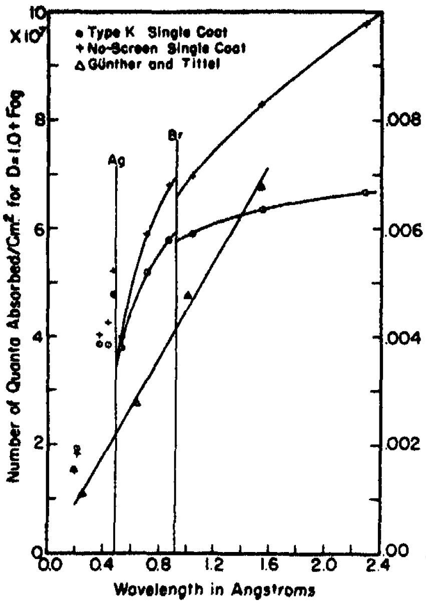

FIG. 8. Similar to Fig. 7 but expressed in terms of number of quanta absorbed per square centimeter. Data of Günther and Tittel included for comparison. Their results are the number of quanta per silver atom freed by the radiation.

The decrease in efficiency with increasing quantum energy shown in Fig. 7 may be explained in part by the idea that if an x-ray quantum of a certain low energy is sufficient to expose a grain, energy is wasted if a larger quantum exposes a similar grain. The ionizing power of electrons as a function of energy and the absorption of electrons by the gelatin must also be important contributory factors in this decrease of efficiency with decrease in wave-length.

In Fig. 8 the results are given in terms of the number of quanta absorbed for a developed density of 1.0 above fog. For the sake of comparison, data of Günther and Tittel[22] are included. In their experiments, they exposed the emulsion to the point of solarization and analyzed it for the amount of silver *photolytically* freed. Their results are expressed here as the number of quanta absorbed per silver atom freed. With due regard to the risk involved in comparing results obtained on different photographic materials, and in extrapolating from exposures producing solarization to those required to give a density of 1.0, we suggest that the graphs of Fig. 8 indicate proportionality between the amount of latent-image silver and the developed density in the shorter wave-length region where it may be assumed that several grains are rendered developable by one quantum.[16] At wave-lengths longer than the Br *K* limit, our results for Type K Single Coat show a tendency toward parallelism with the wave-length axis. Since density is proportional to the number of developed grains (see reference 1, p. 229), this would indicate a trend toward the one-grain-per-quantum condition. A slight suggestion of this is apparent for No-Screen Single Coat in the same wave-length interval. It appears that with the materials examined here the exposure of more than one grain per quantum extends to longer wave-lengths than in the case of materials studied by other experimenters.

Comparison of Figs. 7 and 8, which show different aspects of the same thing, indicates that while short-wave-length x-ray energy is less efficient than long-wave-length energy, the high energy quanta are more efficient than the low energy quanta, *when considered as quanta*. The high energy quanta simply are not as efficient as they should be, considering their energy. Some reasons for this are mentioned in the preceding paragraph. Pelc[23] concluded that the same absorbed energy always renders the same number of grains developable, regardless of wave-length. Our results are quite contrary to this.

The closest approach to the present method of investigation of x-ray spectral sensitivity was that of Berthold, and Berthold and Glocker.[24] They used the radiation from x-ray tube targets of various elements filtered by an element which would tend to isolate the $K\alpha$-lines. It is our opinion, expressed earlier, that this does not give as homogeneous a radiation as the filtered fluorescence. Furthermore, considering the date of their work (1923–24), absorption data for air and silver bromide may not have been sufficiently accurate. Also, there is some question as to whether or not their air ionization chamber gave readings proportional to roentgens, i.e., proportional to the energy absorbed in air. All of this, in addition to the differences in photographic emulsions which probably exist, practically eliminates a valid comparison of the two experiments. Later, however, Glocker recomputed his results using more reliable absorption data[25] and observed sudden breaks in the sensitivity curve at the Ag *K* and Br *K* limits when the sensitivity was expressed for the *same energy absorbed in the emulsion* at the different wave-lengths. The change at Ag *K* was about 10 per cent but was quite small at Br *K*. In general, the efficiency of utilization increased with increasing wave-length, in qualitative agreement with our results.

Recent work by Sandström[26] showed that for two different photographic materials, the sensitivity ratio between the short- and long-wave-length sides of the Ag *K* limit did not agree with the sensitivity ratio computed on the basis of absorbed energy. He only measured the response for the immediate vicinity of Ag *K* and used density ratios obtained from microphotometer records of exposures to the diffracted continuous spectrum. This is probably a legitimate procedure for his low density exposures. Sandström's average for the two materials he used is only about eight percent higher than the average of 1.65 obtained from column 2 in Table II. (Sandström expressed the ratio as the reciprocal of the ratio used here.) No conclusive explanation was offered for the difference in efficiency of utilization of absorbed energy, but the experimental fact is in good agreement with that found in the present work.

The results summarized in Table II show the pronounced difference of 40 to 49 percent between computed and observed values for sensitivities at the K limit of Ag, and only one to four percent at the K limit of Br.

On referring again to Fig. 7, it appears that a small break occurs at the Br K limit and a larger one at the Ag K limit, similar to the results obtained by Glocker in his revised computations.[25] The result obtained by Sandström[26] at the Ag K limit is equivalent to ours. Although the accuracy of our data is not great and the values are obtained by extrapolation, the agreements noted are strong evidence for the breaks noted in Fig. 7. Glocker ascribed these discontinuities to sudden changes in the relation between fluorescence and photoelectric emission. With this point we agree, but we shall now consider it in more detail.

The true absorption of an x-ray quantum, $h\nu$, results in the emission of a photo-electron whose kinetic energy, E_{kin}, is given by the Einstein photoelectric equation,

$$E_{\text{kin}}=h\nu-W_K,$$

where W_K is the energy required to remove the electron from the K level, for example, of the atom. The K fluorescent emission resulting from the return of an electron to the K level of a silver or bromine atom is not necessarily absorbed in the surrounding emulsion, since the absorption coefficient for this radiation is not exceptionally high, although it is more than twice as great for the bromine fluorescence as for the silver fluorescence.

A moderate difference, however, between $h\nu$ and W_K yields a photo-electron which is effective in exposing. However, just at the absorption limit where $h\nu=W_K$ there will be no exposure from a K electron and, since the utilization of the corresponding fluorescence is not complete, a drop in efficiency may occur. The greater absorption of the bromine fluorescence by the silver bromide may account in small part for the observation that the sensitivity change in the film corresponds more nearly to the absorption change at the bromine K limit than it does at the silver K limit. Furthermore, the K fluorescence yield of silver is about one-third greater than the K fluorescence yield of bromine.[27] Thus a greater proportion of the absorbed energy on the short wave-length side of Ag K results in fluorescence than is the case with Br K. Conversely, there will be relatively more Auger electrons (internal conversion of photon energy) than from the silver. Since the Auger electrons are much more strongly absorbed than the fluorescence, the greater Auger electron yield of bromine increases its efficiency of utilization of absorbed energy. The greater break (see Fig. 7) at Ag K than at Br K is explained therefore by (1) the lesser absorption of the Ag K fluorescence, and (2) the greater Ag K fluorescence yield. Whatever the over-all efficiency of the photographic emulsion in utilizing absorbed x-rays, a small decrease may be expected just at the short-wave-length side of an absorption edge. (This over-all efficiency has been estimated to be only five or six percent.[22])

CONSIDERATION OF ERRORS

From previous experience in the photographic photometry of x-rays, we believe that the measurements of relative exposure on the films fall within the limits of an error of ±3 percent. Uniform development of film strips is the most essential factor in attaining accuracy as good as this, and the machine mentioned earlier[8] has been found very satisfactory in this respect. All the films of one kind were taken from the same box, thus keeping film variation at a minimum.

An ionization-chamber reading was made before and after the film exposures for each kind of radiation. They were very consistent. In only a single instance was there a difference as great as six percent between the "before" and "after" readings. The ionization chamber had a scale of ten divisions so that tenths of a division were estimated. The fiber was in good focus, and the scale divisions were of such a size that estimating of tenths could be done with reasonable accuracy. The exposure in roentgens was taken as the mean of the two readings. Relative sensitivities of the two films studied are believed to be fairly well established but measurement of absolute values involves several uncertainties.

Referring to Fig. 5, it will be noted that the first point on the short-wave-length side of the K limit of silver causes the curve to approach the limit in a very different manner from the corresponding approach to the K limit of bromine. It may also be noted that this radiation ($K\alpha$ of antimony) is nearer an absorption limit than is any other radiation used. Therefore, sufficient spectral impurity could have just the effect observed, while equivalent impurity in the other radiations near the K limits might have a negligible effect.

As mentioned before, the radiations used were tested for homogeneity by their absorption curves in aluminum or copper. While this method is not extremely sensitive, the alternative of photographing the spectrum diffracted

TABLE II.

Spectral region	Ratio of film sensitivities (from Fig. 6)	Computed ratio of absorbed energy	Ratio $\frac{\text{computed}}{\text{observed}}$
K limit of Ag	Type K 1.70 No-Screen 1.60	Both films 2.38	Type K 1.40 No-Screen 1.49
K limit of Br	Type K 2.24 No-Screen 2.19	Both films 2.27	Type K 1.01 No-Screen 1.04

---

[27] A. H. Compton and S. K. Allison, loc. cit., p. 489.

by a crystal requires great care in interpretation. A *very faint* background density near a spectral line of moderate density must be *integrated* with respect to wave-length before its value with respect to the line can be properly assessed since, as in our exposing arrangement, the spectrum is not spread out, but line and entire background both fall on the same area.

Although the absorption test did not indicate good purity for the $K\alpha$ of 74 W and 78 Pt, we do not believe that this alone introduces a serious error, inasmuch as there are no absorption edges for AgBr near these wave-lengths. Rather, the calibration of the ionization chamber[5] in this region is uncertain because its sensitivity was found to change on a continuous spectrum basis and we used it here on a homogeneous spectrum basis. Under these conditions, therefore, we do not have great confidence in the exact number of roentgens per scale division of the instrument.

Each point on the curves in Figs. 3 and 5–8, inclusive, represents the average of three separate determinations, i.e., the experiment was performed three times, for each of which the films were developed together. This procedure introduced a development variation between runs, since temperature and strength of developer could not be controlled as accurately as in a more elaborate apparatus. To give a truer picture, therefore, of the accuracy of determination of relative sensitivity to the different radiations, the runs were reduced to a common development basis. This was accomplished by determining the ratio, r_1/r_2, of the roentgens to give a density of 1.0+fog at each wave-length for runs 1 and 2, for example, and multiplying all of the values of r_2 by the *mean ratio*. The largest value of the mean ratio which it was necessary to use was 1.11, thus indicating a maximum development difference of 11 percent. While this procedure was used to correct for development differences, it also includes any other systematic differences which may have been associated with a given run. It is most likely, however, that development conditions were the only significant differences between runs. On making corrections for development differences, it was found that the average spread of data is 4.7 percent. This was calculated as follows: Since there were three runs, there were three values to be averaged for each datum point in Figs. 2 and 3. The values of maximum percentage spread of all data were averaged, giving the average spread of 4.7 percent. The greatest spread found for any datum was 12.5 percent. Energy relations given in Figs. 6–8 were derived from these averaged data.

CONCLUSIONS

(1) X-ray films of nearly the same atomic composition and therefore having similar x-ray absorptions do not necessarily have similar relative spectral sensitivities.

(2) X-ray energy absorbed in an emulsion is more efficiently used at long than at short wave-lengths. Large x-ray quanta are more effective than small quanta but, as the energy efficiency indicates, not in proportion to their energy.

(3) The sudden change in sensitivity of film to incident x-rays in crossing the K limit presumably cannot be computed simply on the basis of absorbed energy. This apparent discrepancy may be due to the negligible value of kinetic energy of K photo-electrons just on the short-wave-length side of the absorption edge and to the loss of fluorescence radiation.

(4) A photo-electron may render a single grain developable and also waste some of its energy in the gelatin. Or it may expose several grains near the end of its path after losing some of its energy at such high velocity that the ions formed are widely separated and the grains penetrated are therefore not exposed. If an incident quantum has only sufficient energy to remove an electron from its energy level, this electron can do no exposing and the fluorescent quantum resulting from its return may not be absorbed. Thus, some x-ray energy may be absorbed without producing latent image. The relative importance of these various factors will depend upon grain size, grain-size distribution, and proportion of gelatin. Hence, different x-ray emulsions may vary in relative spectral sensitivity even though they absorb similarly.

ACKNOWLEDGMENTS

We should like to express thanks to several colleagues for valuable contributions: to R. L. Griffith for the spectrogram in Fig. 1; to G. Kornfeld for the opportunity to discuss certain phases of the work; to H. J. Dietz for making some of the radiators; and particularly to E. J. Hunemorder (now with the Dow Chemical Company) for his painstaking care in preparing various filters and in holding the x-ray tube to constancy of output during exposures.

Decade Pulse Counter for Geiger-Müller Tubes

BJÖRN ÅSTRÖM
Nobel Institute for Physics, Academy of Sciences, Stockholm, Sweden

(Received December 20, 1949)

A pulse counter of decade type, which does not require any components with narrow tolerances, has been designed. A direct reading system for the total count has been used, which eliminates all calculations. Several instruments of the type described here have been put to daily use for more than half a year without any failure.

INTRODUCTION

COUNTING of pulses from Geiger-Müller tubes has in general been made by using scalers of the binary type consisting of a number of scale-of-two circuits.[1,2] The reading of the total number of pulses registered by such a pulse counter is often troublesome and tedious and mistakes may easily be made in the computations of the interpolations required by such a system. For a long time it has, therefore, been felt desirable to design a pulse counter of the decade type, where it should be possible to read directly the figures of the number of pulses counted. Several such counters have already been published.[3-7]

The pulse counter, to be described here, has the following features: (1) The number of pulses counted is directly indicated on the front panel. Units and tenths in illuminated figures and hundreds in a five figure mechanical register. (2) The register and the electronic circuits can easily be reset to zero. (3) All resistances and condensers have standard values with 10 percent tolerances. (4) The instrument has proved to be very reliable and insensitive to power line fluctuations. (5) The sensitivity is high, which gives better plateaus, specially when small Geiger-Müller tubes are used. (6) The mechanical construction is such that all parts are easily accessible for control and service. (7) The

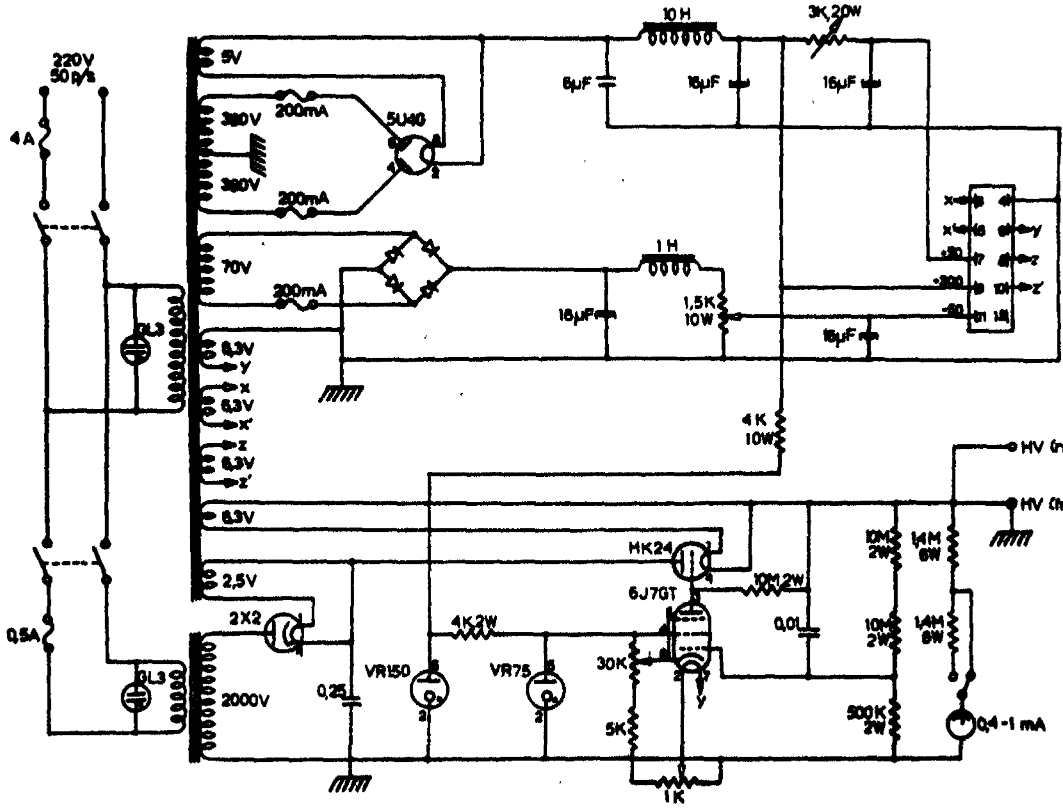

FIG. 3. Circuit diagram of the power supply.

high voltage supply for the G-M tube is capable of supplying enough current for a quenching circuit of the Neher-Pickering type.

CHOICE OF DECADE SYSTEM

After some preliminary experiments it was decided to use the decade principle outlined by Baker.[8] In this circuit only five double triodes are needed for a scale-of-ten and the two triode systems in one tube may have a common cathode, which makes it possible to use the inexpensive miniature tube 6J6. Indication of the number of counts stored in the decade can easily be realized with ten miniature neon lamps, and the circuit is not critical when grid current limiting is introduced.

BLOCK DIAGRAM

As seen from Fig. 1 and Fig. 3 the pulse counter consists of the following main parts: pulse amplifier with discriminator, two decades with their respective pulse-forming circuits, the driving circuit for the mechanical register, and the power supply with a stabilized high voltage rectifier for the G-M tube. An external quenching circuit can be connected and there is also an output plug for operating an oscilloscope or a counting rate meter. Finally there is another plug for connecting a fast external mechanical register or a loud speaker.

PULSE AMPLIFIER AND DISCRIMINATOR

The pulse counter is generally used without a quenching circuit for the G-M tube and thus the first tube in the pulse amplifier is a cathode follower. The connection to the G-M tube is made through a 150-ohm coaxial cable, which may be made as long as 100 cm without introducing any harmful attenuation when normal G-M tubes are used. The second tube is a conventional pentode amplifier, with the grid return to a positive voltage to decrease the sensitivity to positive pulses. Discriminator action is realized by varying the grid bias of the first tube in the pulse forming circuit of the first decade. At maximum sensitivity, the pulses counted are 0.15 volt or larger and at minimum sensitivity, the corresponding pulse amplitude is 1.0 volt.

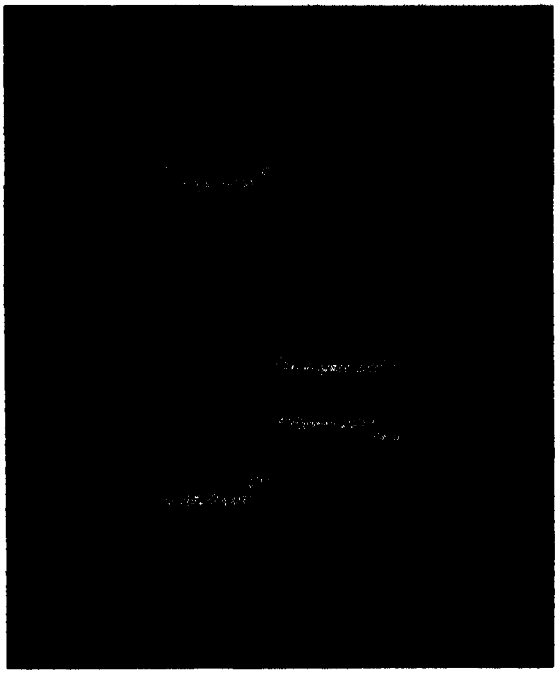

FIG. 5. Oscilloscopic picture of the plate (upper curve) and grid voltage (lower curve) of one triode system when ten successive pulses are fed to the decade. Initial condition is with the tube non-conducting. Plate current is started by the fifth pulse.

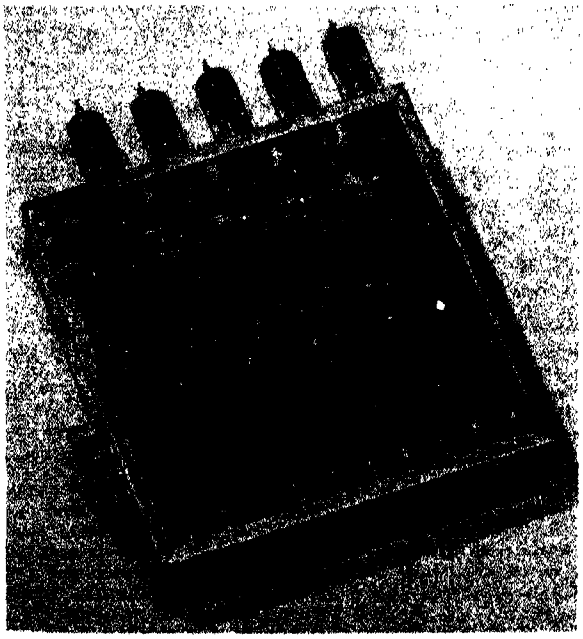

FIG. 4. Mechanical construction of the decade unit. Two units are used, mounted on the main chassis with the neon lamps close behind a window in the front panel.

PULSE FORMING CIRCUIT

To make sure that the decades work properly it is necessary to feed them with pulses that are equalized, and this is made by means of two pulse forming circuits of the type used in Eniac and described by Sharpless.[6] This type of pulse-forming circuit has been chosen because of its reliability; but it may be possible to design a pulse-forming circuit, good enough for this purpose, containing fewer components and with less power consumption. The pulses, from the pulse former used, have 70 volts amplitude and a length of 3 μsec.

DECADES

The circuit of the decades is given in Fig. 2 and the mechanical lay-out can be seen in the photograph in Fig. 4. They are constructed as separate units and are connected to the instrument by means of an eight-terminal plug.

The working principle of the decades can be described as follows. Each double triode is connected in a scale-of-two circuit with the grid potential of the non-conducting system far below cut-off. The connection between the five scale-of-two stages is made through a coupling resistor, as a result of which the plate potential of the tube proceeding contributes to the grid potential of the tube following. Starting with upper triodes conducting, the grids of four of the non-conducting triodes are connected to the plates of four conducting triodes, which have a low plate voltage, and thus only increase the grid voltage very little. The grid of the fifth non-conducting triode on the other hand is connected to the plate of a non-conducting tube and in this case the grid potential is raised almost to the cut-off value. The tube, which contains this grid, will thus be triggered when a negative pulse of limited amplitude is fed to the common cathode bar. Successive pulses will trigger the five scale-of-two circuits from one stable condition to the other, and the next five pulses will trigger them back again one after another. After ten pulses, the decade has completed one cycle of operation and has returned to the initial condition.

---

[8] G. T. Baker, J. Sci. Inst. 25, 127 (1948).

The indicating lamps are so connected that the starting voltage is reached only when both the limiting resistors are connected to the plates, which are in a conducting state, and that happens only to one lamp in each part of the cycle.

Figure 5 shows an oscilloscope picture of the grid voltage and the plate voltage in one triode system when ten pulses are fed to the decade. The diagram of the plate voltage in particular gives a very good indication that the decade works properly.

The resistances used in the decades have all values with 10 percent tolerances and it has proved appropriate to make an adjustment of the whole system after the resistors are soldered in place. This is easily made in the following way. Before the tubes are put in their places pin number 6 of the decade plug is connected to a stabilized voltage of +150 volts (VR 150). Pins 5 and 7 are grounded. The voltage between ground and the ten grid points (the connection of the resistances 50 K, 100 K, 300 K, and 470 K) is measured and adjusted by shunting the grid resistors (50 K) with large resistors, so that the measured voltage for the ten points does not vary more than 1 volt. The voltage is about 45 volts and generally about five resistances of the value 800 kohms, 1 megohm or 2 megohms, will be necessary for one decade.

The plate current in the two halves of the 6J6 tubes used, should not differ more than 0.3 mA for the combination $E_b = 230$ volts, $R_a = 35$ kohm and $E_g = 0$. The current is about 5 mA. This requirement is fulfilled by about 90 percent of unsorted tubes from the manufacturer. When the decades are placed in the counter, pulses are fed from a pulse generator to the input and the cathode potentiometers (1 k) are adjusted to a point between the two positions where the decade starts to work improperly. The interval between these two positions should be about half the value of the potentiometer, if everything is in order.

The tube 6SN7 to the right in Fig. 1 is not essential for the functioning of the circuit but serves to increase the reliability by stabilizing the voltage between the grids and the cathodes of the decade tubes, if the tubes used do not all have the same plate current.

The complete instrument can resolve pulse pairs of 10 μsec. separation, and for the electronic circuit the maximum counting speed for uniformly spaced pulses is about 40 kc/sec. without any adjustment and about 80 kc/sec. after some readjustment of the cathode resistor.

REGISTER DRIVING CIRCUIT

The built-in register is of the telephone type with zero reset. It has a maximum counting speed of about 20 pulses/sec. but the driving circuit has been so designed that a special register with ten times higher counting speed can also be used. The cathode follower circuit has been used to make it possible to ground one side of this external register.

POWER SUPPLY

All voltages that are necessary for the pulse counter and the G-M tube are delivered from a conventional power supply, the circuit of which can be seen in Fig. 3. The high voltage stabilizer has coarse and fine controls and the voltmeter has a depressed zero point and two ranges, extending between 600–1400 volts and 1200–2800 volts. Ten percent line fluctuations will change the high voltage less than 0.2 percent at 1000 volts and has no other effect on the functioning of the counter. After a warming-up period of 15 minutes the temperature drift is negligible.

MECHANICAL CONSTRUCTION

The pulse counter with the decades is mounted on a 17-in. standard chassis made of 3-mm Al sheet and the power supply is mounted on another chassis of the same type. Both chassis fit into a box made of angle-bar-iron and iron sheet. All resistors and condensers are mounted on boards and more attention has been paid to a surveyable and reliable layout than to compactness.

RESULTS

A number of pulse counters have been built of the type described, and they have all behaved very well without any adjustments other than those described. The oldest one has been in daily use for more than a year without any repair other than replacement of one rectifier tube.

A Null-Coil Pendulum Magnetometer*, †

C. A. DOMENICALI‡
Laboratory for Insulation Research, Massachusetts Institute of Technology, Cambridge, Massachusetts

(Received December 20, 1949)

A null-method magnetometer is described for the measurement of magnetization of small single crystals of polycrystalline specimens of ferromagnetic materials. It may also be used for measurements on para- and diamagnetic materials. The specimen is placed in an inhomogeneous magnetic field inside a "null-coil" of known geometry, and the current through the coil is adjusted so as to reduce the net magnetic moment of coil and specimen to zero. This coil is rigidly attached to the lower end of a sensitive pendulum and the null-position of the pendulum is observed with the aid of a projection-microscope. This method eliminates the necessity of measuring the force on the specimen and the gradient of the magnetic field. The conditions are discussed under which the absolute error may be reduced to arbitrarily small values. The secondary field arising from the current in the null-coil is, in general, negligible; however, a simple method is described for its elimination.

INTRODUCTION

CONSIDER a region in space having a non-homogeneous magnetic induction field $\bar{B}$ with cylindrical symmetry with respect to a z axis. A small specimen of magnetic moment m_s placed on the axis of symmetry and oriented parallel to the z direction experiences a force parallel to this direction**

$$(f_z)_s = m_s(dB_z/dz)_s. \qquad (1)$$

The subscript on the derivative refers to the effective gradient throughout the volume of the specimen. The magnetization of the specimen, derivable from the magnetic moment m_s, is obtained from a knowledge of the force and the field gradient; this relation is the basis of a number of magnetometers.[1, 2]

If the specimen is replaced by a coil with a current producing a magnetic moment m_c parallel to the z axis, this coil experiences a force

$$(f_z)_c = m_c(dB_z/dz)_c. \qquad (2)$$

If now the specimen is fastened inside the coil with the moments in opposition the force is the difference between Eqs. (1) and (2). By varying the coil current, the coil-specimen combination may be restored to its original equilibrium position in the magnetic field, if the forces $(f_z)_c$ and $(f_z)_s$ are made equal and opposite. If the effective field gradients acting on the specimen and coil are equal, the return to the equilibrium position implies that

$$m_s = m_c = iAN, \qquad (3)$$

where i is the current through the coil, A its effective cross-sectional area, and N the number of turns on the coil.

Obviously the effective gradients acting on the coil and on the specimen will not, in general, be equal, so that even if the forces $(f_z)_s$ and $(f_z)_c$ are equal and opposite, the magnetic moments m_s and m_c are not necessarily equal and opposite. There are two ways of circumventing this difficulty: The pendulum magnetometer may be calibrated with a specimen of known magnetic properties and the same shape and size as the specimens to be measured; or one may obtain a magnetic field geometry in which the "effective gradient" is the same for specimen and coil. The first method was applied to the present instrument. Both methods will be discussed.

I. THE MAGNETOMETER

The most important component of the null-coil pendulum magnetometer (Fig. 1) is the balancing or

[2] R. Buehl and J. Wulff, Rev. Sci. Inst. 9, 224 (1938).

null-coil. In the present instrument this consists of 302 turns of No. 36 double-silk-covered copper wire, wound in six layers on an aluminum cylinder 10.8 mm long and 11.68 mm diameter. The mean diameters A_1, A_2, $\cdots$ and numbers of turns N_1, N_2, $\cdots$ of each layer were recorded, and their products N_1A_1, N_2A_2, $\cdots$ added to give an over-all effective constant $NA=392.7$ cm^2. The coil is inserted into a thin cylindrical copper shell to which is soldered a smaller diameter thin wall copper tube to form a T-joint (Fig. 1). The resistance of the coil, exclusive of leads, is approximately 15 ohms; the null-coil currents had to be kept <250 ma at room temperature to avoid undue heating.

In designing a null-coil for a given application it is convenient to calculate the magnetic moment in terms of the mean coil diameter, the number of turns, resistance of wire, and power dissipated as

$$m=\left(\frac{1.96\times10^{-3}Wd^3N}{r}\right)^{\frac{1}{2}}, \tag{4}$$

where m is the magnetic moment of the coil in c.g.s. units, W the power dissipated in watts, d the mean diameter in cm, N the total number of turns, and r the resistance of the wire per unit length in ohms/cm.

The specimen was cemented with neutral Canada balsam into a cavity in the center of a small, balsa wood "boat" (Fig. 1). The boat, made slightly larger than the hole in the aluminum coil form, was forced into place inside it. The thermocouple, attached to the null-coil, was placed in direct contact with the specimen. The 25-cm silica tubing, fitted at its upper end into a thin wall, brass tube (the "pendulum tube"), was joined to the "pivot tube" as shown in Fig. 1. Two hard steel needles at the ends of this "pivot tube," resting in a hole and groove, respectively, in two glass beads, formed the pivots for the pendulum. A damping arm consisting of a brass tube at right angles to both the pivot tube and the pendulum tube, carried a copper rectangle at each end which fitted into the narrow gap of a small electromagnet. Thus the motion of the pendulum could be damped electromagnetically. Attached to the tubes were two adjustable counterbalancing weights. The complete pendulum system could be rotated about a vertical axis.

Displacement of the pendulum was observed by the position of a cross hair fastened to the silica tube of the pendulum. This cross hair, illuminated with an intensely bright microscope lamp, was projected onto a ground-glass screen rigidly attached to the magnetometer stand. A small lateral displacement of the hair was thus magnified 40 times.

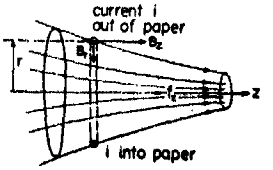

FIG. 2. Loop in non-homogeneous field of cylindrical symmetry.

The electromagnet could be used under steady load at a maximum induction field of *ca.* 0.5 weber/m^2 (5000 gauss); the pole pieces were shaped to give a gradient (gauss/cm) of approximately $3\frac{1}{2}$ percent of the total induction, a percentage found to be fairly constant for all intensities. The pole pieces, which were different in diameter (6.68 and 6.22 cm), had concave pole faces; the amount of concavity required was determined by trial and error. At the time that the magnetometer was built the Laboratory did not possess a large electromagnet; consequently, because of the large gap (6.5 cm) required for the experiments, the methods outlined for calculating the appropriate pole face shape could not be used.

II. PERFORMANCE OF THE INSTRUMENT

With specimens of magnetic moments of the order of 3×10^{-3} amp. m^2 (3 c.g.s.) the relative sensitivity of the magnetometer at intermediate fields is of the order of 0.05 percent of this value, that is, much higher than the accuracy with which the null-coil current can be read. The absolute sensitivity depends upon the geometry of the magnetic field, the size of null-coil, and other factors as indicated. If the null-coil was located in the center of the gap, the absolute value of saturation magnetization of a nickel sample of the same shape and size as the magnetite specimens later investigated was found to be correct to within one percent, if calculated according to Eq. (3). This was checked by measuring ballistically the saturation magnetization of a nickel cylinder from which the small sample was later taken.

The variation of the *indicated* value of magnetization with the axial position of the null-coil in the electromagnet gap was found to be almost linear, and to amount to ±4 percent for a ±5-mm axial displacement of the null-coil.

The coil itself and other parts of the pendulum in the vicinity of the electromagnet gap contained traces of ferromagnetic impurities. Consequently, upon application of a magnetic field with no specimen inside the null-coil, the pendulum showed a deflection which increased slowly with field. The maximum null-coil current necessary to restore the pendulum to its zero position was only 0.5 ma, however, whereas the current required for compensation of a magnetite specimen [magnetic moment $\simeq3\times10^{-3}$ amp. m^2 (3 c.g.s.)] was of the order of 200 ma. This maximum value of 0.5 ma was found to be independent of temperature over the range from $+24°$ to $-186°$C.

III. ELIMINATION OF NULL-COIL FIELD

Although the field caused by the null-coil is, in general, small compared with the applied field, a simple method of reducing it to an arbitrarily small value may be used, if required, by employing two coaxial coils with currents in opposite directions. If the two coils, of equal length, are long compared with their diameters and have cross-sectional areas A_1 and A_2, and if the coils are wound with the same total number of turns N, the field at the common center of the coils is zero for all values of current if they are connected in series and traversed by the same current I in opposite directions. The magnetic moment is now

$$m_c = (NI/10)(A_1 - A_2) \tag{5}$$

when I is measured in amp., A_1 and A_2 in m², and m_c in amp. m².

IV. ANALYSIS OF MAGNETOMETER FIELDS

It was stated in the Introduction that if the effective magnetic field gradients for the null-coil and specimen are made equal by choosing the proper field geometry, the desired magnetic moment of the specimen can be found simply from the coil current and the known characteristics of this coil. We have investigated the conditions under which these effective gradients are equal for coil and specimen, and ways in which such conditions can be met by a proper design of the electromagnet pole pieces. Two particular cases of field symmetry in the magnet gap are of interest here; namely, a magnetic field (Fig. 2) of cylindrical symmetry about the longitudinal axis of the magnet poles, and a field (Fig. 3) symmetrical with respect to a plane, which to a first approximation may be treated as a two-dimensional field.

The mathematical procedure is as follows.†† We consider only a single turn of the null-coil. We replace the specimen by an equivalent surface current of density $\mathbf{J}_s = \mathbf{M} \times \mathbf{n}$, where $\mathbf{M}$ is the magnetization vector (assumed uniform), $\mathbf{n}$ is an outward-pointing unit vector normal to the surface of the magnetized body, and again we consider only an element of this surface current of axial length dz.

The axial force acting on the coil loop and that acting on the specimen loop are equated, and this expression involves the radial field component B_r. Introducing the magnetic moments of the two current loops, we investigate the conditions necessary for the equality of the moments. In the case of cylindrical symmetry this leads to the field components $B_r = Ar$ and $B_z = -2Az + C$, and to a potential function $\psi = A(z^2 - \frac{1}{2}r^2) - Cz + G$, where A, C, and G are constants. A similar calculation for the case of a two-dimensional field gives $B_z = Az$, $B_x = -Ax + C$, $\psi = \frac{1}{2}A(x^2 - z^2) - Cx + G$.

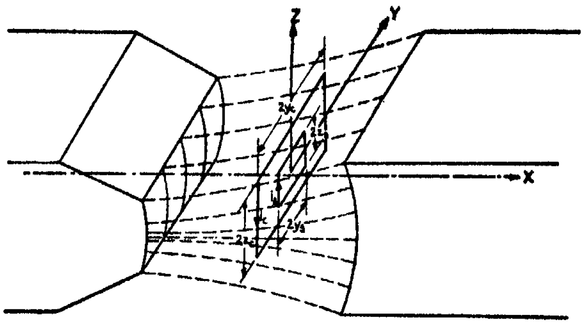

FIG. 3. Magnetic field non-homogeneous in two dimensions.

The procedure for finding the shape of the pole faces is as follows. Having decided upon the desired (and available) values of the field components, we establish the reference point for the coordinate system, and then calculate the values of the constants A, C, and G. In this way we find the shape of the equipotential surfaces in the electromagnet gap. The pole faces are now cut out so as to coincide with the appropriate equipotential surfaces.

It is clear that the analytical method outlined will not give an exact solution of the problem of pole-face shape since the solution given assumes that the pole faces are infinitely large and accurately represent equipotential surfaces. However, if the distance between the pole faces is small compared with their diameters, our solution should give a good first approximation to the solution, thereby serving as a time-saver in the operation of turning these pole faces on the lathe.

Electron Component in Geiger Discharge*

G. G. Kelley, W. H. Jordan, and P. R. Bell
Oak Ridge National Laboratory, Oak Ridge, Tennessee

(Received December 27, 1949)

Observation of the wave form of current during a Geiger discharge indicates the presence of a component due to electron collection ammounting to as much as 50 percent of the total energy involved in the discharge. It appears, therefore, that the initial ion sheath can have a mean radius of the order of 10 to 15 times the radius of the center wire. Apparatus is described, wave forms are shown and the method used to evaluate electron component and mean radius of ion sheath is indicated. Results for two tubes with different quenching vapors are tabulated.

INTRODUCTION

INVESTIGATORS of Geiger discharge have been of the opinion that the ion sheath formed about the center wire during a discharge is initially so thin that its electrons are collected without making an appreciable contribution to the pulse. Alder *et al.* performed an experiment which seemed to confirm this view, and Wilkinson, ignoring space-charge effects, arrived at a figure of three percent for the electron contribution.[1,2]

Using an experimental procedure similar to that described by Alder *et al.*, but with a faster amplifier, we have obtained evidence that as much as 50 percent of the energy involved in the discharge is used to collect electrons. The first work done along this line was reported at the 1948 annual meeting of the American Physical Society in January, 1949. Recently the experiment has been repeated with considerably faster equipment.

APPARATUS

The equipment used in the recent work consists of a Geiger tube, with variable voltage power supply, connected directly to the 200-ohm input of a high speed synchroscope which has been developed at the Oak Ridge National Laboratory.[3] The vertical amplifier in this instrument has a maximum gain of 1000 and a rise time of about 6.5×10^{-9} sec. A built-in delay line allows the sweep to be triggered 0.15 μsec. before the signal appears at the vertical plates. The fastest sweep is 0.28 μsec. in total duration. The voltage across the Geiger tube is held essentially constant during the discharge by a 0.1-μf condenser from cathode to ground. The voltage developed across the input terminals of the synchroscope in series between the anode of the tube and ground is therefore a measure of discharge current which in turn may be seen to be a measure of the rate at which electrical energy is being used by the discharge. Traces from individual discharges appearing at the face of the cathode-ray tube were photographed, using a moving film camera, with the film moving fast enough to separate individual traces.

METHOD

On the assumption of an infinitesimal ion sheath starting from the surface of the counter wire, an expression may be easily obtained for the shape of the discharge pulse. A development of this expression is given by Alder *et al.* and by others. The shape of any particular pulse depends, of course, on the location and direction of the path of the initial radiation. The discharge will burn in both directions along the wire until it reaches one end of the counter and will continue then in only one direction until it burns out at the other end. The curves shown in Fig. 1 were plotted for a discharge starting at one end of the tube. The parameter t_0 is the time required for the ion sheath to travel from $r=0$ to the actual effective initial radius of the ion sheath and t_s is the duration of the burning time; that is, the time required for the whole ion sheath to be formed. These

FIG. 2. Photograph of a series of pulses from tube B with an overvoltage of 115 v. The source was about one foot from the center of the tube and was uncollimated.

curves also apply to discharges which start at the center of the tube since t_e is halved in this case.

A series of pulses obtained using the apparatus described is shown in Fig. 2. It will be seen that the pulses are quite different from the curves of Fig. 1. They are somewhat distorted because of the non-linearity of amplifier gain but even when corrected they cannot be made to fit the curves of positive ion contribution. A tracing of one of the pulses, one in which the burning originated near the center of the tube, is shown in Fig. 3(a). Figure 3(b) is the pulse corrected for amplifier gain, and Fig. 3(c) is a curve obtained from the formula with constants adjusted to give the best fit after the burning time. There is no measurable difference between the curve and the pulse for times more than just slightly greater than the burning time. When this theoretical curve is subtracted from the pulse there is obtained a relatively rectangular remainder of considerable amplitude, shown in Fig. 3(d). Just such an effect would be expected from electron collection. Due to the fact that the mobility of electrons is very much greater than that of positive ions, the electrons are collected essentially instantaneously as they are produced and give rise to a constant current, building up as fast as the beginning of the ion sheath can be established, and lasting only during the burning time.

The mean radius of the initial ion sheath may be evaluated from the ratio of electron collection energy to the total energy involved. This is the ratio $(i_e t_e)/Q$ where i_e is the magnitude of the electron component of the current. This ratio represents the portion of the total potential, V_T, through which the mean electron has fallen. Thus,

$$\frac{V}{V_T}=\frac{i_e t_e}{Q}=\frac{\ln r/a}{\ln b/a} \quad \text{or} \quad r=a\left(\frac{b}{a}\right)^{i_e t_e/Q}.$$

The value of Q, the quantity of ion pairs formed, in coulombs, was determined by electrically integrating the discharge current. A cathode follower was added

1370	95	2.50	0.54	1.35	4.32	0.29	2.3
1390	115	2.95	0.46	1.35	4.59	0.22	1.6

between the tube and synchroscope to provide a high impedance input, which input was shunted by a condenser large enough to integrate the discharge current. Then $Q=e_{\max}/C_T$ where C_T is the added capacity plus the tube and circuit capacity.

RESULTS

With the equipment used originally, which involved an amplifier with a rise time of 2.5×10^{-8} sec., the corners of the wave forms were rounded to the extent that there was some ambiguity as to the magnitude of the electron component. For this reason it was necessary to apply the process just described (that of fitting the theoretical curve to the tail of a pulse and determining the remainder during the pulse) for each evaluation. With the newer equipment, however, the electron component could be measured directly, subject to small statistical fluctuations which could be accounted for easily by eye. Results for two tubes are given in Table I. Both were thin-wall glass tubes with cathode dimension 7×0.7 in. using 4-mil center wires. Tube A was filled with 9.6 cm of neon and 0.6 cm of amyl acetate. The Geiger threshold was at 846 v. Tube B was filled with 8.2 cm of neon and 2 cm of ethyl alcohol. Its threshold was at 1275 v. It will be noticed that the electron component of the energy does not increase as rapidly with overvoltage as the total energy and in fact in tube B appears to decrease, although the differences may be within the experimental error.

The pulse rise time of tube A was measurable and decreased with overvoltage from 2.3×10^{-8} sec. at 870 v to 0.5×10^{-8} at 950 v. The rise time of the pulse from tube B was too fast to be measured at all values of overvoltage with the amplifier available. It is estimated from the fact that it appeared slightly slower than the step function response of the amplifier that the rise time of this tube lies somewhere between 0.3×10^{-8} and 0.5×10^{-8} sec. The fall time of the electron component was in all cases slower than the rise, probably due to the fact that the ends of the anode are not sharply defined.

Design of Logarithmic Voltage Dividers

F. V. Hunt and O. D. Sledge*
Cruft Laboratory, Harvard University, Cambridge, Massachusetts

(Received January 11, 1950)

Suitably shaped electrodes attached to a thin sheet of isotropic conducting material, such as one of the newly developed conducting plastics, can make available a specified distribution of potential at a contact sliding along an edge of the sheet. Electrode contours are evaluated for the assumption of a logarithmic potential distribution along the straight-line edge of a voltage-divider strip cut out of the conducting sheet. The ratio of the total length for contact travel to the maximum width of the strip controls the attenuation rate. For a specified attenuation rate (db/in.), the three non-straight edges of the divider strip can be scribed or punched by repeated use of a single curved template or die. Alternative electrode configurations for attachment to rectangular strips of material offer simplification of construction at some sacrifice of linearity of the logarithmic scale.

In the spring of 1937, as a part of the graduate study program for one of us (ODS), we undertook the analytical problem of finding what disposition of fixed electrodes on a thin, plane sheet of conducting material would produce a logarithmic variation of potential along a straight-line edge of the material. Although an exact solution of the problem proved not too difficult, it appeared to have little more than academic interest at that time since available materials had conductivities that were either too high or too low to yield useful values for the overall resistance of the voltage divider. Since conducting plastic materials have now been developed which appear to have values of resistivity appropriate for such service, it seems worth while to present the results of a restudy of this problem.

METHOD OF ATTACKING PROBLEM

The general design problem is attacked in the following way. Two-dimensional current flow is assumed in an infinite plane sheet of conducting material. The desired variation of potential along some particular straight or curved line is expressed mathematically and taken as a boundary condition on the current flow. A secondary boundary condition is expressed by requiring that one of the current flow lines be the straight or curved line along which the variation of potential is prescribed. All the equipotential lines and current flow lines compatible with these boundary conditions are then determined. The desired voltage divider is then extracted from the infinite sheet by making four cuts, two along equipotential lines and two along current flow lines. Electrodes can be attached to the edge surfaces exposed by the equipotential cuts, perhaps most easily by electroplating since the material is conducting, and are to be maintained at appropriate fixed potentials. The divider strip is left free and insulated along the edges exposed by the flow line cuts. The desired variation of potential is then available at a contact sliding along one of these flow line cuts, provided no current is drawn from the movable contact. The latter restriction is seldom serious in practice since the variable potential is usually to be applied to the very high resistance grid circuit of a succeeding amplifier stage.

---

* Now at Central Radio Propagation Laboratory, National Bureau of Standards, Washington, D. C.

DETAILS OF EXACT SOLUTION

It will be assumed that the x axis of the coordinate system of Fig. 1 is to represent the straight line along which the potential is to vary logarithmically. Then the first boundary condition is expressed by the requirement

$$V(x, 0) = V_0 e^{-kx}, \tag{1}$$

in which V_0 represents the potential at the origin and k is the prescribed attenuation scale-factor in nepers per unit of length along the x axis. In order that the x axis also be a line of current flow, it is necessary that the normal component of the electric field vanish along the axis; thus

$$\partial V/\partial y = 0 \quad \text{for} \quad y = 0. \tag{2}$$

Equations (1) and (2) represent, therefore, the boundary conditions which are to be imposed on an otherwise-general solution for two-dimensional current flow in the conducting sheet represented by the x,y plane.

If a solution of Laplace's equation is assumed in the form of a product of two functions—one of x alone and one of y alone—the variables can readily be separated and the solution cast in the form

$$V = f_1(x)f_2(y) = e^{kx}(A_1 \sin ky + A_2 \cos ky) + e^{-kx}(A_3 \sin ky + A_4 \cos ky), \tag{3}$$

where the A's are arbitrary constants. Three of these constants vanish conveniently when the boundary conditions (1) and (2) are imposed on (3), leaving the equation for the potential distribution in the form

$$V(x, y) = V_0 e^{-kx} \cos ky. \tag{4}$$

By setting $V(x, y)$ equal to various constant values, this relation determines the shape of the equipotential lines in the x,y plane.

An equation for the current flow lines in the x,y plane can be found by setting up a function $W(x, y)$ which is conjugate to $V(x, y)$. The form of this function is established by differentiating Eq. (4) and substituting the derivatives in the Cauchy-Riemann relations $\partial V/\partial x = \partial W/\partial y$ and $\partial V/\partial y = -\partial W/\partial x$. After integration, the conjugate function emerges as

$$W(x, y) = V_0 e^{-kx} \sin ky + W_0. \tag{5}$$

Typical flow lines are then determined by assigning various constant values to Eq. (5). Since W_0, the value of W at the origin, can be merged with these arbitrarily assigned constant values, it is apparent that the flow lines are geometrically similar to the equipotential lines since the sine and cosine functions are complementary. This similarity turns out to be very useful in the actual construction of voltage dividers.

Several typical flow lines and equipotential lines are shown in Fig. 1. In one sense these complete the formal solution of the problem since, as suggested above, the desired voltage divider "strip" can be lifted out of the infinite plane by cutting along these lines. However, several practical questions influence the choice of the lines along which cuts are to be made. For example, it is to be noted that the potential of a line passing through the ordinate that makes $ky = \pi/2$ is zero for all values of x. A cut along this line parallel to the x axis can serve as a site for the attachment of a zero-potential electrode. Then if the high potential electrode is applied to the edge exposed by a cut along the line $OA''A'A$, and if the conducting strip lying between the x axis and edge BWC extends indefinitely to the right in Fig. 1, a strictly logarithmic variation of potential will appear along the entire x axis as required by the design specifications. However, it is more common to

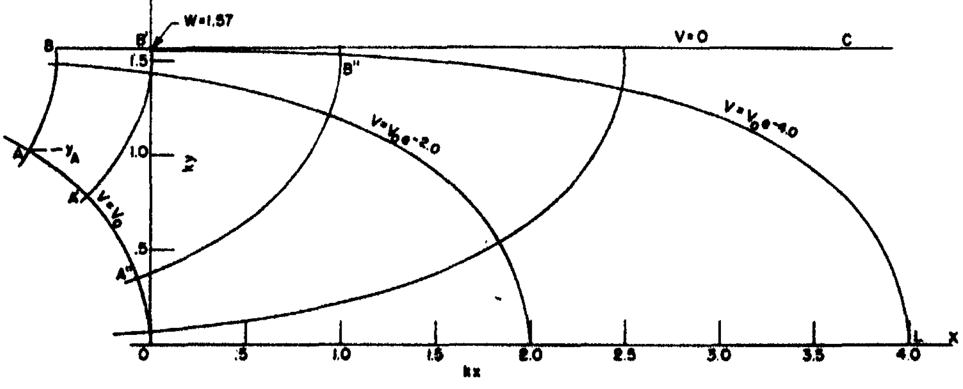

FIG. 1.

require only that some specified maximum of attenuation be reached within a specified distance along the x axis. This condition will be satisfied if the upper edge of the conducting strip is cut along the particular curved equipotential line corresponding to the maximum required attenuation. An electrode attached to this surface can then be maintained at the appropriate not-quite-zero potential by introducing a small external "wing" resistor between this electrode and ground.

In order to make the final cut which will free the finite divider strip from the infinite x,y plane, it is only necessary to choose among flow lines of which AB, $A'B'$, and $A''B''$ in Fig. 1 are typical. The potential distribution along the x axis is the same whichever of these cuts is selected for the left-hand edge of the divider strip, but the total resistance between the electrodes is profoundly affected by the choice. Since the total resistance is a primary design parameter, it is important to determine its magnitude in terms of the electrode geometry and the specific resistivity of the conducting sheet. If the current density at any point x,y is resolved into two components, these currents can be written at once in terms of the resistivity and the potential gradient. Thus

$$u_x = -(1/\rho)(\partial V/\partial x), \quad u_y = -(1/\rho)(\partial V/\partial y); \qquad (6)$$

where u_x is the component of current density (amperes/cm^2) flowing along the $+x$ axis, u_y is the corresponding current density component along the y axis, and ρ is the specific volume resistivity of the conducting material in ohm-cm. Substituting Eq. (4) in (6) gives

$$\begin{aligned} u_x &= u_0 e^{-kx} \cos ky, \\ u_y &= u_0 e^{-kx} \sin ky. \end{aligned} \qquad (7)$$

where $u_0 = kV_0/\rho$ is the current density at the origin. The resultant of these two components of current density is just

$$u = u_0 e^{-kx}, \qquad (8)$$

which leads to the interesting conclusion that the total current density at any point is independent of the y ordinate or distance from the contact surface of the divider. Equation (8) also indicates that the current density is attenuated along the x axis at the same rate as is potential, as might have been anticipated in view of the assumed uniform resistivity of the conducting material.

The total current supplied by the external circuit is to be found by integrating the current density over the surface of the high potential electrode. This can be set up in the form

$$I_{\text{total}} = t \int_{0-A} u ds, \qquad (9)$$

where t is the (uniform) thickness of the conducting sheet (cm) and ds is an element of path length along the high potential electrode. The result of this integration is

$$I_{\text{total}} = \frac{tu_0}{k} \tan ky_A \qquad (10)$$

where y_A is the ordinate of the point A (Fig. 1) or tip of the high potential electrode. When the value of u_0 is introduced, the total resistance between the high potential electrode and "ground" ($V=0$) is given as

$$R_{\text{total}} = \frac{V_0}{I_{\text{total}}} = \frac{\rho}{t} \cot ky_A. \qquad (11)$$

When the divider strip is cut along the equipotential corresponding to maximum attentuation, and terminating at $x=L$, the total resistance is reduced by $R_{\text{total}}e^{-kL}$ which must then appear in the wing resistor, connected as indicated by R in Fig. 2a.

It was mentioned above that the distribution of potential along the variable contact surface is independent of the choice of flow line (e.g. AB or $A'B'$) along which the plate is cut. The three flow lines indicated in Fig. 1 were drawn so as to intersect the V_0 equipotential through the origin at ordinates which would make $\cot ky_A$ equal to $\frac{1}{2}$, 1 or 2. This freedom of choice gives the designer an independent parameter with which to control the overall resistance of the divider, and is the more convenient because all the flow lines are geometrically similar. Moreover, the equipotential lines are also similar to each other and (with an inversion around the x axis) to the flow lines. Thus all the curved lines appearing in Fig. 1 can be drawn by using a single template. Alternatively, sheet material could be punched in any of the various allowed shapes by using a single curved die, the inversion being handled by punching equipotentials from one side of the sheet and flow lines from the other.

ENGINEERING DESIGN

In laying out a template or die for the required curvilinear cuts, it is useful to rewrite Eq. (4) explicitly for the equipotential representing the maximum attenuation N_L. This may take the form

$$\frac{L-x}{L/N_L} = -20 \log \cos\left(0.1151 \frac{y}{L/N_L}\right), \qquad (12)$$

in which N_L is in decibels and the numerical factor $0.1151 = (20 \log_{10} e)^{-1}$. Equation (12) can then be solved for a unique set of associated numerical values of $(L-x)$ and y (see Table I), each measured in terms of an arbitrary unit of length, L/N_L, representing the distance of contact travel per decibel change in attenuation.

Figures 2a and 2b illustrate the shape of divider strips for values of L/N_L of 0.1 inch per decibel and 0.2 inch per decibel respectively. For each of these the electrode profile BDL is derived from Table I. The procedure in laying out such a divider strip is as follows:

TABLE I. Equipotential template layout.
Unit of length $= L/N_L$.

$L-x$	y	$L-x$	y
0	0	10	10.85
1	4.09	15	12.09
2	5.62	20	12.77
3	6.81	30	13.37
4	7.71	40	13.557
5	8.46	60	13.635
7	9.62	∞	13.644

the specified length of contact travel OL is marked off in units of L/N_L, which is equivalent to marking off on OL the desired decibel scale. The electrode profile BDL is then plotted from the data of Table I and a template prepared to lie within $BDLO$. The high-potential electrode profile OA can then be drawn congruent to the lower portion of BDL by sliding the template along the line OL until L coincides with O. The insulated cut AB can then be drawn by turning the template over about the straight edge OL and shifting it upward and to the left so that the straight edge OL lies along a horizontal through the point W, the ordinate value that makes $ky=\pi/2$. According to the last entry in Table I, W has the ordinate value 13.644 L/N_L. This is, incidentally, the maximum width of material required for a divider strip to yield any specified rate of attenuation. If the resistance multiplier term, $\cot ky_A$, is to be unity, the proper AB line will be obtained when the vertex of the template L lies vertically over the origin O thus placing the tip of the high potential electrode A at $y_A=6.82$. For resistance multipliers of ½ or 2, the template should be moved to the left or right as required to bring the intersection at A to the ordinate value 9.62 or 4.03 respectively as determined from the relation

$$\frac{y_A}{L/N_L}=8.686\cot^{-1}(R_{\text{total}}t/\rho). \qquad (13)$$

The examples shown illustrate the general characteristic that dividers for a small attenuation range tend to be relatively wide and short while those for a large attenuation range appear long and narrow. The minor role played in the design by thickness of the material would suggest that a surface distribution of conducting material could be employed. If a homogeneous material is used in very thin slabs, a strip shaped as in Fig. 2a might be wrapped around a cylindrical form to provide for angular rotation of a contact arm.

FIG. 2a.

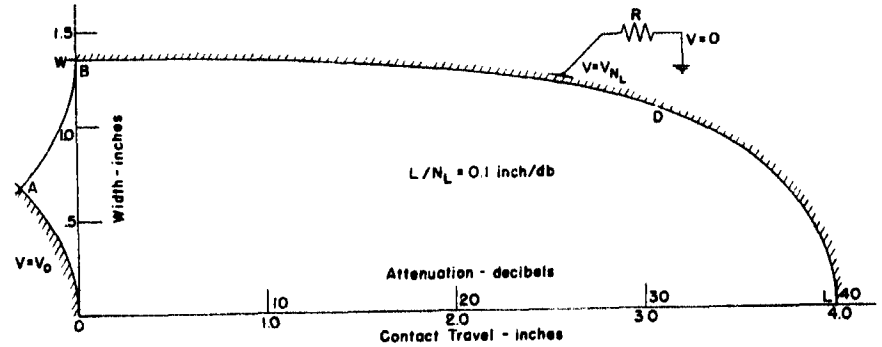

FIG. 2b.

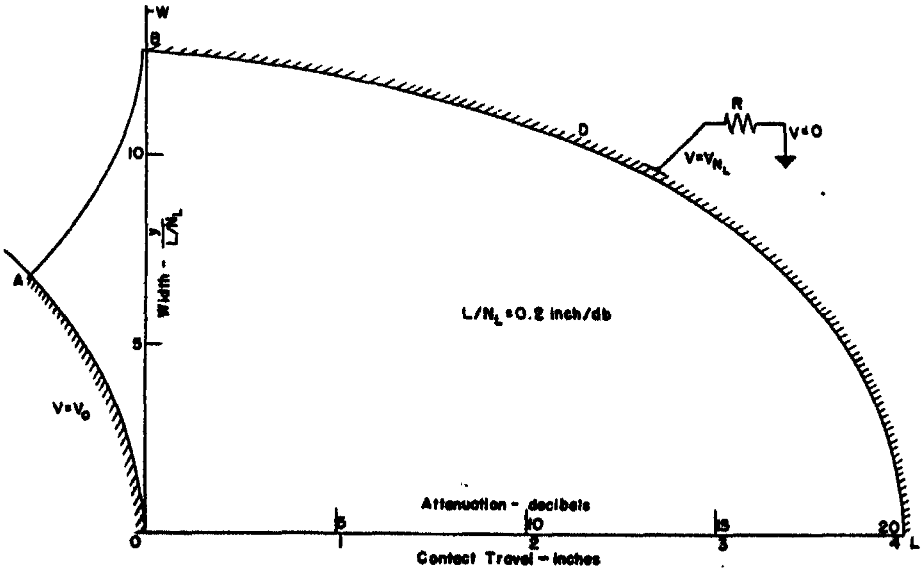

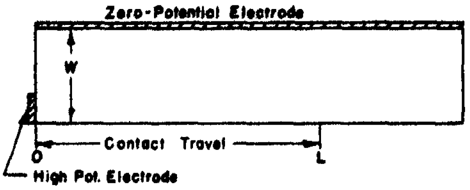

FIG. 3.

APPROXIMATE SOLUTIONS

The shapes of the boundary surfaces prescribed by the foregoing exact solution are so relatively simple as to make approximations for further simplification of marginal value. One configuration illustrated in Fig. 3 was studied, however, and may be useful under some circumstances. The conducting material was assumed to be available in the form of a rectangular strip to which electrodes could be attached along the straight line edges. A zero-potential electrode was applied along the full length of the upper side at a distance from the origin corresponding to W of Fig. 2. The high potential electrode was applied along a portion of the vertical OW and extended from 0 to an ordinate $A=0.32W$. Under these conditions a decibel scale of attenuation, linear within about one per cent, was found to be available for a distance OL, which is less than the total length of the strip by about $1.5W$. The attenuation *rate* is determined by the width of the strip ($W=13.6L/N_L$) as in the exact solution requiring curved electrodes. Also as in the exact solution, the resistance multiplier is primarily determined by the length of the high-potential electrode, although this length can probably not exceed one-third of the width without adversely affecting the linearity of the scale for small values of attenuation. The "price" paid for the rectilinear disposition of electrodes is the overhang of material beyond the range OL within which the decibel attenuation scale is linear. The accuracy limits quoted for linearity of the attenuation scale were assessed by tests on this configuration in an electrolytic tank.

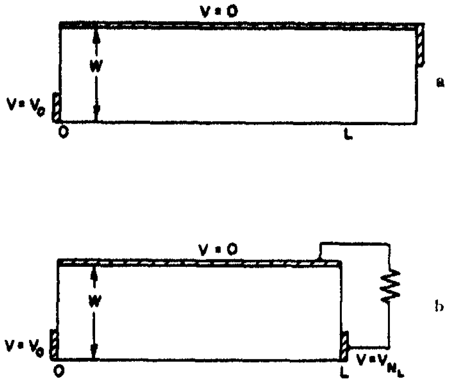

FIG 4.

It seems likely that the amount of overhang might be substantially reduced if the low potential electrode were extended around the corner and along part of the free edge as indicated in Fig. 4a. In fact it seems likely that a rectangular configuration of this type, when used in conjunction with a suitable wing resistor, might be capable of eliminating the overhang entirely. Another electrode configuration that seems to approximate the ideal somewhat more closely is shown in Fig. 4b. In this case the zero-potential electrode extends only along the upper surface. A third electrode, similar to the high potential electrode of Figs. 3 and 4a, is attached at L and approximates by a straight line the lower portion of the equipotential corresponding to maximum attenuation N_L. In the absence of the conducting material to the right of L, this electrode would assume a potential higher than that corresponding to N_L, but it can be brought back to the correct potential by connecting in shunt a suitable external resistor as indicated. No experimental data are available yet for establishing tolerance limits on the linearity of attenuation afforded by the arrangement of Fig. 4b.

EXTENSIONS OF THE SOLUTION

The case of straight-line motion of a contact arm has been worked out above in some detail because this conformed to the requirements of a voltage divider for use in a high speed power-level recorder. It should be possible, however, to introduce a transformation of coordinates that would permit these results to be carried over to cases involving circular symmetry. The general nature of the required configuration of electrodes can usually be inferred qualitatively by inspection, but the exact shapes required will be influenced by additional boundary conditions imposed by constructional requirements.

Pentode Counting or Control Ring*

BENJAMIN L. MOORE
The Computation Laboratory, Harvard University, Cambridge, Massachusetts

(Received January 15, 1950)

The 6AS6 pentode has been used in a very stable counting or control ring whose input is essentially independent of amplitude and wave shape. Values of supply voltages and circuit parameters are not critical. Control voltages corresponding to one or more stable states of the ring may be obtained very easily.

INTRODUCTION

IN the past a number of ring or counting circuits have been described. The operation of many of these circuits depends to a large extent on the amplitude, wave shape, and pulse repetition rate. Some of the circuits require careful selection of vacuum tubes for successful operation. In this paper is described a very stable 6AS6 pentode counting or control ring[1] whose operation is essentially independent of the amplitude, wave shape, and repetition rate of the incoming pulses, and does not require a careful selection of tubes.

RING CIRCUIT

The 6AS6 pentode, whose suppressor grid has essentially the same control of the plate current as the control grid, is the basic element of the ring. Two of these pentodes are connected as a direct coupled trigger pair, as shown in Fig. 1, using the screens of the tubes as "plates." The important feature of this trigger pair to be noted is that the suppressor grid has control of the plate current of the tube whose screen is conducting, and has no control of the plate current of the tube whose screen is not conducting. It is this characteristic which is used to operate the ring.

Figure 2 is a schematic circuit of a ring of ten pentodes. Opposite tubes are connected as the trigger pair in Fig. 1, and for clarity the voltage divider resistors and filament wiring have been omitted. Normally all suppressor grids are biased to cut-off, those of the odd-numbered tubes being connected to one input, and those of the even-numbered tubes to a second input. The plate of each tube in the ring is connected to the screen of the next tube.

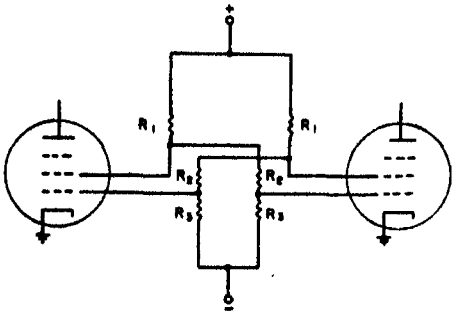

FIG. 1. 6AS6 pentode trigger pair using the screens as plates.

As each tube is one of a trigger pair, half the tubes in the ring will always be conducting. Assume that tubes one through five are initially conducting. A positive pulse on input 1 will result in plate current in tubes 1, 3, and 5. As the screens of tubes 2 and 4 are already conducting, the additional currents through the plates of tubes 1 and 3 will not change the conducting states of these tubes. The plate current in tube 5, however, will lower the screen voltage of tube 6, thus cutting off tube 1 and causing tube 6 to conduct. A second pulse on input 2 will similarly cut off tube 2 and turn on tube 7. Thus alternate pulses applied to inputs 1 and 2 will cause the ring to step once for each pulse.

When power is first applied to the ring, the order of the conducting tubes is random. There are several methods of setting the trigger pairs, so that the proper sequence of tubes is conducting initially. One of the simplest ways of doing this is to insert momentarily, by means of a manual switch, a high resistance between R_3 and the negative power supply in half the voltage dividers.

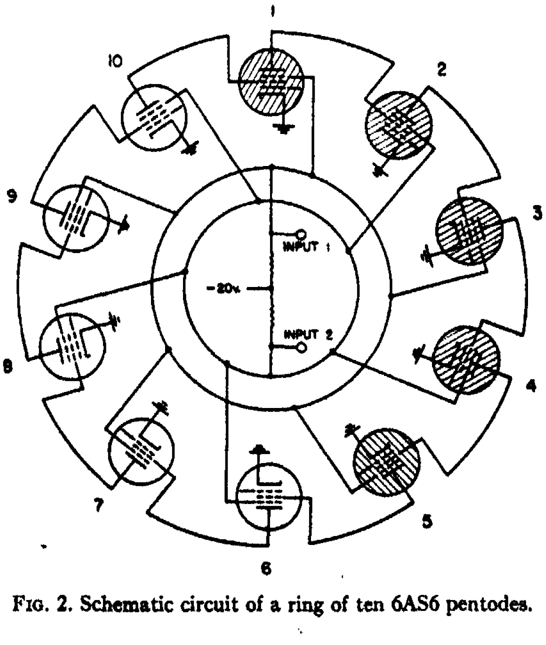

FIG. 2. Schematic circuit of a ring of ten 6AS6 pentodes.

[1] A preliminary report on this work was given at the June, 1949, meeting of the American Physical Society at Cambridge, Massachusetts [Phys. Rev. 76, 465 (1949)].

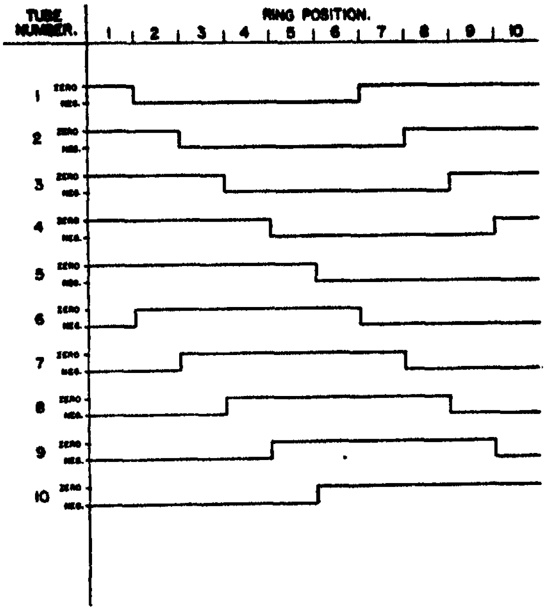

FIG. 3. Grid voltages as a function of ring position.

There are no limitations on the wave shape or maximum width of the input pulses. In fact, the only limitations placed on these pulses are that they do not occur simultaneously on both input lines, and that each pulse raise the suppressor grids above a minimum threshold potential for a sufficient length of time to permit the trigger pair to trip.

The circuit has proved to be very stable in operation. Tube characteristics and values of resistances and supply voltages are not critical. No difficulty has been experienced with five percent tolerances on the latter two items, and careful selection of vacuum tubes has not been necessary. It should be noted, however, that maintaining a close tolerance on resistance and voltage values will permit more variation in tube characteristics, which are more difficult to control.

Using only reasonable care to minimize wiring capacitance, with values of $R_1 = 22{,}000$ ohms, $R_2 = 39{,}000$ ohms, $R_3 = 75{,}000$ ohms, and positive and negative supply voltages of 150 volts each, the circuit has operated reliably with pulses of one microsecond duration at repetition rates of several hundred kilo-pulses per second on each input. This circuit was developed as a component of the Mark III computing machine, and no attempt has been made to extend the operating range to higher pulse repetition rates. Consequently, the repetition rate mentioned above is not necessarily an upper limit. By-passing resistor R_2 with a small condenser will speed up the trigger action or permit operation at the same speed with somewhat larger values for the resistances. For example, approximately the same operating characteristics as above can be obtained with $R_1 = 39{,}000$ *ohms*, $R_2 = 75{,}000$ *ohms*, and $R_3 = 150{,}000$ ohms, using a 25 micromicrofarad condenser to by-pass resistor R_2. These larger resistors reduce the power required, and make the tolerances on both the resistances and tubes even less critical.

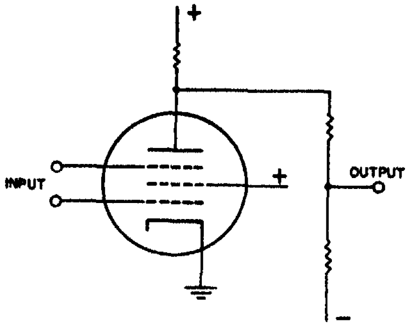

FIG. 4. 6AS6 pentode gate.

The number of tubes in the ring is essentially limited by the power available to drive the suppressor grids. In general, for a larger number of states than, say, 10, it is more economical to use two smaller rings coupled together such that the second ring moves one position for each complete cycle of the first. For example, a ring of 4 and 6 would give 24 stable states.

CONTROL VOLTAGES

In many applications, it is desirable to obtain control voltages corresponding to one or more positions of the ring. Figure 3 shows the potentials of the various control grids for each stable state of the ring. By connecting the control grid and suppressor grid of the pentode gate shown in Fig. 4 to grids of two tubes of the ring, it is possible to make the gate conduct or not conduct for one or more stable states of the ring. For example, by connecting to grids of tubes 1 and 5, the gate will conduct for stable state 1 only, and by connecting to grids 6 and 7 it will conduct for states 3 through 6. The output of the gate, by means of a voltage divider, can be made to operate between zero and some negative voltage which can be used to operate another gate directly.

Low Temperature X-Ray Diffraction Apparatus

DONALD F. CLIFTON
Institute for the Study of Metals, University of Chicago, Chicago, Illinois

(Received January 23, 1950)

When studying transformations at sub-zero temperatures it is often convenient to be able to carry out treatments such as cold-working and annealing and to transfer the specimen, at temperature, to the x-ray diffraction camera. Several cameras have been designed, primarily for the x-ray spectrometer, in which this is easily done. For constant temperature work a flask, having a nozzle which allows cold liquid to flow over the specimen, is used. The holder is such that the specimen can be put in, in correct alignment, while in a cold bath. Two types of cameras giving variable temperatures are described. One, using cold gas blown over the specimen for cooling, permits putting the specimen in place under liquid nitrogen and keeping it at this temperature while it is aligned in the spectrometer. Rapid changes and accurate control in the range up to nearly room temperature are possible. A more versatile camera with a working range from 77°K to over 375°K uses liquid nitrogen as a coolant. Temperature control is by balancing the heat conduction along a tube with a heater near the specimen. This camera allows inserting the specimen at any chosen temperature in the working range but does not allow as rapid temperature changes in the cold gas camera.

INTRODUCTION

WHEN studying transformations at sub-zero temperatures it is often convenient to be able to carry out treatments such as cold-working and annealing and to transfer the specimen, at temperature, to the x-ray diffraction camera. Several cameras have been designed, primarily for the x-ray spectrometer, in which this is easily done. They have proved convenient for x-ray spectrometer studies of transformations and photographic studies of lithium and other polymorphic samples.[1]

CONSTANT TEMPERATURE TYPE CAMERA

For experiments where a constant temperature, such as the boiling point of a liquid gas or the temperature of a mixture such as dry ice and ether, is satisfactory, a stream of the coolant may be flowed over the specimen[2–4] or sprayed on it.[5, 6]

A simple flask to flow a stream of coolant over a specimen that meets the requirement for putting a sample in cold, and is adaptable to both the spectrometer and film cameras is shown in Fig. 1. The nozzle is of large diameter for most of its length so gas bubbles do not block it. It is insulated with a plastic sleeve. The small outlet tube extends through the bottom of the large tube and well up into it to form a trap for solid particles, such as ice, which settle out. A rod with a long taper on the end fitting into the outlet tube is adjustably supported by an arm at the top of the flask giving control of the coolant flow which is kept slow to minimize x-ray scattering by the coolant.

Nozzle A has a plate and spring to hold a stationary specimen in correct alignment. Nozzle B is for rotating powder specimens and oscillating single crystals. The outlet tube in nozzle B is off center and inclined to direct the coolant stream at the specimen. The rod which carries the specimen passes through the center of the nozzle in a fairly closely fitted bearing which is nearly liquid tight and through another bearing on the arm at

the top of the flask where it is connected to the drive mechanism.

The flask itself is of thin metal insulated with ¾ inch of Styrofoam[7] which keeps evaporation loss of liquid nitrogen to about ¼ liter per hour. A glass vacuum flask with a Kovar[8] seal at the nozzle could be used[9] but it is doubtful if the saving of coolant would be worth the loss of simplicity and ruggedness.

Specimens are easily put in the proper position in nozzle A under liquid nitrogen or other coolant. Loading nozzle B under a coolant is simplified by a sleeve on which the specimen can be aligned before it is put on the rod. The flowing coolant protects the specimen from ice during transfer to the camera.

The spectrometer camera is a 1½-inch diameter tube mounted on cross slides for centering the specimen in the x-ray beam. The camera top[10] is an easy fit in the tube and has a hole in the center in which the flask nozzle is a close fit. The windows for the x-ray beam are cellophane kept free of ice by warm air from a hair dryer. A drain is provided for non-volatile coolants.

For work with film a commercial 71.6 mm powder camera[11] is used. The specimen table shaft is removed from its bearing and the flask nozzle fits in its place. A coolant drain has a length of rubber tube to make it light tight.

With a liquefied gas as coolant the drain can be partially blocked and a dry atmosphere automatically maintained protecting the specimen from ice. With other coolants a slow stream of dry gas is introduced into the camera.

Normal film speed can be maintained by warming the outside of the camera without affecting the specimen temperature.

GAS COOLED VARIABLE TEMPERATURE CAMERA

Blowing cold gas over the specimen is a convenient method of cooling with control of the temperature.[12-14] The cold gas camera for the spectrometer is shown in cross section in Fig. 2.

The hood, which directs the cold gas over the specimen, is clamped to a vertical rod so it can be lifted to allow the base cup and specimen to be put in under it with cold gas flowing. The flexible joints in the cold gas transfer tube are of stainless steel flexible hose.

The base of the camera is a plastic cup with a short boss on the bottom to locate it in the spectrometer. An aluminum sleeve, extending from about 5 mm from the bottom of the cup to flush with the top is supported on three centering screws and carries the specimen holder on an internal shoulder. The specimen holder is a copper tube about 40 mm long by 25 mm diameter with a 15

mm high opening extending slightly over half around for the x-ray beam window. The specimen is held by two springs to a copper plate behind the window opening. There are fins on the back of this plate to give better cooling.

A cold specimen can easily be put in the holder under liquid nitrogen. Then with the base cup full of nitrogen the specimen holder is placed in the aluminum sleeve and will keep cold by conduction long enough to get it under the hood. The flask from the constant temperature camera can be used, as in Fig. 2, to introduce liquid nitrogen through the hood during adjustment thus saving the nitrogen in the large Dewar flask for controlled temperature work. The evaporating nitrogen keeps a dry atmosphere around the specimen preventing icing during the preceding steps.

Using liquid air or nitrogen as a coolant the source of cold gas can be either tank gas cooled by running through the liquid gas or gas evaporated from the liquid. The first method uses only about one-half as much liquefied gas as the latter but does not give as sensitive temperature control.

Control circuits for the two types of cooling are shown in Fig. 2. Control of the temperature is conventional in both cases: manually by the Variac controlling the current in a heating coil in the liquefied gas or by the stopcock controlling the flow of tank gas or automatically by a temperature controller operating a relay or a solenoid valve with part of the input bypassed to minimize overshooting. The regulator keeps the temperature within about ±1°C and manual control can keep it well within ±0.5°, especially with the heating coil. The temperature can be changed rapidly and stabilized quickly at the new value which is the chief advantage of this type cooling. About 4 liters of liquid nitrogen per hour are required with the heating coil for operation at 120°K.

CONDUCTION COOLED VARIABLE TEMPERATURE CAMERA

A third method of cooling is by conduction through a metal block with the coolant at a distance from the specimen.[15,16] To get variable temperature the block supporting the specimen can be reduced in cross-section area, reducing its heat conductivity so the specimen temperature can be raised by a heater on the block near it.[17,18]

A cross section of the conductivity camera is shown in Fig. 3. The temperature range of the camera is from about 70°K (evacuating over the liquid nitrogen in the flask) to a maximum dependent on the temperature the camera materials will stand. The flask for the coolant is of metal insulated with Styrofoam. A ¾-inch tube of stainless steel extends from the bottom of the flask and pressed into its lower end has a copper block with a flat surface milled on one side for the specimen, which is held in place by springs. The heating coil around the copper block is electrically insulated from it with thin mica. A copper piston with a Styrofoam washer gives control of the level of the coolant in the tube for varying the heat conductivity. This makes it possible to get fairly rapid cooling yet keep liquid nitrogen consumption reasonably low when near room temperature. Icing of the specimen is prevented by introducing a slow stream of dry nitrogen near the top of the camera.

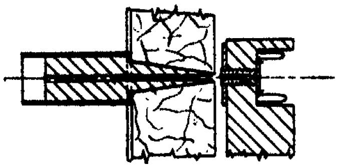

FIG. 4. Pinhole system for conduction cooled camera.

The plastic collar on the tube is held in place by a set screw, so the position of the specimen in the camera can be adjusted, and is a close fit in the camera. The leads to the heater are brought through the collar and the leads for the thermocouple, which is usually embedded in the specimen, through a slot on the side.

The camera is a 3-inch diameter metal tube closed at the bottom and mounted on cross slides on the spectrometer. A Styrofoam block inside the tube has window openings matching those in the tube and a 1-inch diameter central hole for the specimen holder. A foot on the specimen holder closely fitting this hole keeps the specimen centered in the camera. Cellophane windows, one inside the Styrofoam and the other on the outside of the tube, are shellaced to slow the diffusion of moisture through them.

To transfer a specimen at any desired temperature from the air or liquid bath in which it was prepared to the camera the specimen holder is brought to temperature in the camera, taken to the bath, the specimen put in place in the holder, and returned to the camera. The temperature cannot be controlled exactly during the transfer ±10° being about the practical limit. At low temperatures a little ice is picked up during the transfer and will gradually form in the camera but ice lines have not been detected on the spectrometer charts.

For use with film the camera is made with a larger window and for better insulation the inner cellophane window replaced by fairly thick Styrofoam as the slightly greater x-ray absorption is less serious with film. For back reflection pictures a conventional cassett and pinhole system can be used. For transmission the pinhole system is shown in Fig. 4. The front pinhole in the copper specimen holder keeps to a minimum the area of the specimen not in contact with the copper. The back pinhole, separate from the front, gives a reasonably long collimator yet conducts a minimum of heat to the specimen. A ¾-inch square lead shield behind the specimen holder protects the film from x-rays scattered by the air between the pinholes and any diffracted rays

from the back of the front pinhole. The plastic collar on the specimen holder is keyed to the camera to keep the pinholes aligned.

The temperature of the camera is readily controlled by the position of the plunger and the heating current. The piston may be removed to obtain maximum cooling rate and replaced when the temperature is to be raised. With correct positioning of the piston liquid nitrogen consumption can be held to about 1½ liters per hour over most of the sub-zero temperature range. Constant heating and cooling rates can be maintained over the entire temperature range.

If long runs are to be made on either the constant temperature or the conductivity cameras, automatically refilling the flasks from a large storage dewar is convenient.[19, 20]

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

Pulse Type Regulated High Voltage Supply for G-M Tubes*

Richard J. Watts
The Los Alamos Scientific Laboratory, Los Alamos, New Mexico

(Received January 16, 1950)

A pulse type 1000-v variable high voltage supply is described. This supply utilizes a 6BG6 tube to interrupt the current through a standard inductance. Rectification is by means of a CK1013 cold-cathode rectifier which eliminates a well-insulated filament transformer. The output is shunt regulated by means of a 2C53 tube. An advantage of these supplies is the small size 5×5×6 in. and the economy in cost. Standard parts are used throughout. Ripple at 1000 v is 80 mv. Regulation curves are given.

INTRODUCTION

Despite the wide use of G-M tubes, there is as yet to the author's knowledge no variable regulated high voltage supply commercially available suitable for incorporating in a chassis with other equipment. The use of commercial r-f equipment entails the necessity for adding additional regulation, or if a regulated supply is used the equipment is in general too large to permit room for other components on the chassis. The following instrument is an attempt to rectify these difficulties. A paramount consideration is reliability since G-M tubes are often operated for many hours consecutively.

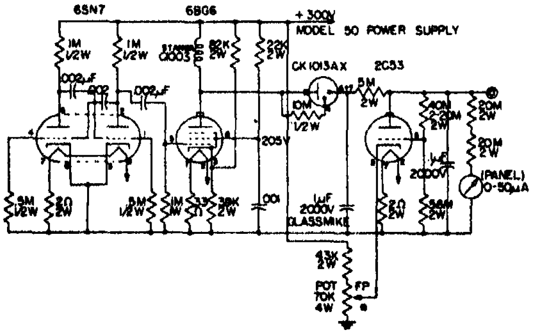

Fig. 1.

CIRCUIT

The pulse type high voltage supply has been investigated in a very adequate manner by Siezen and Kerkhof.[1] These supplies are based upon the periodic interruption of current through an inductance L. Assuming that this inductance is shunted by a stray capacitance Cp, the peak voltage V_m of the transient oscillation caused by the interruption can be deduced from the energy equation

$$\tfrac{1}{2}Li_m^2=\tfrac{1}{2}C_pV_m^2;$$

hence,

$$V_m=i_m(L/cp)^{\frac{1}{2}}.$$

Thus, if $i_m=12$ ma, $L=50$ henrys, $C_p=50$ μμf, $V_m=12$ kv. The advantages of this type of supply can be enumerated as follows:

(1) The interruption frequency can be made high enough so that there can be a substantial reduction in the size of the filter.

(2) The frequency can be made low enough so that no interference is generated.

(3) The inductance L may be small enough so that stray magnetic fields are eliminated.

(4) Insulation requirements on the a.c. side are less severe because of the transient nature of the oscillations.

(5) V_m is a function of i_m, hence, V_m can be adjusted by varying the bias.

(6) The high voltage generation by a tube limits the output. Hence, the output may be shorted with no injury to the circuit.

---

FIG. 2.

Figure 1 is a schematic of the circuit used. A multivibrator has been chosen for the repetition frequency although a blocking oscillator or other means could have been used. This was done in the interest of economy. The repetition frequency was measured to be 200 c.p.s. By means of a Tektronix oscilloscope the usual multivibrator wave pattern was observed. The wave shape on the grid of the 6BG6 showed a 170-v drop in 2 μsec. followed by an exponential rise of 100 v in about 2.5 msec. followed by a square wave of about 2.5-msec. duration. It is necessary to place a large negative voltage on the grid of the cut-off tube in order that it does not conduct during the time the large transient voltage is on the anode.

In order to eliminate the need for a well-insulated filament transformer for the rectifier, a cold-cathode high voltage rectifier was used. If voltages higher than 1200 v are needed, it is necessary to replace this cold-cathode rectifier with an 8016. This, combined with a change in bias on the 6BG6, permits a 3-kv output provided the Stancor C1003 choke is immersed in transformer oil.

Regulation is obtained in the conventional manner by means of a 2C53 tube shunt regulator. At 1000-v output the drop across the anode load of this regulator is 500 v.

To obtain a variable output voltage the bias on the cathode of the 2C53 tube is varied. This bias is obtained from the 300-v supply. The control for this bias plus the 0–50 microammeter is mounted on the front panel of the associated equipment.

PERFORMANCE

Figure 2 illustrates the manner in which this supply is laid out. The performance of the instrument will depend to some extent on the supply voltage used with it. The curves in Fig. 3 were taken with a Model 50 supply. This supply is similar to the circuit described by Higinbotham, Gallagher, and Sands[2] with the exception that more current output is provided.

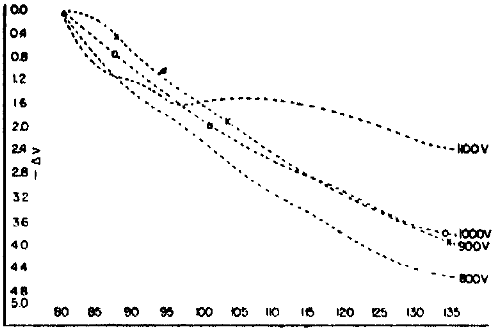

FIG. 3. Line voltage.

To obtain some idea of the regulation the following method was used. By means of a Variac the line voltage input to the low voltage power supply was set at 80 v a.c. The output of the high voltage supply was set at 800 v. 800 v of bucking batteries were then employed so that a general radio 728-A high impedance voltmeter could be set on the 10-v scale. The line voltage was then varied in steps of 5 v and the change in the voltmeter reading was noted. The process was repeated at 900, 1000, and 1100 v. This information is plotted in Fig. 3. It will be noted that the supply is stabilized to 0.1 percent change in output d.c. voltage per ten percent change in the line at 115 v a.c. Of course, this good performance should be attributed to the well-regulated low voltage supply. However, since this supply is one commonly used with scaling circuits the results are germane.

To improve reliability and insure long life it should be noted that all the filament voltages have been reduced by means of resistors. The filament supply is 6.3 v a.c. taken from the associated low voltage supply. The efficiency of the supply is not good, being of the order of four percent. However, since G-M tubes require very small currents (usually less than 3 μa), the efficiency is relatively unimportant since one can afford to waste power provided the input power is not a serious drain on the low voltage supply.

The input power in this case is 3.6 w or 300 v at 12 ma. Since this is easily furnished by most supplies used in conjunction with this circuit no attempts were made to improve the efficiency.

Ten of these circuits have been built and operated continuously for six months with no failures from any cause whatever. Output ripple voltage is about 80 mv as measured with a Ballantine Model 300 voltmeter. This was considered sufficient for the purpose in hand. However, this value can be reduced by inserting an appropriate condenser between the plate and the grid of the 2C53.

Thermistors. Part I. Static Characteristics

OTTO J. M. SMITH
Division of Electrical Engineering, University of California, Berkeley 4, California

(Received January 5, 1950)

The fundamental thermistor equations are presented as functions only of electrical quantities and constants, and independent of temperature measurements. The universal curves allow one to predict the static characteristics of thermistors as circuit elements. The two most significant characteristics are the power coefficient of resistance, and the negative incremental resistance. These can be computed, or read from the universal curves, if the resistance and four parametric constants are known. These five values can be determined from six convenient measurements: the resistance and change of resistance with current at very low current, at the maximum voltage point, and at maximum current.

INTRODUCTION

A THERMISTOR has a large negative resistance-temperature characteristic, and is a sensitive conversion element for the measurement of fluid flow, vacuum, radiant energy, and temperature. It can be used as a circuit element, displaying high positive resistance at high frequency simultaneously with low negative resistance and high inductance at low frequency. It can be used as a time-delay lock-in or lock-out device, and as a variable-mu element in volume controls and dynamic volume expanders.

The static curves of the W.E. 1-B thermistor are shown in Fig. 1. At low power, the resistance decreases with increasing temperature, causing the family of curves to intercept the origin at different slopes. For a single ambient temperature, as the thermistor temperature increases due to its internal losses, the rate of resistance decrease becomes so great that the voltage reaches a maximum near 30°C rise, and then decreases again. For high sensitivity to energy, either radiant or losses within the thermistor, it is usually operated below the maximum voltage point. For a circuit element with negative incremental resistance, it is operated above this point.

PREVIOUS WORK

Becker, Green, and Pearson[1] of the Bell Telephone Laboratories have published a comprehensive treatment of the electrical and thermal properties of thermistors and semiconductive material. They defined the temperature coefficient of resistance, a, as

$$a=(1/R)(dR/d\theta). \qquad (1)$$

They showed that this coefficient decreased with increasing temperature in the following manner:

$$-a=(D/\theta^2)+(c/\theta).$$

The term (c/θ) is a correction to account for the fact that the logarithm of the resistivity is not quite proportional to the reciprocal of the absolute temperature. The previous work has used temperature as the independent parameter. If an electrical quantity such as resistance or current is to be used, then the thermal dissipation constant becomes a very significant factor.

CONSTANTS

θ_0 Absolute ambient temperature in degrees Kelvin,
$\Delta\theta$ temperature rise above θ_0 in degrees centigrade,
a_0 temperature coefficient of resistance at θ_0, ohms per ohm per degree centigrade,
K dissipation constant in watts per degree centigrade rise, $W/\Delta\theta$,
k incremental dissipation constant, $dW/d\theta$,
m power coefficient of resistance in ohms per ohm per watt, $(1/R)(dR/dW)$,
n dimensionless correction exponent, equal to $c/a_0\theta_0=-cs$,
R resistance of thermistor, V/I,
r incremental resistance of thermistor, dV/dI,
W watts dissipated in thermistor, VI,
s parametric constant for each thermistor, $=-1/a_0\theta_0$,
x independent variable, $=W/K\theta_0=\Delta\theta/\theta_0$,
g correction exponent for dissipation constant.

The subscript $_0$ refers to values at the ambient temperature. The subscript $_1$ refers to values at maximum voltage. The constant s is positive, and varies from 0.073 for W.E. D-159923 which has a temperature coefficient of 0.046 ohm per ohm per degree, to a maximum s of 0.112 for W.E. 1-A, a bead type for time delay applications, which has a temperature coefficient of only 0.030. The correction exponent n has values that usually lie between $+3$ and -3.

The temperature coefficient a is about minus four

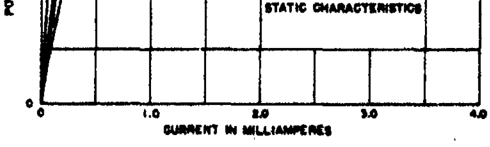

FIG. 1.

---

[1] See Bibliography.

percent per degree at room temperature, and decreases to about 1.3 percent at 200 degrees. The power coefficient of resistance diminishes to 0.1 or 0.01 of its cold value, at elevated temperatures, but its actual value depends upon the physical size of the thermistor. The largest change is in the resistance, which can diminish by a factor greater than one thousand.

The dissipation constant K in watts per degree rise does not vary until the temperature is sufficient to cause increased convection or radiation losses. Figure 2 shows the power required by four typical thermistors, and Fig. 3 shows the manner in which the dissipation constant varies. D-159923 was designed for a circuit element, and is enclosed in an evacuated bulb. It requires only 0.2 milliwatt to reduce the resistance to $1/e$ of its ambient value. The 1-B thermistor is mounted in a fiber tube. It has an a of only -0.031 and requires 10 mw to reduce R to $1/e$ of R_0.

The rapid rise of power at high temperature, if caused by increased radiation, should be a function of the fourth power of the absolute temperature. Actually, the exponent is different for different units, and for D-159923, it is approximately

$$W=K_0((\Delta\theta)+k''(\Delta\theta)^6).$$

k'' is of the order of 3×10^{-12}. Differentiation yields the incremental dissipation constant:

$$k=dW/d\theta=K_0(1+6k''(\Delta\theta)^5).$$

An expression that will hold for all thermistors will be given later.

By definition, the product of the incremental dissipation constant times the power coefficient of resistance is the temperature coefficient of resistance:

$$a=km. \tag{5}$$

At room temperature, with negligible losses in the thermistor,

$$K_0=k_0. \tag{6}$$

$$a_0=K_0m_0. \tag{7}$$

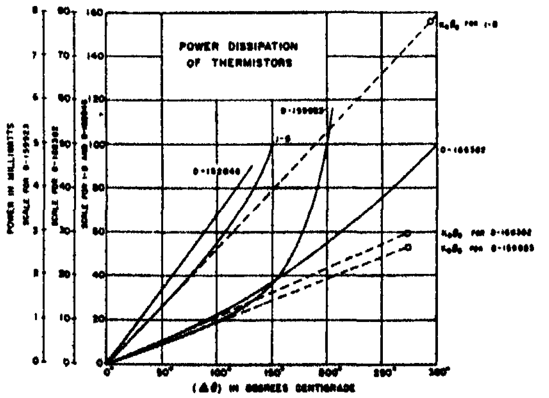

FIG. 2.

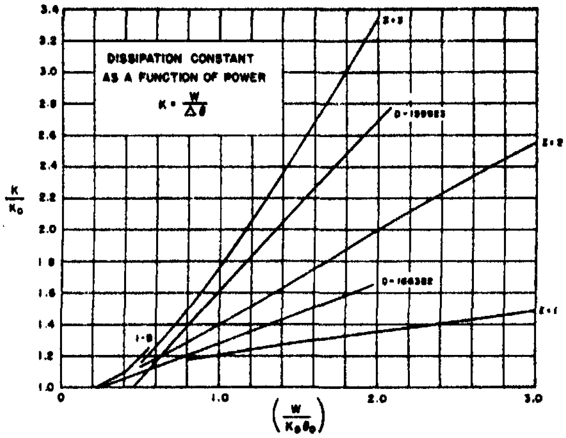

FIG. 3.

Even at the maximum voltage point, k_1 is only a negligible fraction of a percent greater than K_1.

At the maximum voltage point, $R_1=V_1^2/W_1$. Differentiating R to obtain the power coefficient, it becomes,

$$m_1=dR/RdW=-1/W_1. \tag{8}$$

The power coefficient is therefore the negative reciprocal of the measured power at the maximum voltage point. The temperature coefficient at the maximum voltage is similarly simple:

$$a_1=-k_1/W_1. \tag{9}$$

APPROXIMATE RELATIONS

A few rule-of-thumb approximations can be generalized from the fact that the temperature coefficient is almost inversely proportional to the absolute temperature squared. The logarithm of the resistance is inversely proportional to the absolute temperature. At 30°C rise, the voltage reaches its maximum, the incremental resistance becomes zero, and the direct-current resistance has decreased to 0.3 times its ambient value. At 300°C rise, which is possible with only the most rugged elements, $R=R_0/1000$, and the incremental resistance $r=-R_0/2000$.

UNIVERSAL TEMPERATURE COEFFICIENT CURVES

Figure 4 shows the manner in which the temperature coefficient of resistance decreases with increasing temperature. This is a plot of the equation,

$$a/a_0=(1-nW/K\theta_0)/(1+W/K\theta_0)^2, \tag{10}$$

which was derived* from Eq. (2) by algebraic substitutions. The maximum voltage restriction Eq. (9) above can be expanded to read

$$a_1/a_0=-1/a_0\theta_0(W_1/k_1\theta_0). \tag{11}$$

If k_1 is considered equal to K_1,

$$a_1/a_0=s_0/x_1. \tag{12}$$

---

* The derivations are given in the Appendix.

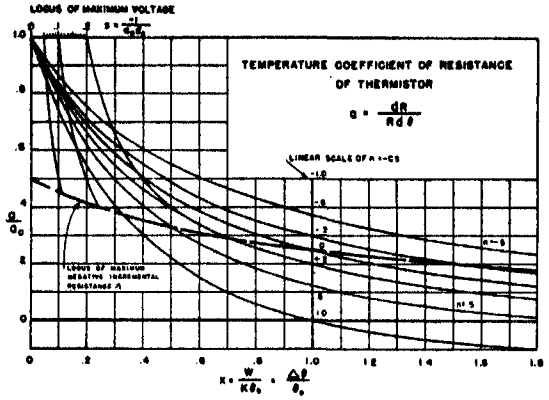

FIG. 4.

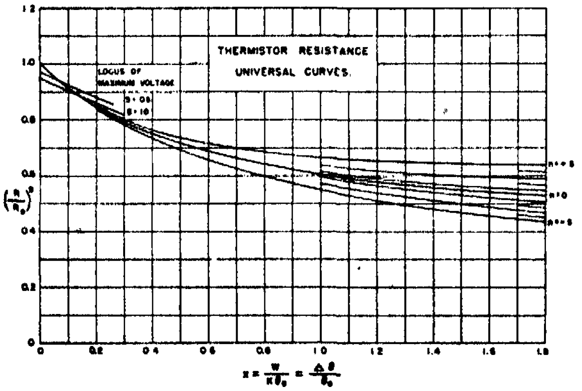

FIG. 5.

This is the auxiliary equation plotted in Fig. 4, whose intercepts with Eq. (10) determine the maximum voltage points. Figure 4 can be used to determine the sensitivity of a thermometry application.

To design temperature compensation circuits, Fig. 5 is more convenient. It shows the decrease in thermistor resistance with increasing power. These curves are plots of

$$(R/R_0)^s=(1+x)^{+n}\exp[-x(1+n)/(1+x)]. \quad (13)$$

A set of loci for maximum voltage intercepts are also shown. These are plots of the auxiliary equation

$$(R/R_0)^s=(1+x)^{-((1+x)^2s/x-1)/x} \times\exp[((1+x)s/x-1)]. \quad (14)$$

To use Fig. 5 for any given thermistor, the constants n, s, and K_0 must be known. These can be determined from the following measurements:

R_0 resistance at ambient temperature, with internal temperature rise less than 0.1 degree, or else corrected back to ambient temperature using Eq. (13) with $n=0$.

θ_0 measured ambient temperature.

m_0 power coefficient of resistance from a measurement of the current necessary to decrease the resistance about two percent, (0.5°C rise); since m_0 is decreasing 4 percent of its value per degree *rise*, *it is therefore important* to correct it back to the ambient temperature, in this case an increase of about one percent.

R_1, W_1 both measured at maximum voltage; to prevent burning out the thermistor, when it reaches the negative resistance region, a fixed series resistance must be used which is at least half as big as R_0. A 100-volt d.c. supply is usually adequate.

$$s_0/x_1=a_1/a_0=m_1/m_0=-1/W_1m_0. \quad (15)$$

Equation (14) could be solved for x_1 using the measured R_1/R_0 and s/x_1 from (15), but this is difficult analytically. A graphical solution for x_1 and s is provided in Fig. 6, a maximum voltage nomograph for Eq. (14). The correction exponent n can be read from either Fig. 4 or 5. K_0 is $W_1/x_1\theta_0$. Since s and n vary approximately as the absolute temperature, it is important to record the room temperature θ_0 at which the tests were made. c is $-n/s$; D can be computed from Eq. (2) if it is desired.

If these curves are to be used for a thermistor with an arbitrary elevated ambient temperature θ_a, the new constants can be determined as follows:

$$s_a/s_0=n_a/n_0=(\theta_a/\theta_0)(1-n_0\theta_0/s_0)/(1-n_0\theta_a/s_0). \quad (16)$$

$$s_a/s_0=\theta_a/\theta_0(1-n_0\Delta\theta/\theta_0). \quad (17)$$

INCREMENTAL RESISTANCE

Above the maximum voltage point, the resistance decreases so quickly that the incremental resistance becomes negative. In this region, the resistance to high frequency is positive, but it is negative to frequencies less than about one-fourth the reciprocal of the thermal time constant. This is occasionally a useful function to

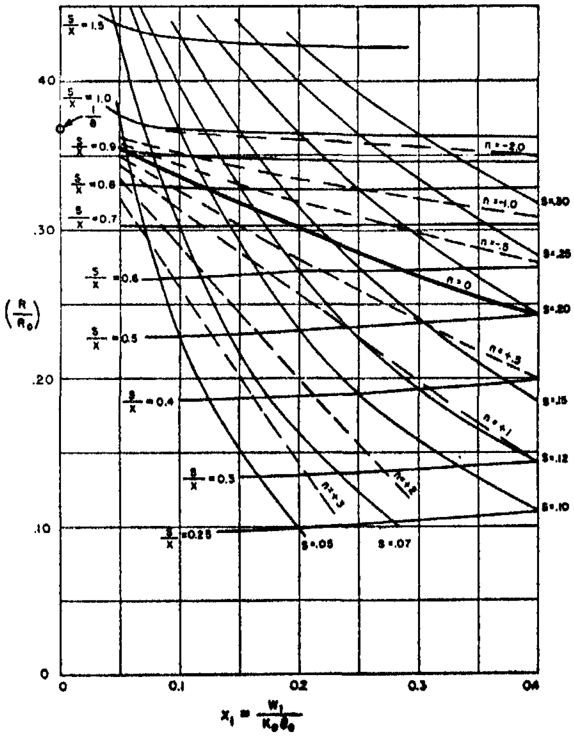

FIG. 6. Maximum voltage nomograph.

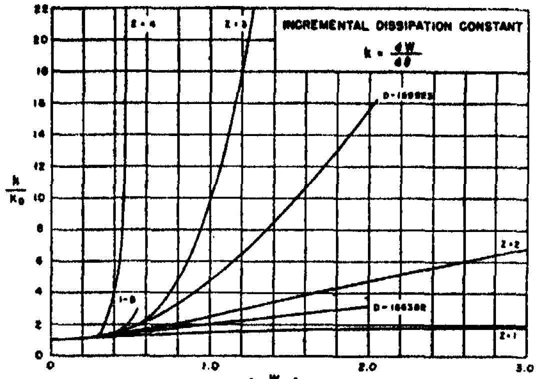

FIG. 7.

have in a d.c. control system. The volt-ampere curve is moderately linear in the vicinity of the maximum incremental resistance. When biased in this region, the a.c. resistance (V/I) might be one-tenth of the cold resistance R_0. The incremental, or resistance for d.c. changes, (dV/dI) might be minus one-fourth of the a.c. value. The bias supply must have an internal impedance greater than $r=dV/dI$ for the current to be stable in this region.

The incremental resistance and the power coefficient of resistance are related by definition.

$$Wm=Wa/k=(r/R-1)/(r/R+1). \tag{18}$$

With this, one can compute the power coefficient from a measured incremental resistance. This equation is indeterminate at zero dissipation, and consequently m_0 has to be measured directly as previously mentioned.

The incremental resistance is

$$r/R=(1+Wm)/(1-Wm). \tag{19}$$

With Eq. (19), r/R can be computed if m is known as a function of the power. This relationship is

$$m/m_0=(1-nW/K\theta_0)/(1+W/K\theta_0)^2(k/K_0). \tag{20}$$

Both of the dissipation constants are variables for which an analytic expression would be desirable. Figure 3 shows the manner in which K/K_0 has been observed to vary experimentally, and Fig. 7 illustrates the same thing for k/K_0. The equation to represent this additional loss at high temperatures should preferably be a function of W and not of the temperature, as unfortunately are Figs. 4 and 5. The form which seems to fit best is

$$(K/K_0)^y=1+k'(W/K_0\theta_0)^z. \tag{21}$$

Substituting W/θ for K, and differentiating, one obtains

$$k/K_0=\frac{(1+k'(W/K_0\theta_0)^z)^{(y+1)/y}}{1+k'(W/K_0\theta_0)^z-(zk'/y)(W/K_0\theta_0)^z}. \tag{22}$$

The relationship between the two constants is

$$k/K_0=\frac{(K/K_0)^{(y+1)}}{z/y+(1-z/y)(K/K_0)^y}. \tag{23}$$

The last form is particularly well-suited for choosing the value of y which matches the observed phenomena. Figure 8 is a plot of the experimental curves, along with Eq. (23) for $y=3$, which appears to be the best value. The parametric variable z is fixed for a given thermistor, and is a measure of the rate of increase of the dissipation constant. The arbitrary constant k' influences only the low wattage part of the curve. An approximation for Eq. (22), which is satisfactory for low values of heating is

$$k/K_0=1+k'(z+1)(W/K_0\theta_0)^z/3. \tag{24}$$

From Eq. (23), and experimental values from the curves in Fig. 8, z can be computed to be 3.595 for the 1-B, and 2.61 for the D-159923. Substituting these values plus points from the curves in Fig. 7 into Eq. (24), it can be computed that both curves go through the point $(k/K_0=1.145;\ W/K_0\theta_0=0.289)$. Substituting these values into Eq. (24) gives an analytic expression for k':

$$k'=0.435/(z+1)(0.289)^z. \tag{25}$$

The incremental resistance is therefore analytically determined by Eqs. (19), (13), (20), (21), and (22), and (25). It can be expressed as a function of power only, and independent of temperature rise. The power coefficient of resistance is plotted in Fig. 9 from Eq. (20). These curves allow one to make a single measurement of incremental resistance at maximum current, compute the power coefficient from Eq. (18), and read off the value of the correction exponent z, from Fig. 9.

The basic curve, marked $K=K_0$, is for a massive thermistor whose dissipation constant does not vary.

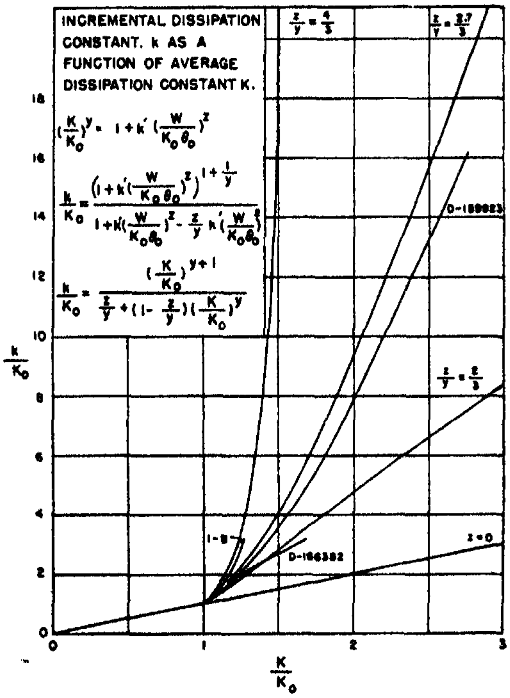

FIG. 8.

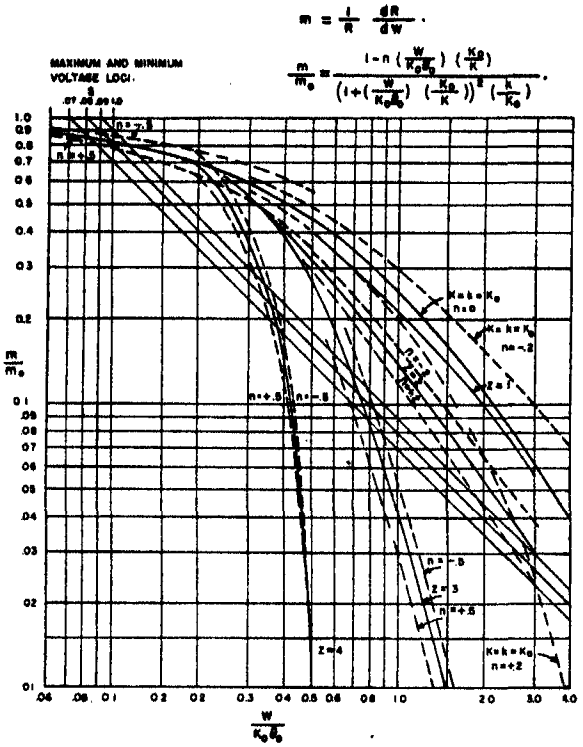

FIG. 9. Thermistor power coefficient of resistance.

The usual element, however, follows a curve like $z=3$. It can be seen that the value of n determines the curve for low wattages, and that z, which has no effect below 60°C rise, has a marked effect at higher wattages.

The incremental resistance Eq. (19) can be rewritten as

$$r/R=\frac{1-(W/K_0\theta_0)(m/m_0)/s}{1+(W/K_0\theta_0)(m/m_0)/s}$$

$$=\frac{1+(Wa_0/K_0)(m/m_0)}{1-(Wa_0/K_0)(m/m_0)}, \qquad (26)$$

or

$$r/R=\frac{s(1+x)^z k/K_0-x(1-nx)K/K_0}{s(1+x)^z k/K_0+x(1-nx)K/K_0}. \qquad (27)$$

Equation (26) includes the three parameters s, n, and z, as well as the independent variable $(W/K_0\theta_0)$, which is proportional to watts only, and therefore is more convenient than the variable x. The manner in which the incremental resistance varies with n and s is shown in Figs. 10 and 11 respectively.

The maximum ratio of negative to positive resistance is found in a thermistor with an almost constant dissipation constant K, high temperature coefficient of resistance (low s), and n slightly negative (−0.2 or −0.3). It occurs at a temperature rise of about 300°C, and r/R has a value of approximately one-half. The effect of the rapidly increasing dissipation constant K in some thermistors (z equals 3 or 4), is to cool the thermistor so effectively that the power coefficient of resistance is very low, and the change in resistance is small. This effect is shown in Fig. 12. It is possible to operate a thermistor so that it will not have a negative incremental resistance. In Fig. 9, it is seen that this would happen when the maximum voltage locus is tangent to the curve. This situation exists if the room temperature is elevated. Since s and n increase with ambient temperature, if the thermistor were operated at 200 degrees centigrade, the constants might be $s=0.12$, $n=0.5$, and $z=4$, and there would be no negative V-I slope.

Figure 12 shows the manner in which the negative incremental resistance varies with the dissipation exponent z. For high negative resistance circuit efficiency, r/R should be large, and z should not exceed 2.

These characteristics which have been presented are useful in predicting the transient response of a thermistor. The time constant is a function of the dissipation constant, and the equivalent inductance and critical frequency (at which the series a.c. resistance becomes

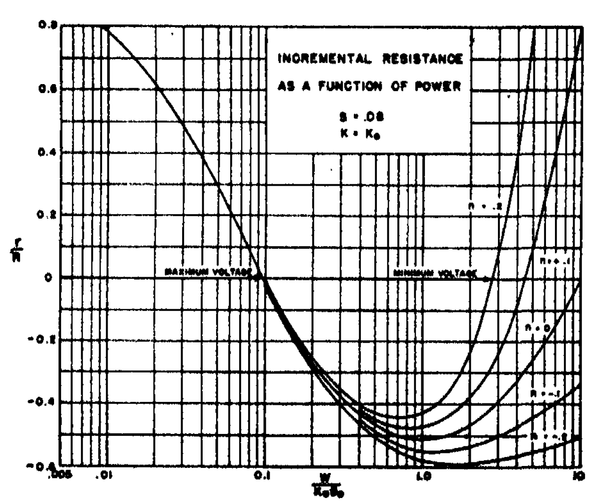

FIG. 10.

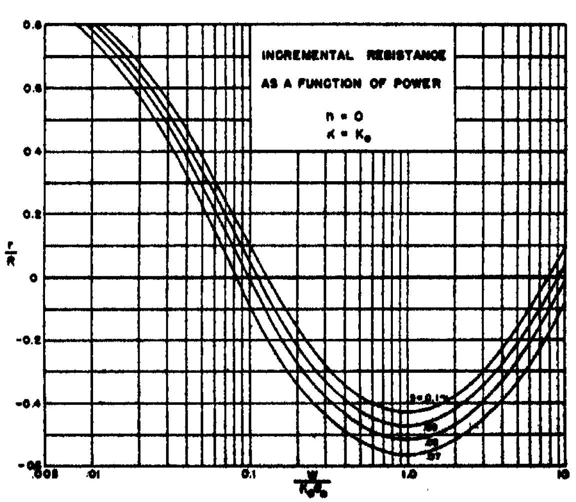

FIG. 11.

zero) are functions as well of r/R and R_0. Figure 7 shows increases in the incremental dissipation constant of over ten times the cold value, and correspondingly large changes in time constant have been observed.

SUMMARY

Curves have been presented of the temperature coefficient, dissipation constants, d.c. and incremental resistance, and power coefficient in terms of three constants, n, s, and z, and low power values of R_0, K_0, and m_0. An examination of all these curves indicates that it is possible to satisfactorily represent all of the effects of the constant n by appropriate small changes in the constants s and z. At low powers, n can be assumed zero, and s computed as though it were. At high powers, where the effect of n is significant, changes in z have an even greater effect, and therefore an equivalent z can be determined again upon the assumption that n is zero. This will give correct electrical characteristics, but computed temperature rises will differ from the actual values.

APPENDIX

Temperature Coefficient.

$$-a=(D/\theta^2)+(C/\theta). \qquad (2)$$

$$D=-a\theta^2-c\theta$$

$$a\theta^2+c\theta=a_0\theta_0^2+c\theta_0$$

$$a=\frac{a_0\theta_0^2-c(\theta-\theta_0)}{\theta^2}=\frac{a_0-c(\Delta\theta)/\theta_0^2}{(\theta_0+\Delta\theta)^2/\theta_0}$$

$$c=na_0\theta_0$$

$$W/K=\Delta\theta$$

$$a/a_0=(1-nW/K\theta_0)/(1+W/K\theta_0)^2$$
$$=(1-nx)/(1+x)^2. \qquad (10)$$

Resistance.

$$D=-a_0\theta_0^2-c\theta_0=-(1+n)a_0\theta_0^2=(1+n)\theta_0/s.$$

$$a=dR/Rd\theta=-D/\theta^2-c/\theta \qquad (2)$$

$$a=-(1+n)\theta_0/s\theta^2+n/s\theta. \qquad (28)$$

Substituting $\theta/\theta_0=(1+x)$,

$$a=-(1+n)/s\theta_0(1+x)^2+n/s\theta_0(1+x). \qquad (29)$$

Integrating Eq. (28),

$$\ln R=(1+n)\theta_0/s\theta+(n/s)\ln\theta+\text{constant},$$

at $\theta=\theta_0$, $R=R_0$,

$$\ln(R/R_0)=(1+n)(\theta_0-\theta)/s\theta+(n/s)\ln(\theta/\theta_0)$$
$$=(1+n)(-x)/s(1+x)+(n/s)\ln(1+x).$$

$$(R/R_0)^s=(1+x)^n\exp[-x(1+n)/(1+x)]. \qquad (13)$$

At the maximum voltage point,

$$a_1=-k_1/W_1. \qquad (9)$$

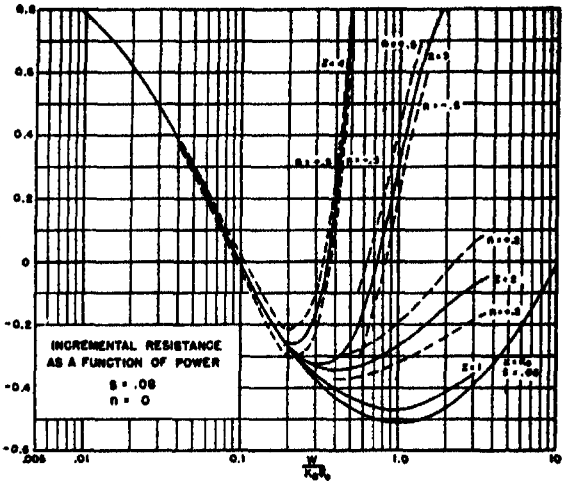

FIG. 12.

If $k_1=K_1$,

$$a_1=-1/x_1\theta_0. \qquad (30)$$

Setting Eqs. (29) and (30) equal will yield the value of n at maximum voltage.

$$-(1+n)+n(1+x)=-s\theta_0(1+x)^2/x\theta_0$$

$$n=(1-(1+x)^2s/x)/x. \qquad (31)$$

$$(1+n)x/(1+x)=1-(1+x)s/x. \qquad (32)$$

The locus of maximum voltage on resistance scales would be:

$$(R/R_0)^s=(1+x)^{[(1-(1+x)^2s/x)/x]}$$
$$\times\exp[-1+(1+x)s/x]. \qquad (14)$$

The solution for x in Eq. (14), if (s/x) and (R/R_0) are known, is best performed by assuming values of s and x and computing R/R_0. This can then be plotted as a nomographical solution. Five-place accuracy must be maintained in the computation.

The value of s is almost indeterminate, because it is not particularly important for the low wattage part of the curve whether the change in resistance is attributed to the correct values of s and n, or whether n is quite inaccurate or assumed to be zero, and the value of s slightly altered to compensate. To measure experimentally the maximum voltage point, a small very low frequency current should be superimposed upon the d.c. bias, and the bias adjusted for a null in the measured low frequency voltage across the thermistor. Frequencies with periods less than six times the thermal time constant, or incremental step changes in the d.c. bias cannot be used because the thermistor will appear initially as a linear resistance, and then the voltage will change transiently to its final value, as the temperature of the thermistor changes. For very precise values of s and K_0, a_0 should be determined at room temperature by mounting the thermistor next to a thermometer bulb, wrapping the whole with cotton tape, and measuring the resistance for a few degrees C rise. This value of a should be corrected back to a_0 in the same manner as the m_0 measurement. Then $K_0=a_0/m_0$, s can be computed from Eq. (15), and n from Eq. (31).

Variation of constants with ambient temperature.

$$s_0=-1/a_0\theta_0$$
$$s_a/s_0=a_0\theta_0/a_a\theta_a.$$

Substituting Eq. (10),

$$s_a/s_0=\theta_0/\theta_a(1+\Delta\theta/\theta_0)^2/(1-n_0\Delta\theta/\theta_0)$$
$$n_a/n_0=s_a/s_0=\theta_a/\theta_0(1-n_0\Delta\theta/\theta_0). \qquad (17)$$
$$n_a/n_0=\theta_a/(\theta_0(1+n_0)-n_0\theta_a).$$

Incremental Resistance

$$I=V/R$$
$$dI=dV/R-VdR/R^2$$
$$(V/R^2)(dR/dI)=dV/RdI-1=r/R-1.$$
$$I^2R=W$$
$$2IRdI+I^2dR=dW$$
$$2RdI/IdR=RdW/WdR-1=1/Wm-1.$$

Eliminating dI/dR.

$$r/R-1=2Wm/(1-Wm)$$
$$r/R=(2Wm+1-Wm)/(1-Wm)$$
$$=(1+Wm)/(1-Wm). \qquad (19)$$

Solving for Wm,

$$r/R-rWm/R=1+Wm$$
$$Wm=(r/R-1)/(r/R+1). \qquad (18)$$

Power Coefficient

$$m=dR/RdW=dR/Rd\theta(dW/d\theta)=a/k. \qquad (5)$$

$$m/m_0=(a/a_0)(K_0/k).$$

From Eq. (10)

$$m/m_0=(1-nW/K\theta_0)/(1+W/K\theta_0)^2(k/K_0). \qquad (20)$$

This is plotted in Fig. 9 as

$$m/m_0=(1-n(W/K_0\theta_0)(K_0/K))/(1+(W/K_0\theta_0)(K_0/K))^2(k/K_0).$$

From Eqs. (19) and (5)

$$r/R=\frac{1+(Wa_0/K_0)(m/m_0)}{1-(Wa_0/K_0)(m/m_0)}$$
$$=\frac{1-(W/K_0\theta_0)(m/m_0)/s}{1+(W/K_0\theta_0)(m/m_0)/s}. \qquad (26)$$

The maximum voltage restriction can be easily derived from Eq. (26) by setting $r/R=0$.

$$m_1/m_0=s/X_1. \qquad (15)$$

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

Thermistors. Dynamic Characteristics. Part II

OTTO J. M. SMITH
Division of Electrical Engineering, University of California, Berkeley 4, California

(Received January 1, 1950)

The thermistor sinusoidal and transient response characteristics are presented, as a function of the dissipation constant and incremental resistance. Equations are given for time constant, critical frequency, equivalent inductance, and Q. The construction of a low frequency oscillator is discussed, as well as possible non-linear filter applications.

INTRODUCTION

THE first part of this paper presented universal curves of thermistor static characteristics as a function of easily measurable electrical quantities.

The dynamic response to sinusoidal and step functions of current are given here.

THERMISTOR APPLICATIONS

A thermistor is a resistance with a high negative temperature coefficient of resistance. They are semiconductors similar to Thyrite except that their resistance changes with temperature instead of applied voltage. They are usually made of fused oxides of manganese, nickel, and cobalt, and are extremely stable for long lengths of time.

Thermistors can be used for sensitive temperature indicating devices because the resistance changes about 4 percent per degree C. They can be used as sensitive bolometers for microwaves or visible light, if connected in a bridge circuit to balance out ambient temperature changes. A thermistor can be used as a non-linear circuit element in many of the same applications as a carbon-filament light bulb. For example, the output of a bridge using thermistors in opposite arms is sensitive to applied voltage, and will have a null at a specified voltage. This can be used as the reference and sampling circuit in a voltage regulator.

A thermistor in the feed-back circuit from the output of an oscillator will change temperature with the amplitude of oscillation, increasing the negative feedback for an increased output voltage. In this application it is an amplitude stabilizer.

A thermistor network in series with a loud speaker will perform the function of a volume expander with the time constant determined by the thermal lag of the thermistor. This can be chosen to give fast expansion and slow compression at rates most pleasing to the ear.

A thermistor can be used as a volume-control device or a controlled a.c. impedance in a function generator. The a.c. signal is capacitively coupled at low level through the thermistor, and a large d.c. bias current is passed directly through the thermistor to control the magnitude of the output a.c. signal. If the output is taken across the thermistor, it varies approximately as ϵ^{-14I}, where I is the d.c. bias current. This has the distinct advantage over variable-mu tubes of not introducing distortion in the a.c. signal.

LOW FREQUENCY OSCILLATIONS

Time delays of seconds and minutes are realizable with thermal transients. They seem to be inherently capable of long time delays, for with good thermal insulation, it is not difficult to obtain a time constant of an hour in a physical space of only a few inches. The thermal time constant of a thermistor no larger than a one-watt resistor can duplicate the effect of 100,000 henries.

The sizes of the frequency-determining elements in a low frequency oscillator are usually excessive. An L−C oscillator to generate 0.005 c.p.s. might have 10,000 henries and 100,000 microfarads, though a phase shift circuit to perform the same function would need only two 30-microfarad condensers and two one-megohm precision resistors.

Very low frequency oscillations occur not only on transmission lines and bridges, but also in mechanical and electrical servo mechanisms. There is a need for a laboratory low frequency oscillator for testing the "soaking" effect or interfacial capacity of condensers, and the response characteristics of servomechanisms, process control analogs, and structural analogs.

TIME CONSTANT

A thermal reservoir surrounded by thermal insulation has a logarithmic time constant for small temperature changes, of $T_\theta = H/k$, where H is the heat capacity in watt-seconds per degree centigrade, and k is the incremental dissipation constant in watts increase required per degree centigrade rise. In Part I of this article curves were presented showing how the thermistor dissipation constant varied with the thermal power being radiated. The thermal time constant T_θ decreases markedly with increasing power, because of the increase in k.

The electrical time constant T_e is less than the thermal time constant for increasing temperatures (decreasing resistance), and is greater than the thermal time constant for decreasing temperatures. Since the electrical quantities are complicated functions of the thermal transient, the electrical time constant cannot be applied blindly to a logarithmic transient.

If the thermistor is heated slightly above the equilibrium temperature for the operating bias, and allowed to cool again, $\Delta\theta = \Delta\theta' e^{-t/T_\theta}$, where $\Delta\theta'$ is the initial temperature rise above the final value in degrees centigrade. The resistance equation is

$$(R/R_0)^s = e^{-x/(1+x)}. \tag{1}$$

The variable x is equal to $\Delta\theta/\theta_0$, and s is a constant about 0.07. Substituting the temperature transient into Eq. (1), and differentiating with respect to time, gives an initial rate of

$$dR/dt = R'\Delta\theta'/s\theta_0 T_\theta. \tag{2}$$

If the electrical time constant is defined with reference to the initial conditions, it is the resistance change divided by the rate.

$$T_e = (R_0 - R')/(dR/dt) = T_\theta(R_0/R' - 1)/\ln(R_0/R'). \tag{3}$$

$$T_e = T_\theta(e^{x/s(1+x)} - 1)/(x/s(1+x)). \tag{4}$$

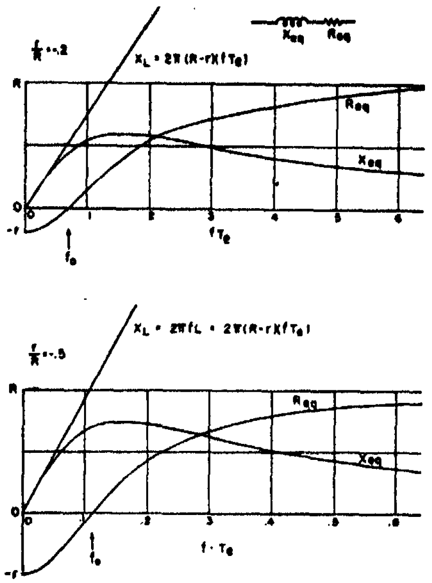

FIG. 3. Thermistor equivalent series constants.

If the change is only a few degrees, an adequate series approximation is

$$T_e = T_\theta(1 + x/2s(1+x) + x^2/6s^2(1+x)^2). \tag{5}$$

Typical values for a transient drop in temperature of 10 degrees are 55.5 percent increase in resistance, and $T_e = 1.26 T_\theta$. If the transient involves only a small percentage change in temperature or resistance, then the two time constants are equal. If the transient is a rise in temperature, x should be considered negative. For a large rise in temperature due to a sudden increment in current, most of the resistance change occurs at the beginning, and the electrical time constant is very short. A 100 degree rise (factor of 30-resistance drop) has an electrical time constant of one-half of the thermal constant. A 400 degree rise (factor of 10,000 resistance drop) has an electrical time constant of 0.06 times the thermal constant.

If the transient is a drop in temperature, the initial change in resistance is very slow, and reaches a maximum rate as the temperature nears its final value. For a drop of 100 degrees, the initial rate corresponds to an electrical time constant of three times the thermal value, a maximum rate is reached at about one thermal time constant, and the resistance has made 68 percent of

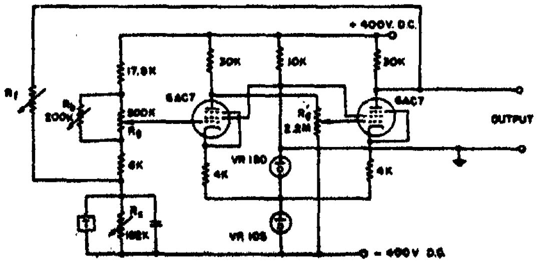

FIG. 4. Thermistor oscillator.

its change in 1.3 thermal time constants. For a drop of 400 degrees (increase in resistance of 10,000 times), the initial change in resistance corresponds to an electrical time constant of 120 times the thermal time constant, but the resistance change increases so rapidly that the resistance is up to 68 percent of its final value in 3½ time constants. This has the characteristics of a time delay circuit with "snap action."

TRANSIENT RESPONSE

The transient response of a thermistor depends upon the steady d.c. bias. At zero bias, the a.c. and d.c. resistances are equal. A square wave of current would produce a square wave of voltage. If a d.c. bias current is superimposed, however, the voltage wave will have the shape shown at (a) in Fig. 1. When the current increases, the voltage increases instantaneously an amount $R\Delta I$, but as the thermistor heats and the resistance drops, the voltage decreases a small amount $(R-r)\Delta I$ at a rate given by the equivalent electrical time constant. R is the total voltage divided by the total current, while r is the incremental resistance or dV/dI. If the bias current is increased until the incremental resistance is negative, then the voltage response to a current square wave will have the shape shown at (b) in Fig. 1.

Equivalent circuits for thermistors are given in Fig. 2. Circuit (a) is valid only for the transient component, but holds even if the incremental resistance r is negative. If the percentage current change is small enough that the transient is logarithmic, then the equivalent inductance is

$$L=(R-r)T_e. \tag{6}$$

For the W.E. 10-A thermistor, biased to maximum per unit negative incremental resistance, T_e is 100 seconds, R is 1000 ohms, r is -300 ohms, and L is 130,000 henries. Circuit (b) represents correctly both the transient and the steady-state current. The self-impedance of the thermistor has the same form as the transfer impedance of circuit (c) in Fig. 2.

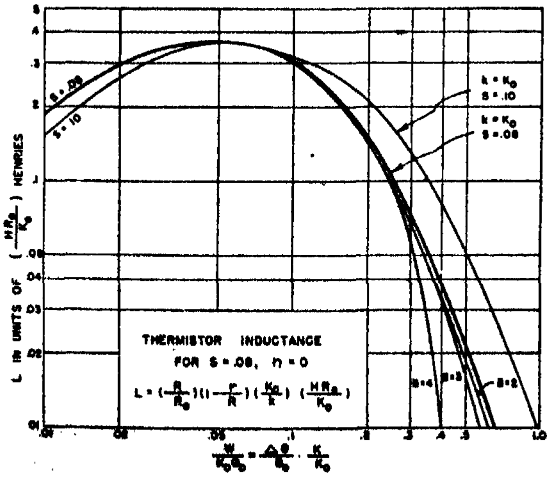

FIG. 5.

SINUSOIDAL RESPONSE

The sinusoidal response for small current amplitudes matches exactly the same equivalent circuit as for transients [(a) in Fig. 2]. The total impedance of this circuit is

$$Z=R_{eq}+jX_{eq}.$$
$$Z=r+(R-r)(\omega L)^2/((R-r)^2+(\omega L)^2)$$
$$+j(R-r)^2(\omega L)/((R-r)^2+(\omega L)^2). \tag{7}$$

Both the resistive and reactive components vary with frequency. This variation is shown in Fig. 3 for two typical bias settings, giving percentage negative resistances of 20 percent and 50 percent respectively. The value of L in circuit (a) is constant, and at very low frequencies, the shunting resistance $(R-r)$ is so large compared to the reactance that the entire L appears in the series equivalent circuit, as shown by the correspondence of X_L and X_{eq} in Fig. 3 for low frequencies. At very high frequencies, X_L is so great in comparison to $(R-r)$, that it is effectively shorted out, so that the resultant X_{eq} is only $(R-r)^2/X_L$, which diminishes hyperbolically with increasing frequency.

The equivalent resistive component is $R=V/I$ at high frequencies and $r=dV/dI$ at very low frequencies. If the bias is sufficient to make r negative, then there is some intermediate frequency at which R_{eq} is zero. This is called the critical frequency, f_0.

$$2\pi f_0=(R/L)(1-r/R)(-r/R)^{\frac{1}{2}}. \tag{8}$$

$$f_0=[(-r/R)^{\frac{1}{2}}]/2\pi T_e. \tag{9}$$

Near three times the critical frequency, the Q of the circuit is one, and as the frequency is reduced, Q increases until it becomes infinite at the critical frequency. Typical values for a $1-B$ thermistor are $R=6000$ ohms, $r=-1500$ ohms, $L=5150$ henries, $T_e=0.7$ seconds, and $f_0=0.11$ c.p.s.

LOW FREQUENCY OSCILLATOR

If the thermistor is paralleled with a condenser whose reactance is less than X_{eq} at f_0, the combination will oscillate continuously. If the capacity is increased, the

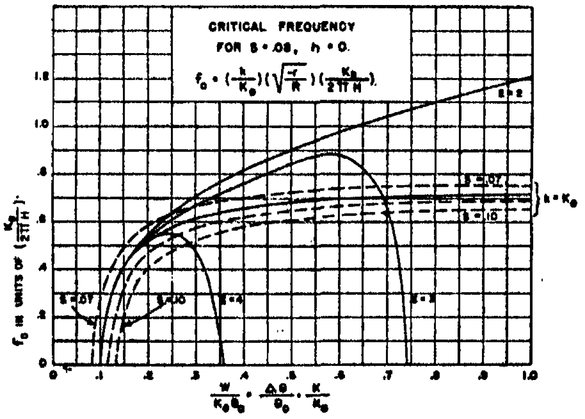

FIG. 6.

frequency will diminish, and the amplitude will rise because of the increase in the series negative resistance. The amplitude of oscillation stabilizes at the point where the a.c. energy dissipated in the internal impedance of the constant-current bias supply is just equal to that generated by the negative resistance. The series impedance $R_{eq}+jX_{eq}$ can be replaced by equivalent parallel values, R_p and X_p, the condenser C, and the parallel loading resistance R_c. Their values for frequency f are:

$$R_p=R_{eq}(Q_p^2+1), \tag{10}$$

$$X_p=X_{eq}(Q_p^2+1)/Q_p^2, \tag{11}$$

where

$$Q_p=X_{eq}/R_{eq}=R_p/X_p. \tag{12}$$

For sustained oscillations at the frequency f, the capacity must be

$$C=1/2\pi fX_p=Q_p^2/2\pi fX_{eq}(Q_p^2+1). \tag{13}$$

The amplitude must be small for the output to be sinusoidal. This is fulfilled when R_c, the loading resistance, is just equal to $-R_{eq}$. Since the negative resistance varies with frequency, R_c must be adjusted by the tuning control.

A word of caution concerning the adjustment of experimental oscillators is in order. If the frequency is set for much less than f_0, and if loading is not provided in the form of high series resistance in the condenser circuit, or high parallel conductance, then when the switch is first turned on, the condenser will charge slowly, and the thermistor will remain cold. As the thermistor begins to heat when the condenser is fully charged, it goes through a large temperature transient as described before, with a very short time constant. The condenser discharges suddenly and the thermistor burns up.

The oscillator can be tuned to frequencies above f_0 by supplying a small amount of positive feedback with a two-stage d.c. amplifier. One satisfactory design is shown in Fig. 4 for a W.E. 1−B thermistor. Since the inductance decreases almost hyperbolically with increasing frequency (constant reactance), the oscillator can be tuned over a ten-to-1 frequency range with a ten-to-1 instead of a 100-to-1 capacitor. The variable resistor R_b adjusts the d.c. bias current; R_a adjusts the d.c. level of the output signal, and is usually set to give zero volts d.c. output. R_f controls the positive feedback, and R_s provides loading for controlling the starting transient. The gain of each stage is limited to 10 by negative feedback. This oscillator will deliver 40 volts peak-to-peak with 14 percent second harmonic and no measurable third harmonic.

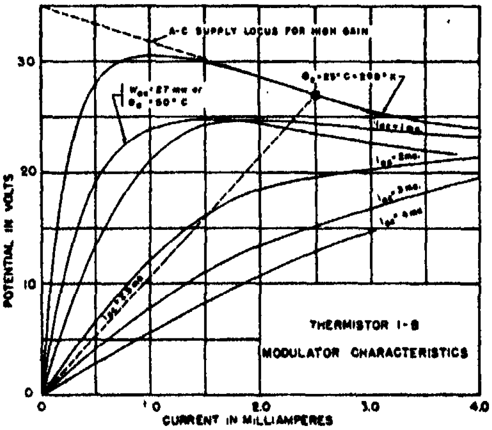

FIG. 7.

Bias tuning can be used on a thermistor oscillator either with or without feedback. The reason for this is apparent from Fig. 5, which shows that the inductance diminishes in the same manner as the resistance for increasing bias power dissipated, above the maximum voltage point.

$$L=(R/R_0)(1-r/R)(HR_0/K_0). \tag{14}$$

$$f_0=[(-r/R)^{\frac{1}{2}}](k/K_0)(K_0/2\pi H). \tag{15}$$

Figure 6 shows the variation in critical frequency with bias. It indicates the region in which feedback is not necessary. Between $W/K_0\theta_0$ of 0.11 and 0.3, the critical frequency increases by a factor of 6, and in the same region, from Fig. 5, the resonant frequency also increases, but only by a factor of two, for fixed parallel capacitance. In the same region, the incremental resistance increases by a factor of nine. The effective negative resistance, therefore, increases markedly, and the amplitude of oscillation rises with bias. Above $W/K_0\theta_0$ of 0.3, however, the rate of change of critical frequency becomes small, the incremental resistance begins to decrease, and the resonant frequency rises at a more rapid rate, all three effects tending to keep the amplitude constant independent of the bias tuning, and eventually to decrease the amplitude at very high bias.

Notice that the inductance is independent of bias for $W/K_0\theta_0$ of 0.05, which is just before the voltage reaches the peak of its curve (15° rise). Here the incremental resistance is changing quite rapidly. On the other hand, the negative resistance reaches a peak at about $W/K_0\theta_0$ of 0.3, (90° rise) and here the inductance is decreasing quite rapidly. It is difficult, therefore, to adjust a simple capacitively-tuned oscillator so that both amplitude and frequency are independent of bias changes.

FILTERS

A biased thermistor can be operated as a filter element near its critical frequency, but its characteristics are different from an ordinary inductance. The reactance is almost constant over a wide range of frequencies, and if used in an R−L network, phase shifts could be obtained which would be relatively independent of frequency.

It is interesting to note from Fig. 5 that the inductance is more than one-half of its maximum possible value for a range of $W/K_0\theta_0$ of 0.01 to 0.17, corresponding to temperature rises from 3 degrees to 50 degrees. The parallel resistance which the equivalent internal inductance L sees is $R-r$ ohms for a constant-current (infinite impedance) source. The internal Q is therefore

$$Q_i = k/\omega H = 1/\omega T_\theta. \qquad (16)$$

This has the units of power dissipated in watts per degree divided by thermal energy stored in watt-radians per degree. The external series Q_s for the same condition is X_{eq}/R_{eq} or

$$Q_s = (R-r)Q_i/(R+rQ_i^2). \qquad (17)$$

At low bias currents, r is almost equal to R, and Q_s is very low. At the maximum voltage point, $Q_s = Q_i$.

MODULATOR

If the thermistor is common to both an a.c. and a d.c. circuit, variations in d.c. can change the a.c. impedance and voltage. It can therefore be used as a modulator, in single units or bridge circuits, but the modulating frequency must be less than the critical frequency.

If the a.c. supply is high impedance and delivers constant current, the conversion voltage gain for a small alternating current and a large direct-current bias is

$$A = de_{ac}/de_{dc} = i_{ac}(R-r)/I_{dc}(-r). \qquad (18)$$

This is negative. At low bias levels when $r=R$, A is almost zero. At maximum voltage $r=0$, and A approaches a very large gain, but this is not realizable because the input impedance r goes to zero for changes in E_{dc}.

Figure 7 shows the d.c. V−I curves for a 1−B thermistor for several a.c. bias currents. These curves are reversible; that is, they are valid a.c. V−I curves for a set of d.c. bias currents. The equations given in Part I of this paper hold for modulator applications if W represents the total watts dissipated, $(i_{ac}^2+I_{dc}^2)R$. If the a.c. power, W_{ac}, were constant, then the curves in Fig. 7 would look just like the set for different ambient temperatures, the correspondence being $\theta_a = \theta_0 + W_{ac}/k$. Since the a.c. current is constant in Fig. 7, the slope r is more positive than for the constant-power curves.

Figure 8 represents a practical form of modulator circuit. For maximum power gain, the d.c. input impedance should equal the thermistor impedance for changes in current, which is the initial slope of the curves in Fig. 7, or R. The total output impedance is also R, and can be matched with a transformer to a rectifier, amplifier, or other device. (The incremental output impedance is r.) If the d.c. input increases, the output current and the output voltage will each increase by the factor $1/(1+dR/2R)$, where dR is negative. The change in output power will be approximately

$$dW_{ac} = -W_{ac}(1-3dR/4R)dR/R. \qquad (19)$$

The a.c. power dissipated internally in the thermistor does not change if the output load r' is equal to R. The change in d.c. power input required is

$$dW_{dc} = dR/mR. \qquad (20)$$

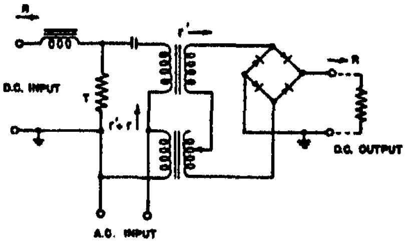

FIG. 8. Basic thermistor modulator.

This follows from the definition of m as the power coefficient of resistance. The power gain for matched impedances is approximately

$$G = dW_{ac}/dW_{dc} = -W_{ac}m = (r/R-1)/(r/R+1). \qquad (21)$$

The d.c. input should be small to make dR/R in Eq. (19) negligible. If the a.c. bias is too small, the gain will be low because of insufficient current to vary. If the bias is too high, G will again be low because m will be small due to small changes in input power having negligible effect on the resistance. The maximum possible gain occurs when the product of $W_{ac}m$ is a maximum. This maximum product corresponds to a line tangent to the curves in Fig. 9, Part I, with a slope of −45°. The value of $W_{ac}/K_0\theta_0$ is 1 for $k=k_0$, and 0.2 for $z=4$. The corresponding values of m/m_0 are 0.25 and 0.65.

The maximum gain occurs at the same values of bias power as the maximum negative incremental resistance, as can be seen by comparison with Fig. 12, Part I. The a.c. bias supply is stable, however, because of the external loading resistor r'.

The power gain for $k=K_0$ and $n=0$ is approximately

$$G = -W_{ac}m_0/(1+W_{ac}/K_0\theta_0)^2. \qquad (22)$$

The maximum possible power gain is

$$G_{\max} = -K_0\theta_0 m_0/4 = -a_0\theta_0/4. \qquad (23)$$

This is about three for the ordinary thermistor. For $Z=4$, this gain drops to 0.13 $a_0\theta_0$ or about 1.66.

The thermistor appears as a negative incremental resistance to the a.c. bias supply. This can be used to supply thermal positive feedback by reducing the output resistance r' until it is just slightly greater than r, the slope of the a.c. V−I curve for the power W_{ac} (top curve in Fig. 7). r' will be one-half to one-fourth of R.

If the resistance changes an amount dR, then the change in output power will be

$$dW_{ac} = -2dRW_{ac}r'/R^2(1+r'/R). \qquad (24)$$

The increase in a.c. current increases the losses within the thermistor. The internal feed-back power is

$$dW_i = W_{ac}dR(r'/R-1)/R(r'/R+1). \qquad (25)$$

The change in resistance is due to the total input watts,

$$dW_{dc} + dW_i = dR/mR. \qquad (26)$$

The power gain is

$$G' = dW_{ac}/dW_{dc} = -2W_{ac}mr'/R((r'/R+1) - W_{ac}m(r'/R-1)). \quad (27)$$

The numerator term ($W_{ac}m$) can be replaced by the matched impedance gain G. The same denominator term can be replaced by the function of r given in Eq. (21). Simplifying:

$$G' = G(r/R+1)/(r/r'+1). \quad (28)$$

If $r' = -r$, the a.c. system is critically unstable, and the gain becomes infinite. The gain can be made as arbitrarily large as one dares, the price being an increasingly longer time constant because of the thermal delay on the feedback. The bias current and load resistance fix the input a.c. voltage.

$$V_{ac} = i_{ac}(R+r') = (R+r')(W_{ac}/R)^{\frac{1}{2}}. \quad (29)$$

In a high gain system, the input voltage has to be adjusted carefully, because small changes in it are just as serious as small changes in r'.

Mr. Jay Stone, Engineer at the Ames Laboratory, Moffett Field, California, designed and built the low frequency oscillator described in this paper as an M.S. thesis.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

A Monitor for Low Intensity Gamma-Rays*

J. B. H. Kuper and R. L. Chase
Brookhaven National Laboratory, Upton, New York

(Received January 23, 1950)

A recording monitor for low intensity gamma-radiation has been developed, using a simple and inexpensive form of dynamic condenser electrometer in connection with an ionization chamber and a commercial recording potentiometer. Use of a rate of drift method at relatively low voltage sensitivity eliminates difficulties with contact potentials and grounding key kicks. The instrument gives an indication and recycles when 5 microroentgens have been received. Normal gamma-background current is 4 to 5×10^{-15} amperes and at this sensitivity the instrument is extremely rugged and operates outdoors in all weather.

THIS instrument has been developed in response to the need for a device to record gamma-rays of low intensity, of the order of 2 mr per week, continuously and without requiring attention over long periods of time. A major requirement was that the instrument be rugged and capable of outdoor operation in all weather conditions. Considerations of energy dependence dictated the choice of a Bakelite wall ionization chamber operated at atmospheric pressure. Since the current to be expected in a chamber of reasonable size, say 5 liters capacity, is only of the order of 4 or 5×10^{-15} amperes, it was felt that the usual vacuum tube electrometers would give excessive trouble with grid current and drifts when left unattended over periods of several days. Therefore, it was decided to use a simple form of dynamic condenser or vibrating reed electrometer.[1] This type of electrometer lends itself exceptionally well to use in connection with a recorder of the electronic self-balancing potentiometer type such as the Brown "Electronik" or Leeds & Northrup "Speedomax."

Since we are interested in determining the integrated dose of radiation, we used a rate of drift method with automatic recycling after a definite amount of charge has been accumulated. As indicated in the simplified schematic, Fig. 1, the charge accumulated in the ionization chamber is fed to the dynamic condenser and the resulting a.c. signal is removed through the coupling condenser and fed to the amplifier of the potentiometer recorder in place of the signal normally furnished by a chopper. The signal is amplified and used to drive the pen and potentiometer slide wire. The d.c. voltage appearing on the moving contact of the potentiometer is fed back to the coupling condenser and serves to bind on the latter all the charge collected except the residual necessary to furnish an error signal. Given sufficient amplifier gain, the voltage on the potentiometer slide wire contact will be equal to that on the coupling condenser to within a single convolution of the potentiometer slide wire. In the case of the Brown recorder this is 1/1400 of full scale.

In the actual instrument, of course, there is a contact potential difference across the dynamic condenser, and in order to obtain a vanishing error signal the potential applied by the feed-back line must equal the contact potential. This, however, appears only as a zero correction, provided the contact potential does not drift.

A convenient value for the coupling condenser is in the neighborhood of 10 $\mu\mu$f. It is possible to use a comparatively large voltage on the potentiometer, of the order of one volt, and thus minimize the effects of contact potential drifts and kicks due to grounding and

[1] Palevsky, Swank, and Grenchik, Rev. Sci. Inst. 18, 298 (1947).

ungrounding the circuit. This greatly reduces the cost of the electrometer.

The recording potentiometer is arranged to trip a switch when near the upper end of the slide wire. This actuates a grounding key which is held down by a synchronous motor timer for a period of 30 seconds in order to allow ample time for the recorder to return to zero, and is then released. Thus, the instrument is insensitive for 30 seconds out of each cycle and at high dosage rates a suitable correction would have to be made for this fact.

Under normal conditions of background in our location, one cycle takes about 35 minutes and represents about 5 microroentgens of gamma-radiation. In routine operation a message register is used to count the number of cycles and it is not necessary to use the recorder itself. The chart record is useful for observing changes in gamma-ray intensity and for diagnosis in case trouble is experienced.

As indicated in the photograph, Fig. 2, the ionization chamber, dynamic condenser, coupling condenser, and preamplifier are mounted together in a housing suitable for outdoor installation. The recording potentiometer, power supplies, and other accessories are mounted together indoors, and the cable between them may be of any desired length.

The housing for the dynamic condenser and preamplifier was purposely made much larger than necessary in order to provide some shelter for the ionization chamber from direct rainfall. The dynamic condenser was made by modifying the modulation condenser of a surplus AN/APN-1 radio altimeter.[2] The original ceramic insulator supporting a pair of stator plates was removed and discarded and a new stationary electrode supported with Teflon or fluorethene insulation was provided. Silver plating of this electrode was found to reduce the contact potential drifts to an acceptably low value.

A half-inch brass tube connects the stationary electrode of the dynamic condenser to the ionization chamber with a 1000-megohm resistor interposed to prevent loss of signal into the ionization chamber capacitance, and to reduce the effects of hum picked up by the chamber center electrode. The coupling condenser consists of a length of brass tubing mounted coaxially with the one mentioned above on three Kovar glass seals. The use of air dielectric for this condenser avoids difficulties with insulator soakage. The dynamic condenser is driven with about one-half volt 60-cycle a.c. obtained from a small stepdown transformer and the 60-cycle error signal is fed to the two stage preamplifier. To minimize hum pick-up the "grounding pin" actuator and preamplifier heaters are operated on direct current. In all probability sufficient gain could be obtained from a single stage of amplification at this point, but it was felt safer to provide a second stage and thus reduce the danger of hum pick-up in the cable between the preamplifier and the recorder. The output of the amplifier was stepped down to an impedance level of a few hundred ohms before being placed on the line. The recording potentiometer was modified to have a full scale range of one volt, and the drive voltage was removed from the mechanical chopper. The signal from the preamplifier was fed directly to the input step-up

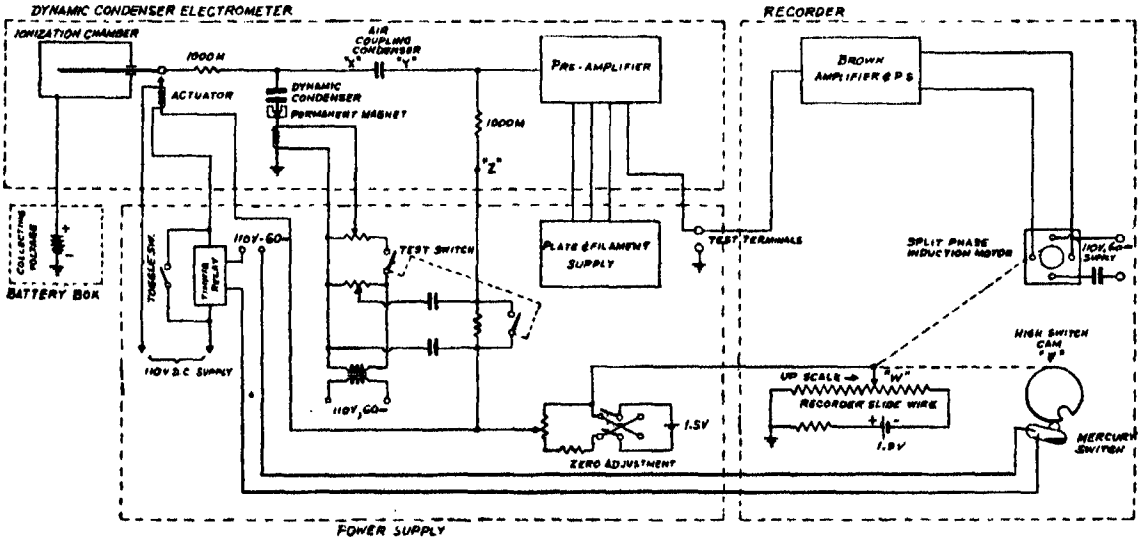

FIG. 1. Simplified schematic of the dynamic condenser monitor. Charge is collected on the insulated line "X" and is bound on the air coupling condenser by an equal and opposite charge at "Y" produced by feeding back the slide wire voltage at "Z." When the recorder reaches a preset point on scale the mercury switch closes, energizing the "grounding pin" actuator and discharging the coupling condenser. After a predetermined time, long enough for the recorder to return to zero, the actuator is released and a new cycle started.

---

[2] We are indebted to Dr. R. J. Moon of the University of Chicago for the suggestion of using the altimeter condenser for this purpose.

FIG. 2a. Photograph of the complete assembly, including power supplies and recorder.

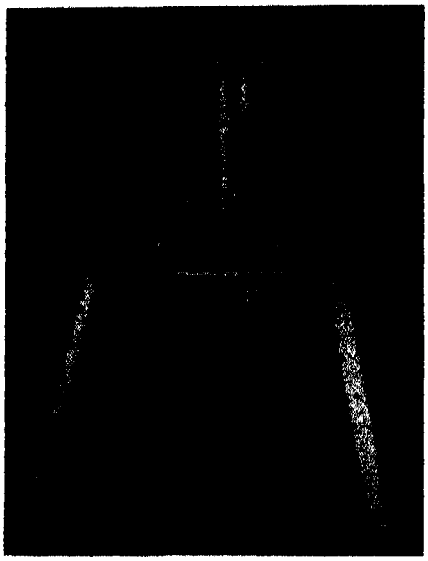

FIG. 2b. Inside view of the electrometer head showing the dynamic condenser, preamplifier and the grounding pin and actuator used for recycling.

transformer of the Brown amplifier. The mechanical chopper was not removed since it is used for the automatic standardization of the working current in the potentiometer. Feed-back voltage from the potentiometer slide wire is applied to the coupling condenser through a 1000-megohm resistor.

The use of 60 cycles for the working frequency in the dynamic condenser is convenient from the standpoint of the potentiometer drive motor which acts as a phase detector in this application. However, if it were not for this consideration a much higher frequency would have been chosen. Not only does the use of 60 cycles seriously complicate the hum problem,[3] but also it requires the use of very high impedances in the input to the amplifier in order to obtain a reasonable conversion efficiency from the dynamic condenser. The first stage of the preamplifier is operated at low screen voltage in order to reduce the grid current as far as possible. Even so, an occasional 6AK5 has so large a grid current as to bias itself into an unfavorable region because of the 1000-megohm grid leak.

In order to simplify servicing of these instruments in the field, suitable test points have been provided. A rough over-all check for satisfactory operation can be obtained by turning the zero adjust knob a definite number of divisions corresponding to a known voltage increment, and checking that the recorder pen moves correspondingly. The pen should move promptly and positively as though to indicate that the control is "stiff." If the over-all gain is too high, overshooting or hunting will be observed in this test. Since there is more than enough gain in both the preamplifier and the main amplifier, it is not sufficient to know that the over-all gain is correct. The gain must be divided between the two parts of the amplifier so that neither is overloaded. This is done by feeding a known a.c. signal to the preamplifier by means of the test signal switch and observing with a high impedance voltmeter or with a calibrated oscilloscope that the correct output voltage is obtained from the preamplifier. The conversion efficiency of the dynamic condenser may be checked by applying a known d.c. voltage through the zero adjust control and observing the preamplifier output. For this test the potentiometer drive motor must be stopped and heater voltage removed from the recorder amplifier. Excessive drive voltage applied to the dynamic condenser will cause it to short occasionally. This will cause recognizable distortion of the wave form at the preamplifier output. Once the conversion efficiency and preamplifier gain have been set to the correct values, the main amplifier gain can be adjusted to give the correct over-all gain.

Because of the feed-back connection variations in gain can be tolerated so long as the gain is somewhat greater than the minimum value necessary to start the potentiometer drive motor when the unbalance signal exceeds that due to one convolution of the slide wire. This makes the whole instrument relatively tolerant of line voltage fluctuation. Nevertheless, we have found it good practice to operate the equipment from a Sola voltage regulating transformer to stabilize the dynamic condenser drive voltage. This is desirable because the zero position depends somewhat on hum pick-up, in addition to the contact potential, and, therefore, is a function of conversion efficiency.

Collection voltage for the ionization chamber is obtained from ordinary B batteries. Since changes in this voltage will appear directly in the record, it is advisable to protect the batteries from sudden temperature changes.

The principal difficulty encountered in building a group of sixteen instruments was, as might be expected, with the insulators. The insulator for the ionization chamber is protected by a guard ring so that none of the high insulation is ever subjected in normal circumstances to a voltage greater than the contact potential of the dynamic condenser. Insulator leakage may appear to accelerate or decelerate the rate of drift, depending on the sign of the contact potential. The sign and approximate magnitude of the contact potential can be determined from the setting of the zero-adjust potentiometer required to bring the recorder to zero.

---

[3] Hum pick-up will cause a displacement of the zero position, and may cause the amplifier to overload, so precautions should be taken to minimize it.

Insulator leakage, provided it is not too severe, may be determined by the behavior of the error signal observed at the output of the preamplifier with the slide wire drive motor turned off. In the absence of leakage the error signal will increase indefinitely as ionization current is collected, until, of course, the preamplifier saturates. If an insulator leak becomes appreciable with respect to the ionization current of a few times 10^{-15} amperes, the error signal will rise to some value and remain constant. Given a knowledge of the ionization current and the contact potential, it is possible to compute the insulation resistance, if one determines the d.c. voltage on the dynamic condenser corresponding to the observed error signal.

We have made satisfactory insulators of molded or polished polystyrene or of machined fluorethene. In some cases machined Teflon has been quite satisfactory, but occasional samples of this material appear to have inclusions which increase the conductivity.

Far more troublesome, however, than ordinary leakage effects, have been difficulties with surface charges on insulators. We have found it of the utmost importance not only to coat with conducting material as much as possible of any exposed insulator surfaces, but also to coat those portions which are supposedly in contact with metal. Neglect of this precaution leads to extremely annoying drifts which appear whenever the ambient temperature is changed suddenly. If an instrument which has been in thermal equilibrium is suddenly moved to a new environment, the apparent ionization current may increase for a period of time followed by a reversal in which the "current" is either greatly diminished or even reversed, and ultimately, after the instrument has come into equilibrium with its new surroundings, a return to the normal rate of drift.

Our explanation for this effect is as follows: The contact surface between the insulator and the metal part supported by the insulator is by no means perfect, especially since in our case both surfaces are machined and not highly polished. Thus, it is possible for charges on the surface of the insulator almost but not quite in contact with the metal to remain indefinitely. Any slight relative displacement of the two surfaces occasioned by differential thermal expansion will change the capacitance across the gap and hence result in an apparent flow of charge. Because of the very small clearances involved, this flow may be surprisingly large. We suspect that a phenomenon of this sort may be at the bottom of many reported cases of stress currents or pyroelectric effects in insulators. Effects of the sort postulated here will presumably disappear in time and their disappearance can be hastened by exposure to a strong gamma-ray source. However, we have found it preferable to eliminate them at the start by careful treatment to insure good contact between the insulator and the adjacent metal part. Teflon and fluorethene are exceedingly difficult to wet with aqueous solutions. We have found it possible to get a satisfactory conducting coat by using Lubrifilm, an alcohol suspension of colloidal graphite.

Another problem which has given us some difficulty is that of alpha-particle contamination of the ionization chamber itself. The ionization current due to gamma-rays of the order of 4 or 5×10^{-15} amperes is equal to that which would be produced by one alpha-particle of average energy every four or five seconds.

Some of our chambers were found to be contaminated to the extent of something like six alpha-particles a minute. Fortunately this was a surface contamination and could readily be removed by cleaning and recoating the chamber with graphite.

The ionization chamber and preamplifier are sealed up, with drier inside, and provision is made for accommodating changes in atmospheric pressure and temperature through a breather balloon. Thus, for the most accurate work it would be necessary to apply a correction for pressure and temperature in the ionization chamber. The joints in the ionization chamber are sealed with Glyptal lacquer and we have so far experienced no trouble with moisture seeping in. The chambers have been operated with a hose played on them with no apparent ill effects. An important advantage of the type of ionization chamber described here is its extreme ruggedness. The instrument is quite insensitive to microphonics. In fact, it is possible to pound on the ionization chamber-preamplifier assembly without causing any effect on the record. Also, on one occasion during a severe windstorm, an instrument was blown loose from its fastenings on the roof of a building and tipped over on its side. This, too, resulted in no appreciable effect on the record.

With a given ionization chamber, coupling condenser, and potentiometer range, the maximum intensity that can be measured is limited by the speed of the recorder drive motor. Making correction for the insensitive time during recycling, we can measure up to about 100 times the normal background intensity without alterations.

It is a pleasure to acknowledge the contributions of our colleagues in the Electronics Division, and particularly Mr. Lloyd Davis.

(Received November 28, 1949)

Micro-needle electrodes of any desired taper and sharpness for insertion into living tissue can be made quickly by electrolytic etching. For stainless steel wire the electrolyte is a mixture of sulfuric and ortho-phosphoric acids. The wire to be pointed is made the anode of a circuit initially carrying about 0.03 amp. Gross shaping of the needle is done by repeatedly immersing the wire and withdrawing it slowly from the bath. Fine shaping of the point is carried out with reduced current. The electrodes are finished by insulating all but the fine tip with a baking enamel. The process described is adaptable to making a batch of micro-needles at one time.

MANY physiological studies require insertion electrodes of a size that will cause minimal damage when they are introduced into neural tissue and which are insulated to record or stimulate only at a very fine electrode tip. Such electrodes have been constructed (Grundfest and Campbell)[1] by shaping thin steel needles with a special grinding technique and then insulating them by dipping in a baking varnish. Electrodes can be made with tips of 5–10μ, but when examined microscopically, the points are somewhat blunt and rough. The chief disadvantage of the procedure, however, is that the electrodes are individually made with a time-consuming technique.

The present paper describes a technique of electropointing of a non-corroding stainless steel wire in an acid bath to produce needle electrodes relatively uniformly and quickly. This technique is similar to that used for electropolishing specimens for microscopic examination. Many needles can be made at one time. Microscopically smooth sharp points can be made any desired shape, size, and taper suitable for the specific application (Fig. 1). The point found most practical for work in the intact mammalian nervous system is shaped like a narrow "V." However, needles have been made with a thin, microscopically sharp, hair-like tip less than 0.2μ in diameter for 1 mm and then coming to a heavier shank. These have been used in tissue cultures.

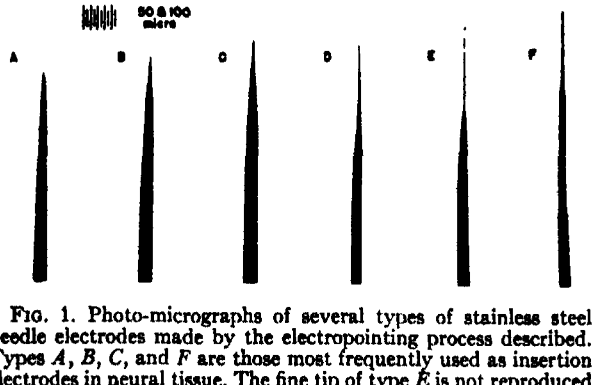

FIG. 1. Photo-micrographs of several types of stainless steel needle electrodes made by the electropointing process described. Types *A*, *B*, *C*, and *F* are those most frequently used as insertion electrodes in neural tissue. The fine tip of type *E* is not reproduced adequately because of bubbles in the mounting medium. The needles shown are without insulation.

Various stainless steels, in the form of 0.25-mm (0.01-in.) diameter wire, were used for constructing the micro-needle electrodes. The most satisfactory is hard-drawn 18-8 wire. We have found stainless steel and particularly the 18-8 composition superior to a carbon steel wire in respect to corrosion in living tissue and preservation of the point after multiple insertions within neural tissue.

The needles are pointed by dipping in an acid made as follows: 34 cc concentrated sulfuric acid (sp. gr. 1.84), 42 cc ortho-phosphoric acid (sp. gr. 1.69), and 24 cc of distilled water to total 100 cc of solution. A portion of this solution is placed into a small metal beaker which is connected to the negative side of a 6-v d.c. source. The wire to be pointed is made the anode. A switch, variable resistance, and milliammeter are included in the circuit. A microscope of low magnification is fitted in front of the beaker so that the stage of electrolytic pointing may be observed at any time by raising the needle out of the acid solution.

The pointing process is carried out by immersing the wire in the acid solution and passing a current through it. At first, the electrolytic action is carried on rapidly to produce a general tapering of the needle. A current of 0.03 amp. per needle produces an optically smooth finish in a satisfactory time. Higher current will cause pitting and such rapid electrolysis that control of the shape of the point is difficult. During the electrolytic pointing process, about 15–20 mm of the wire is repeatedly immersed and withdrawn slowly from the acid to produce the desired taper. Toward the end of the procedure, when shaping of the tip is done, the current is reduced, to make the pointing more easily controlled. Various tapers and points may be obtained by varying the depth of immersion, time of electrolytic action, and current strength. Microscopic examination during this stage is essential. Following electrolytic pointing, the needle should be dipped into 10 percent hydrochloric acid in order to prevent staining of the wire, and then thoroughly washed.

---

[1] Harry Grundfest and Berry Campbell, "Origin, conduction and termination of impulses in dorsal spino-cerebellar tracts of cats," J. Neurophysiol. 5, 275–294 (1942).

Care must be taken with the acid solution used for electrolytic pointing as its concentration is critical. If a small volume of solution is used or if many needles are made at one time the water content of the acid will decrease by electrolytic action, ultimately increasing the electrical resistance of the solution to the point where no pointing will occur. Since the acid is hygroscopic, it must be made freshly as a too dilute acid will not work despite a low electrical resistance.

After the point has been produced, the blunt end of the needle is electroplated with copper in order to present a surface which can be used to solder the needle into a holder rod. The plating is necessary, since the stainless steel would otherwise have to be fixed to the heavier rod either by clamping, silver soldering, or welding. Clamping presents hazards of poor and variable electrical contact while we have found that high heat applied to the fine stainless steel wire often causes softening of the needle shank.

Copper sulfate is employed for the plating process with a copper plate and the blunt end of the needle immersed in the solution. About 20 ma of current per needle (which is connected to the negative pole) and about 2 min. produce a satisfactory well-bonded plating of copper.

Following this, the needle is cleaned with alcohol, dried, and insulated. It is dipped into and then very slowly removed from General Electric Formvar Enamel No. 9825. The enamel is baked for 30 min. at 125°C. The enamel is usually diluted to obtain a thin, uniformly deposited coating on the needle. Several coats may be necessary to produce satisfactory insulation. In the insulating process all but the blunt, copper-plated end of the needle is immersed in the enamel, and during the drying the needle is held vertical, with the tip up. This aids retraction of the enamel film from the extreme tip, so that usually the tip is open even after several coats of enamel have been baked on. If it has become insulated, one or two gentle strokes of the tip against very fine abrasive will remove sufficient insulation to permit use as an electrode.

There are several special steps in this procedure worthy of mention. The first is that stainless steel wire as supplied to us on a roll has to be straightened to obviate a curved or bent needle. Such a process, requiring cross rolling, has been done for us by the Art Wire and Stamping Company of Newark, New Jersey. The second is that it is preferable to have a smooth and flawless enamel coating of the needle. Attention must be given to the prevention of dust and other foreign materials from getting on the needles during the enameling and baking processes.

The procedure described in the foregoing is easily adaptable to making a large number of needles simultaneously. All that is needed is to assemble an array of wires on the needle holder, in such a way that they all make contact with the positive input terminal, but do not touch each other. When properly assembled the array can also be plated and insulated as a unit, and stored until needed.

The steps in the manufacture of the microelectrodes are: (1) pointing by an electrolytic process in acid; (2) copper plating of the other end of the needle; and (3) insulation by dipping in an insulating enamel. This technique has produced over one thousand needle microelectrodes for use in the study of bioelectric potentials observed in the mammalian nervous system. They have been made in a variety of shapes and sizes for various studies and have proved satisfactorily durable so that one needle can withstand use in a number of experiments. They cause minimal tissue trauma and permit recording from areas as small as one neural cell.

We wish to express our sincere gratitude to Dr. J. B. Austin, Director of the Research Laboratory of the United States Steel Corporation for his interest and assistance; to Mr. N. C. Beese, Research Department, Westinghouse Electric Corporation, Bloomfield, New Jersey, for samples of wolfram wire and electrolytically pointed wolfram needles which were tried early in the development of the procedure described; and to Dr. Joseph Greenspan, Process and Instruments, Brooklyn, New York, who informed one of us (H.G.) of the existence of the electrolytic pointing process.

Automatic Isodose Recorder with Scintillation Counter as Gamma-Ray Detector

G. J. Hine,* M. Berman, and M. M. Elkind**
Division of Physics and Biophysics, Sloan-Kettering Institute for Cancer Research, New York, New York

(Received November 28, 1949)

This paper describes an instrument for investigating the radiation field of any type of gamma-ray source. A small calcium tungstate crystal together with a light-conducting quartz rod and a 1P21 photo-multiplier tube is used as gamma-ray detector. The lines of constant radiation intensity in a selected plane (isodose curves) are recorded automatically with a good accuracy in a short period of time.

INTRODUCTION

THE use of extended gamma-ray sources for therapeutic purposes requires knowledge of the dosage due to the gamma-radiation. Therefore, the three-dimensional radiation field of gamma-ray emitters has to be determined thoroughly. For practical applications, the lines of constant radiation intensity within a given plane (isodose curves) are frequently the most desirable information.

Based on some ideal assumptions[1] the isodose curves for sources of simple geometric configurations, such as linear sources, can be constructed mathematically. However, the limited account for the absorption in the walls of the linear radium tubes and the radium salt itself prevents accurate calculations of the regions close to the sources and around their ends. For odd assemblies of several linear gamma-ray sources, calculations become extremely difficult, tedious, and time-consuming.[2] Therefore, it is practically impossible to determine for each patient individually the applied or even the most effective radiation distribution. For the use of extended gamma-ray sources, such as Co^{60} where fabricated shapes have been activated in a pile,[3] little information can be obtained by computations.

Several attempts have been made to determine isodose curves experimentally. Radioautographs can be made only for a few simple source arrangements, and the results obtained are not very accurate. An isodose recorder similar to the one described here had been developed by L. D. Marinelli and one of the present authors.[4] However, the ionization chamber employed as a radiation detector could supply only an average radiation intensity over its volume. Leakage and amplification problems have kept the volume of the chamber too large in comparison with the field region of interest; the resolution obtained was therefore rather poor. Furthermore, the usefulness of the instrument was limited for practical purposes by the great amount of activity required for the application of a small ionization chamber. The recent development of scintil-

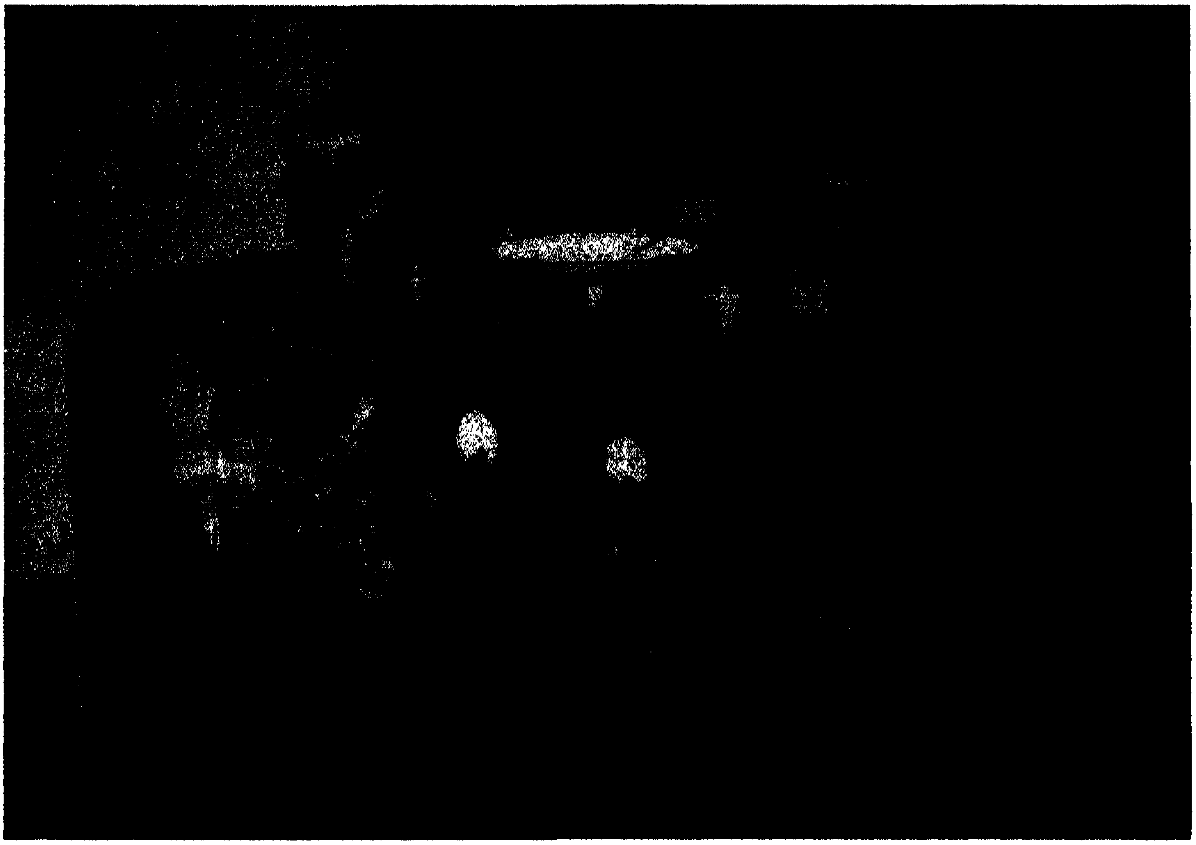

FIG. 2. Recording assembly. On the top plate of the cabinet are shown turntable with recording pen, and Brown motor driving pen leading screw and selsyn *A*.

lation counters provides a small detector with a high gamma-ray efficiency.[5]

The automatic isodose recorder to be described satisfies the demand for tracing radiation fields with a good accuracy in a short length of time. Careful construction of this instrument insures simple and reliable operation.

GENERAL OPERATION OF THE ISODOSE RECORDER

The instrument records a line of constant radiation intensity (isodose curve) within a gamma-ray field for any selected plane. The source is rotated about an axis perpendicular to the selected plane. The detector moves within the plane radially with respect to the rotating source. The radiation intensity as seen by the detector controls its movement through a servomechanism. An increase in radiation intensity due to the rotation of the source causes the detector to move away from the source; a decrease in intensity brings it closer to the source. Hence, the detector is always forced to follow a line of constant radiation intensity. A turntable rotating synchronously with the source and a pen translating simultaneously with the detector permit the continuous recording of the isodose curves.

Isodose curves representing different field intensities can be selected within a plane. Furthermore, by recording isodose curves in various planes one can obtain corresponding three-dimensional isodose surfaces.

Figure 1 gives the working diagram of the complete instrument. In order to minimize any danger of radiation exposure to the operator, the instrument is separated into two groups of asemblies. Electric cables and the hoist cable which is used for raising and lowering the source relative to the scintillation crystal are the only connections between both groups. Two selsyn systems permit remote and synchronous operation. Selsyns *A* and *A'* simultaneously translate the detector and the recording pen, while selsyns *B* and *B'* driven by a synchronous motor rotate both source and turntable.

In order to compare isodose curves obtained in air with those in a scattering medium, the source and detector can be surrounded by water in a tank. The selsyn shaft on which the source is mounted enters the tank through its bottom. A mercury seal preventing water leakage permits vertical translation of the selsyn shaft, as well as rotation with negligible retarding torque.

The recording assembly of the instrument is shown in Fig. 2.

SCINTILLATION COUNTER AND ELECTRONIC CIRCUITS

A small cylindrical calcium tungstate crystal $\frac{1}{8}$ inch in diameter and $\frac{1}{8}$ inch high (volume 0.03 cm^3) used as a gamma-ray detector shows equal efficiency for radiation incident from any direction. Its high gamma-ray sensitivity[5] provides a sufficiently high counting rate even at intensities as low as 10 roentgens per hour. The light flashes from the crystal are conducted through a quartz rod ($\frac{1}{8}$ inch in diameter and 15 inches long) to a 1P21 photo-multiplier tube. The amount of light reaching the photo-tube is further increased by aluminum foil surrounding the crystal as a reflector. The crystal, quartz rod, and 1P21 tube surrounded by a light tight Al cover are assembled together with the preamplifier.

The input and output *RC* time constants of the preamplifier equal that which yields a good signal-to-noise discrimination[6] for this particular crystal. A cathode follower stage provides a low impedance output for the transmission of the pulse through a cable from the detector to the discriminating and integrating circuit (Fig. 3). The amplifier stage (V_1) with the potentiometer R_1 is used as pulse height discriminator. The output of V_1 is fed into a one-stroke multivibrator stage (V_2) for pulse equalization. The integration of the pulses is accomplished by a diode (V_3) and an integrating circuit R_3C_3 whose time constant is approximately 0.5 second. A negative signal is obtained across the integrating circuit as pulses are collected. This signal is opposed by a positive voltage in order to provide zero output from the cathode follower stage (V_4). Potentiometer R_2 sets the positive voltage necessary.

While the detector is on any selected isodose curve, the counting rate is constant (this is accomplished by discriminator R_1), and the output of V_4 is zero. Any deviation from the isodose curve results in either a positive or negative d.c. voltage. This is fed into a "Brown" amplifier[†] driving a motor, the direction of rotation of which depends on the polarity of the input. The motor, in turn, controls the movement of the detector relative to the source (Fig. 1) in such a manner as to bring it back to the isodose curve.

The statistical fluctuation of the output signal is a function of the counting rate and the time constant of the integrating circuit. For a statistical accuracy of about 3 percent, a counting rate of 2000 counts per second was chosen as a minimum. The same degree of accuracy is obtained for all isodose curves by setting potentiometer R_1 in such a position that only 2000 counts per second will pass. This is possible since a wide pulse height distribution is provided by the photomultiplier tube. R_1, then, can be calibrated for the different radiation intensities for any radiation source and subsequently used as isodose selector. The operation of the instrument on 2000 counts per second (or any other selected value) enables the operation of the multivibrator, integrator, and cathode follower stages at the same characteristics regardless of the isodose curve traced.

There are other ways whereby different dose levels could be selected; the grid bias of the last stage could be varied, or the integration time changed. By using one of these methods, the total energy spectrum could always be included. However, independent of the electronic system applied, the instrument has to be recalibrated for each different gamma-ray emitter.

DISCUSSION

Isodose curves can be traced at different speeds, completing one revolution of the source and turntable in 1, 2, 4, or 6 minutes. The 1- and 2-minute speeds can be used only for isodose curves close to the center of rotation. The results are reproducible with an accuracy

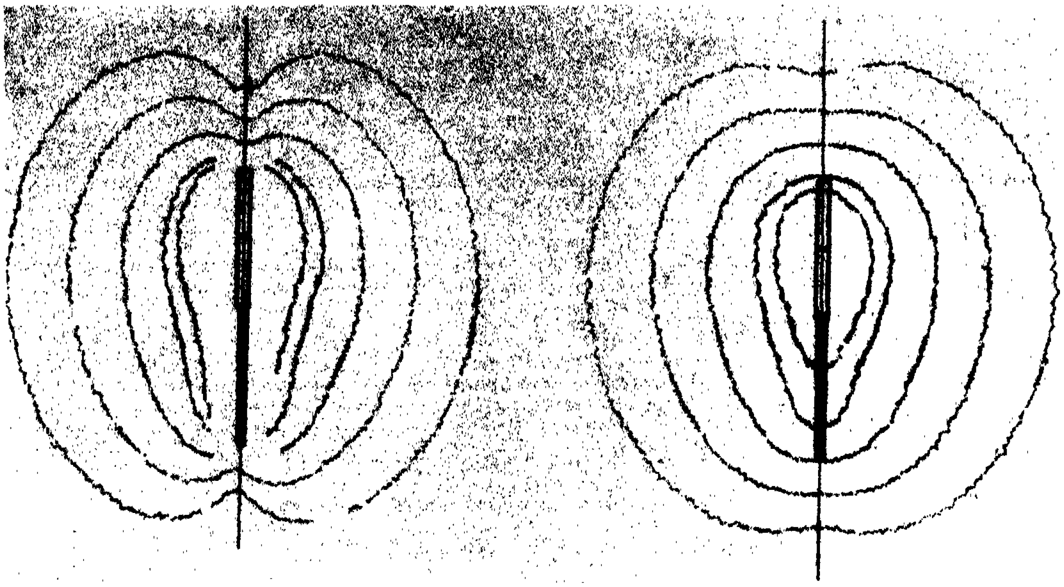

FIG. 4. Isodose curves for 250, 500, 1000, 2000, and 3000 roentgens per 1000 mg-hours of radium (0.5-mm Pt filtration) for a tandem of two 12.5 and two 25 mg sources. Each tube has an active length of 1.2 cm. (a) Isodose curves in center plane of the four tubes. (b) Isodose curves in a parallel plane 0.7 cm above the center plane.

of about ±5 percent, limited by the stability of the electronic circuits and the response of the servomechanism. Both the speed of the isodose tracing and the accuracy obtained are quite adequate for practical clinical requirements. This represents great improvements in comparison with previous methods, but without having reached the ultimate limit. A reduction in crystal size would increase the resolution and would permit the recording closer than 5 mm from the source.

The scintillation counter applied in its present form cannot be calibrated in roentgens so its calibration will hold for the gamma-radiation of different isotopes. The integrating circuit registers the number of pulses produced in the crystal whose height exceeds a certain selected size. No account is given to the amount of ionization produced in the crystal by gamma-rays of various energies. Whereas this would be an advantage for low molecular-weight crystals, the pulse height distribution in the heavy calcium tungstate crystal is not comparable with the ionization in an air-equivalent medium. Therefore, the instrument has to be calibrated for each isotope by means of a standard point source, for which the radiation intensity falls off with the inverse square of the distance.

Since in a scattering medium the radiation field of even a point source has not yet been determined, the response of the scintillation counter cannot be expressed in roentgens for any other medium than air. The amount of light produced in various crystals by gamma-rays of different energy, as well as the change in dosage due to a scattering medium, has to be investigated.

The isodose curves obtained with linear radium sources agree with the calculated results for those regions where accurate calculations are possible. As an example, the isodose curves for a tandem of four linear radium tubes of two different intensities are presented. Figure 4a shows the isodose lines in the center plane of the four sources, and Fig. 4b those obtained in a parallel plane 7 mm above the first one. The absorption around the axis of the tubes is of special interest. Detailed results for a great number of problems will be reported elsewhere.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Mr. L. D. Marinelli for suggesting the instrument and his interest during the course of its development. They are indebted to Mr. R. J. Zabelicky and his group of the SKI Instrumentation Shop for the excellent production of the mechanical assemblies, and they further acknowledge the assistance of Mr. S. Vacirca in setting up the instrument. The work was supported in part by a grant from the ONR.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

A D.C. Amplifier for Biological Application

P. O. Bishop*
Anatomy Department, University College, London
AND
E. J. Harris
Biophysics Research Unit, University College, London

(Received November 1, 1949)

The limitations of direct-coupled valve amplifiers are discussed and a method is given for assessing their performance. A multichannel high gain direct-coupled amplifier is described. This was designed for use in biological applications requiring a high input impedance. The input impedance at the grid is greater than 100 MΩ at 10 kc/sec. The frequency response is flat from zero to over 10 kc/sec. Alternative condenser coupling is provided so that the large amplitude very low frequency noise elements may be eliminated. When the amplifier is direct-coupled the zero shift is of the order of 100 μv peak-to-peak over a period of 30 min. Sufficient voltage gain is available for the limit of useful amplification to be set by the noise generated in the input circuit and first amplifying valve. A parallel balanced circuit is used giving a very high discrimination against in-phase signals. Both the input and output are at earth potential.

AN instrument was required to measure both steady potentials and variations in potential in the nervous tissue which makes up the brain. In the particular application for which the instrument was designed these potentials are led off from discrete microscopic regions in the interior of the brain of an experimental animal by means of microelectrodes which may have a resistance of the order of 10 MΩ or more. The potentials are very small and the amplifier must have sufficient gain to permit recording. It is also desirable to be able to record simultaneously from several different positions in the brain, which means that a suitable number of separate channels of amplification should be available. The main requirements as far as the amplifier is concerned are:

(1) A high input impedance, not falling below 10 MΩ in the frequency range 0–10 kc/sec.

(2) Only differences of potential between the electrodes (neither being earthed) should be amplified and there should be a high discrimination against in-phase changes.

(3) The amplifier should deal with frequencies from zero up to 10 kc/sec.

(4) Input potentials of the order of microvolts are to be amplified sufficiently to operate an oscilloscope for photographic recording, or alternatively to operate a pen recorder (in the frequency range 0–80 c/sec.).

(5) The sensitivity to external disturbances, both electrical and mechanical, should be a minimum without the use of bulky screening.

(6) The d.c. level about which the output is obtained should not be excessive.

(7) The setting-up procedure should be simple.

(8) The apparatus should, as far as possible, be mains operated.

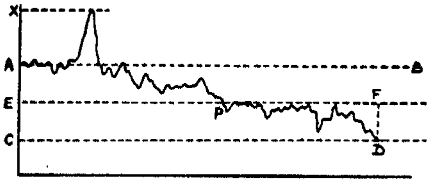

Fig. 1.

It was decided to limit the number of channels to four. Multichannel recording made the additional requirements desirable:

(9) There should be no interaction between channels.

(10) It should be possible to use any particular channel in the absence of any of the others or any combination of channels up to a total of four.

AMPLIFIER LIMITATIONS

The requirements outlined made the use of a valve amplifier essential. The limitations to the amplification of small alternating potentials are well known, but the limitations to the amplification of small direct voltages by a valve amplifier are imperfectly understood. The authors have made a general review of this subject elsewhere[1] so that only a brief treatment is needed here. The spectral intensity of both thermal agitation noise and shot noise is constant and independent of frequency provided allowance is made for the changing impedance of the circuit. A source of frequency-dependent noise was first observed by Johnson[2] and the term "flicker effect" was applied to this phenomenon by Schottky.[3] At very low frequencies, flicker noise becomes considerably greater than anode current shot noise and thermal agitation noise, but not greater than the shot effect of the grid current when the resistance in the grid circuit is made extremely large (i.e. $>10^{12}\Omega$). Under the conditions which are being considered, however, flicker noise is likely to be the determining factor to the useful sensitivity.

Attempts have been made (Macfarlane[4]) to derive mathematical expressions for the flicker effect, but insufficient quantitative information is available for it to be possible to calculate the intensity of flicker noise under any given conditions. An attempt, therefore, was

made to arrive at some estimate of the ultimate sensitivity of d.c. amplifiers from a survey of the literature. This survey revealed widely divergent claims to useful sensitivity, and with the exception of a few papers the methods of expressing the degree of stability attained were unsuitable for any comparative assessment to be made. The lack of agreement is a consequence of the arbitrary distinctions drawn between noise and drift. The term "drift" has never been precisely defined and is rather vaguely applied to undesired fluctuations in the output which occur relatively slowly compared with "noise" fluctuations. Drift used in this sense thus includes very low frequency noise elements, as well as variations due to changes of the operating conditions of the valve (e.g., supply voltages, temperature, etc.).

In the absence of any precise criteria for enabling the distinction to be made, it would appear best not to attempt to differentiate between noise and drift but to regard all the fluctuations of the output balance of the amplifier from whatever cause as though they were noise. Consider a record such as depicted in Fig. 1. The maximum peak to peak fluctuation ($X-C$) may give an entirely erroneous idea of the stability, for with the exception of one large peak the practical performance of the amplifier would be much better than the peak-to-peak figure. What appears to be the correct method for expressing the performance is as follows: A line (CD) is drawn parallel to the original zero (AB) and passing through the point of maximum departure (D) from the zero position. The area between the curve and the line (CD) is measured and divided by the length (CD) to obtain a mean level (say EF). We then obtain the mean fluctuation amplitude over the time considered by division of the total area included between the record and EF [i.e., the area ($APE+FPD$)] by CD. Similarly, the mean fluctuation intensity can be derived from the area included under a plot of the squares of the instantaneous deviations from the base line divided by the time interval. The lower limit of the passband of the amplifier is set by the period of observation; that is, the period over which the record is taken sets an arbitrary limit to the lowest fluctuation frequency which is observed.

Unfortunately, the records given in the literature are unsuitable for the method described above to be applied. Indeed, it would be very difficult to publish a suitable record even if it were available, and such an analysis would be extremely laborious. A possible practical method for obtaining the required figure would be to apply the output to integrating watt meter, such as an ice calorimeter containing a resistance coil, and a reversible electrochemical Coulombmeter in series. The ice calorimeter gives a measure of mean off-balance power, measured from the original zero and the Coloumbmeter provides a measure of the mean off-balance current. By subtracting the product of the square of the latter times the resistance of the watt meter coil, from the former expressed in the proper units, the mean off-balance power, measured from the most favorable zero (the level EF in Fig. 1) is obtained. For the present purpose, however, it was decided to use the maximum peak-to-peak deviation observed in a given period, bearing in mind the limitations of this method. The original balance setting at the commencement of the record remains the point of reference, for it is not admissible to use a time-dependent base line when the usefulness of the apparatus for long-term direct-coupled measurements is in question.

The older papers describing circuits for electrometer valves followed by a sensitive galvanometer have been useful because they usually give figures for the long-term drift of the zero position. The best performance appears to be that of Hafstad[5] who reports an equivalent

Note: 1. The switch S1 should be shown on the input side of R6 and R7 so that feedback is applied in either position of the switch. 2. The high frequency filter (R49 and R50 and C4–8) should be shown at the input of the circuit in Fig. 4. This enables the connecting link between the two units to be at a relatively low impedance to ground.

fluctuation to 30 μv r.m.s. over a period of 40 min. In arriving at this estimate Hafstad used an arbitrary base line which enabled him to neglect a considerable unilateral drift of his zero position. From this base line ordinates were taken every 30 sec. and the root-mean-square fluctuation is determined. When expressed as a peak-to-peak value the shift of the zero position was probably nearer 100 μv for the 40-min. period.

Among the many papers on direct-coupled amplifiers[6–18] that of Buchthal and Nielsen[6] appears to have been overlooked in the literature. The residual instability of the amplifier described by these authors is given as 100-μv shift of the base line over a three-hour period. This paper was published in 1936 and there does not appear to have been any very significant improvements in the performance of direct-coupled amplifiers in subsequent years. In 1948, the authors[19] published figures relating to the performance of a direct-coupled amplifier similar to that described here, the residual instability being of the order of 60 μv peak-to-peak over a period of 30 min.

Thus, it would appear that in the absence of further knowledge concerning the nature of the flicker effect, the limit to the useful sensitivity of a direct-coupled amplifier is set by a probable residual instability of the order of 100 μv peak-to-peak over a period of 30 min. Although short-term (i.e., taking place over several seconds) fluctuations are much less than this, depending on the input resistance and band width, it is evident that the ultimate sensitivity of direct-coupled amplifiers is necessarily inferior to that of condenser-coupled amplifiers in which low frequency noise elements are more or less eliminated. Accordingly, it was decided to provide alternative condenser coupling in the amplifier to be described. A source of long-term instability lies in the aging of the cathode coatings of valves. This is discussed briefly by Gray.† It appears that a correlation exists between the behavior of the two parts of twin valves but the data presented do not allow an estimate to be made of the heater and anode potential stabilities over the term of the observations. If the supplies used when making the observations were subject to any variation, the results might only indicate a similar performance of the two parts of the valve with respect to the potentials rather than similar aging effects.

THE COMPLETE UNIT

The unit, complete except for the duplication of the channels of amplification, is shown in block schematic form in Fig 2(b). Only two channels have so far been constructed, although the main power supplies are sufficient for four channels. Double triode, 6J6, valves heated from a low tension power unit have been used in the first two stages of amplification of each channel. It is, however, likely that other types could be used without loss of performance, and this is discussed later. Each amplifier has a separate electronically stabilized 150-ma supply for series-heating the remaining valves associated with the early stages. This is necessary if an amplifier is to be used in the absence of any or all of the other channels. A further stage of high tension voltage stabilization is also included in each amplifier; this serves to decouple the supplies to the various channels and to stabilize the positive supply with respect to the negative supply. In a differential amplifier it is more important for the positive and negative supplies to be stable with respect to one another than with respect to earth (Johnston[20]). The description of the amplifier which follows refers to a single channel.

THE INPUT CIRCUIT

In order to obtain a high input impedance a cathode follower stage was used. The circuit shown in Fig. 3 has been described in detail elsewhere.[21] Acorn pentodes type 954 are used and the operating potentials and characteristics are shown in Table I, the values given being for one valve.

The valves may be used without grid leaks as the brain tissue provides an earth connection for the grids. The input resistance to the cathode follower is then determined by the insulation resistance between the grid and cathode. The input capacity given in Table I is the calculated value. In practice, stray capacities associated with the pick-up electrode system are of a higher order than the input capacity to the valve. The output impedance of the cathode follower is about 5 kohm, which will not limit the frequency response of the following amplifier in the band width 0–10 kc/sec. The potentiometer $R4$ in the cathode circuit enables the d.c. levels of the two cathodes to be balanced. The valves and grid circuits are included in a probe unit connected by screen cable to a chassis which houses the remainder of the circuit associated with the cathode follower. This chassis also houses the corresponding portions of the other four channels, an arrangement which effects a considerable economy in wiring. Screened leads then provide appropriate connection to the various amplifier channels. The 954's are heated from the 150-ma d.c. supply, resistors in parallel with each valve being provided to ensure the correct heater potential. The high tension supplies to the cathode followers are obtained from batteries. Apart from the floating batteries which provide the screen potentials the high tension supplies could have been obtained from the main power supply by means of cathode followers but in view of the low anode currents it is much simpler to use batteries.

THE MAIN AMPLIFIER

The main amplifier conveniently divides into two separate units; the first of these is required to be highly stable and provide a voltage gain of some 50 to 60 db. The maximum gain of the first unit is 100 db but this is reduced by negative feedback so that the second unit provides the final amplification. With the exceptions of a balance potentiometer and a gain control the adjustments required during operation are included in the second unit. Cathode followers are used as output stages in both units. All the valves in the second chassis are a.c. heated; those in the first are d.c. heated, the 6*J*6's from a floating accumulator, and the others from a stabilized 150-ma supply.

1. The First Unit

The circuit shown in Figs. 2(a) and 3 was derived from one published by Johnston[20] and subsequently modified by the authors.[22] It uses feedback of the mean anode potential of the second stage (which sets the cathode potential of the third stage) onto the anodes of the first stage. This system has the advantage that the mean level of the second stage output is self-stabilized. It was not found practicable to employ this method of feedback to the later stages on account of the curvature of pentode characteristics. When the Ia-Vg relation is non-linear the mean of the two anode potentials of a stage, after an unbalance signal has been applied to the grids, is not equal to the values holding originally. That is, a signal generates a change in the mean d.c. level and this proves to be in the positive direction. If the mean level is fed back to an earlier stage, a component which varies with the signal is also fed back. If now there is any curvature in the characteristic of the preceding stage, the impedances of the individual valves will be unequal when a signal is applied even if they were equal for the zero signal condition. The results would be that the fed-back component from the succeeding stage will be injected more into the side with the lower anode impedance than into the other side and as a lower impedance obtains in the side to which a positive going signal has been applied it will be to this side that the greater proportion of the feed-back potential becomes injected. This will lead to instability and the system cannot be held in a balanced state, it will deviate to and remain at whichever side of balance it is sent by the applied signal.

The output from the first unit was tapped off the load resistors of the cathode followers. This involves about 7-db loss of gain, but reduces the mean d.c. level of the output to about 70 v. The output impedance is about 9000Ω (18,000Ω push-pull).

a. Gain Control and Frequency Response

The maximum voltage gain of the first unit is 100 db and this is reduced by negative feedback from the output to about 48 db. This provides the maximum stability for low frequencies (including d.c.), but of course does not improve the ratio signal-to-"noise," where noise includes all the variations arising between the grid and cathode of the first valve. A stepped gain control is provided by a series of shunting resistors, *R*37, *R*38, and *R*39. It has been found impracticable to increase the feedback more than that required to reduce the gain by the above amount, because, owing to unavoidable phase shifts at higher frequencies self-oscillation occurs. To prevent this, Miller feed-back capacitors *C*1, *C*2, have been applied to the third stage. The frequency response of the whole unit is thereby made 6 db down at 15 kc/sec. However, when less feedback is applied the capacity may be omitted and under these conditions the frequency response is flat to over 15 kc/sec.

If the maximum benefit is to be achieved, feedback in direct-coupled amplifiers should be degenerative for mean d.c. level changes as well as for the differential voltage changes. This is discussed in greater detail elsewhere.[1] When the feed-back factor is large, precautions have to be taken to avoid disturbing the d.c. working voltages of the stage into which the feedback is introduced. This occurs if the feedback is taken from a point at a potential considerably higher than that of the earlier stage. To avoid this the feedback is taken from a tapping on the cathode load resistor of valves *V*5 at which the potential is equal to that of the grids of the first amplifying valve. This arrangement has the added advantage that relatively low valued wire-wound resistors can be used in the feed-back loops. To avoid producing unbalance it is desirable that the resistors should be closely matched in each feed-back circuit.

The feedback is introduced into the grid circuits of the valves *V*2. It will be seen that the output impedance of the valves *V*1 forms part of the feed-back potential divider network. The swamping resistors *R*6 and *R*7 have been introduced to avoid alterations in the feedback factor which would otherwise occur if the input valves are changed. If the output impedances (Zo) of the cathode followers were left to determine the feed-

back factor of the system, the considerable variability (by a factor of as much as 2) of conductance, and therefore of Zo, from valve to valve would be inconvenient. By introducing 50 kohm in series with Zo (which lies between 3.5 and 7 kohm) this effect is swamped. The fact that the resistance of the electrodes varies very considerably makes the introduction of feedback into the input circuit impracticable.

b. Second Voltage-Stabilizing Circuit

Each amplifier channel has a separate voltage-stabilizing circuit (Figs. 3 and 5) to provide the positive and negative high tension supplies to the first two stages. The stabilizer is located on the same chassis as the first amplifier. The shunt valves in the stabilizer are heated from the 150-ma supply and the effects of any fluctuations in this supply are reduced by a simple form of cathode compensation[11] in the shunt valves. This circuit also stabilizes the positive and negative high tension supplies with respect to one another. These features make it possible to relax the requirements for the performance of the main stabilizing unit so that a.c. heating can be used for the shunt valves in the latter. In other respects the circuit of this additional stabilizer is similar to that used in the main power supply.

c. Alternative First Amplifier Valves

The electrode arrangement of the 6*J*6, from the point of view of balancing out the effect of changes in heater potential, is preferable to that of the 12*SC*7. The latter and similar types have, however, the distinct advantage that they can be heated from a supply of only 150 ma (instead of 450 ma) which is easily stabilized by electronic means. As the 12*SC*7 has only recently become available to us, experiments are now being carried out to determine the relative performance of the amplifier using 6*J*6's heated from accumulators and that of an exactly similar amplifier employing 12*SC*7's heated from 150-ma stabilized supply.

The 12*SC*7 is probably no more favorable from the point of view of obviating changes in heater potential than a double triode, such as the 12*SL*7, in which the cathodes are separate. However, the fact that 150-ma heater current can be stabilized more effectively than the supply to the 6*J*6's may offset this disadvantage. A 12*SC*7 specially selected for balance is available under Type No. RCA 1634. Since the development of this apparatus a new valve, the 6*SU*7, which is a 6*SL*7 specially selected for balance and low grid current has become available and this valve is recommended in the Radiation Laboratory Series Handbooks[23] for balanced amplifier applications. A disadvantage is that the heater current is 0.3 amp. There does not appear to be an exactly corresponding 12-v 0.15-amp. valve, the 1634 being the nearest, the latter type is not discussed in the reference.

It is evident that a careful comparison of different valves is desirable, although it is likely that by careful selection comparable performances can be obtained from any twin valve. The criticism of the 6*J*6 made by Valley and Wallman[23] may have been the result of a lower proportion of these valves having such good characteristics as the majority of 6*SU*7's. When selecting valves attention should be paid to the grid current. The 6*J*6, 6 or 12*SL*7, and the 12*SC*7 often have a rather high grid current, up to 1 μa.

The compensating circuit described by Miller[11] was not used in the first stages of the present amplifier because it was considered more desirable to preserve the common cathode load so as to achieve a high discrimination against in-phase signals. Compensation for splitting the cathode load would have meant a considerable increase in the complexity of the circuit.

2. The Second Unit

The second amplifier unit (Fig. 4) includes a high frequency filter, the alternative condenser coupling circuits and output stages as well as two stages of voltage amplification. Jack points and an anode shunting switch are provided for *V*21. The input grids are at about +75 v with respect to earth and the final anodes are at approximately +310 v. The main gain control for the whole channel is obtained by the switch *S*11 in steps of 6 db and a fine gain control is provided by a variable resistor *R*81. The maximum gain of the second unit is about 80 db and a linear output of 200 v peak-to-peak is obtainable. The frequency response is flat to over 10 kc/sec.

a. High Frequency Filter

Several values of high frequency response can be selected by switching capacitors differentially across the input of the second amplifier. The swamping resistors

*R*49 and *R*50 isolate these capacitors from the feed-back loops of the first amplifier.

b. *Alternative Condenser Coupling*

As pointed out, considerable improvement in the signal-to-noise ratio can be achieved by limiting the low frequency response by means of capacitative coupling. By placing the coupling condensers between the two amplifier units the effective values of the coupling condensers are not affected by the adjustment of the feedback in either amplifier.

Several values of time constant can be selected by the switch *S*10. The pairs of capacitors are connected differentially by resistors sufficiently high in value not to alter the time constant appreciably. The pairs of capacitors are, therefore, kept at equal potentials. This avoids a switching surge when the time constant control is operated. In order to reduce stray capacities the capacitor cans have been insulated from earth and from one another. This arrangement has been found satisfactory if the capacitor assembly is well screened. Owing to the cathode feedback in the fourth stage of amplification, the input impedance is much greater than that of the 1 MΩ grid leaks. It is desirable to limit the input impedance to a definite value and this is done by placing a 2-MΩ resistor differentially across the input to the stage. The over-all time constant is then numerically equal to the value of the coupling condensers expressed in microfarads.

c. *The Output Stages*

Two cathode follower output stages are used; one at 150 v provides sufficient current to drive a pen recorder and the other at earth potential gives the full voltage swing provided by the last amplifying stage. The moving coil pen recorder has a 5000-ohm center-tapped coil requiring 120 v across it for the maximum usable deflection from the central zero position. In order to avoid a large standing current in the coils a bridge circuit is used. The 6*V*6's used in the cathode follower circuit have a standing current of about 25 ma which is provided from a separate smoothed supply. By taking the pen recorder output at 150 v it is possible to avoid using a negative high tension supply.

If it is desired to feed a single cathode-ray tube, the plates may be driven directly from the output of the amplifier, which is capable of a peak-to-peak voltage swing of about 200 v. The potentiometer in the anode circuit of the first 6*J*6 stage provides the *Y* shift. When the amplifier is condenser-coupled it will be necessary to use the potentiometer in the screen circuit of the 6*SH*7 stage of the second unit. In the latter case the disadvantage arises that at the lower gain settings the potentiometer becomes relatively ineffective owing to the large negative feedback. This is, however, offset by the fact that the amplifier described here was designed to feed simultaneously into several display units each with its own output amplifier and shift arrangements. For this reason it was desirable that the output of the amplifier should have a mean level at about earth potential. These additional amplifiers and shift controls are included in the display unit and will not be described here.

Gas discharge tubes (*VR* 150) running at 120 μa are used to drop the voltage down to the appropriate levels for the two output cathode followers. Although the actual voltage drop per tube is some 12 v less than with the rated current (5–30 ma), the arrangement has been found to be quite satisfactory at the relatively high level involved.

THE POWER SUPPLIES

1. The High Tension Supplies

Table II shows the approximate current requirements. The main positive and negative high tension supply is shown in block schematic form in Fig. 5 and the circuit details are given in Fig. 6. It is built in two units, the first consisting of the three separate transformer, rectifier, filter circuits and the second of the two series-valve stabilizing circuits together with the switching arrangements for the various channels. The 600-v smoothed supply is subsequently stabilized at +450 v with respect to earth. The +150-v smoothed supply is used for the cathode follower providing output about earth potentials in each amplifier channel, and the negative potential is stabilized with respect to earth to give −250 v and −105 v.

Table III shows the effect of a 1-v sudden change in the output voltages of the respective supplies expressed as an equivalent signal at the input of the amplifier. The effect of a very much smaller change is probably somewhat less than that calculated from the figures as there is less likelihood of non-linearity. It is difficult to ensure that the high tension supplies do not occasion irregularities in the amplifier greater than, say, 50 μv, expressed as an equivalent signal at the input. If it is desired to make the signal equivalent of a change in the high tension less than 50 μv, the effect of slow changes in the output of the stabilized supplies due to changes in the heater current of the shunt amplifying valves become of increasing importance. The effect of these slow changes are of course eliminated by making the amplifier condenser-coupled with a suitable time constant. Thus, the demands on the stability of the high tension supplies never become a limiting feature in the design of the amplifier. The ripple level of the +450-v and −250-v supplies is 2 mv peak-to-peak, and less than 1 mv peak-to-peak, respectively.

FIG. 6.

The Philips-Mullard 85*A*1 stabilizing valve is free from the sudden discontinuities in the current voltage characteristics found in most glow discharge tubes[24] and has a relatively low temperature coefficient.[25]

The result of changes in the output of the filter circuit of the power supply is practically reduced to zero by feeding a portion of the unstabilized supply on to the grid of the shunt amplifying valve. In the case of the positive supply this was done by the parallel bridge arrangement across the series valve,[26] while in the case of the negative supply a small fraction of the unstabilized voltage was taken from the negative side of a resistance network across the smoothed supply.

Perhaps the most difficult feature in the design of the main high tension supplies is the provision of a stable source of heater current to the shunt amplifying valves. When only one amplifying channel is to be constructed the best solution is to use shunt valves of 12.6-v 150-ma heater rating, the heater current being obtained from the 150-ma stabilized supply. Unfortunately, it is inconvenient to adopt this arrangement when several channels are to be used. Various other methods have been tried though none have been found to be very satisfactory. Perhaps the best arrangement is the use of a voltage regulated transformer of the three-limbed type, regulation being obtained by iron saturation. They are designed for constant load and provide some compensation for changes in frequency but have the disadvantage of a considerable stray field. The effects of fluctuations in the heater supply are reduced by the use of the cathode compensation circuit in the shunt amplifying valves.

2. Switching Arrangements

Four switches, one for each amplifier, are provided on the second chassis. When an amplifier is not being used dummy resistive loads keep the current drain on the stabilized high tension supplies constant. The

Note: The transformer should be rated 450—0—450 v.

switching arrangement also enables the heater current to the amplifier to be established before the high tension is applied, and for the reverse to be the case when the use of the channel is discontinued.

3. Stabilized Heater Supply

In an amplifier with 6*J*6 balanced stages without cathode compensation it has been found that a 10-mv change in heater potential is equivalent to a signal of about 0.7 mv at the input. The provision of a sufficiently stable supply of heater current is, therefore, rather difficult and becomes the most critical feature in the design of the amplifier as far as long-term stability is concerned. The use of 6*J*6 valves in the first two amplifier stages makes a separate source of heater current necessary. This supply becomes unnecessary if 150-ma 12.6-v valves are used.

a. Heater Supply Unit

This includes the 150-ma stabilized supply and the low tension transformers for heating the valves of the second amplifier unit. The stabilizing circuit shown in Fig. 7 is very similar to that used in the high tension supply unit except that 12*SC*7 valves are used as the shunt amplifying valves so that they can be heated from their own stabilized supply. The 305-v floating output is held with respect to earth by a *VR* 105 gas discharge tube to give +200 v and −105 v. The valve heaters are placed in series across the output in such a way that the respective heater cathode potential differences are minimal. In the amplifier described in this paper 6*J*6 valves were used in the first two stages of amplification and the valves *V*34 and *V*33 shown in the heater chain in Fig. 7 were replaced by equivalent resistors. The heater chain shown in Fig. 7 represents the arrangement when the 12*SC*7 valve is used in the first two stages.

b. Heater Supply for the 6J6 Valves

The current for heating the 6*J*6 valves used in the first two stages of amplification was derived from lead accumulators of large storage capacity. This supply was earthed by means of the center tap of a resistance network across the terminals. To achieve long-term stability it was found necessary to place the accumulators across the output of a charging unit adjusted so that the net charge current was zero. Even the charging current needs stabilization and this is best done by means of a series-transformer electronic stabilizer.[20]

SETTING-UP PROCEDURE

The link *S*6 (Fig. 3) is connected so that the grid of valve *V*9 is set from the resistance network *R*29 and *R*30. The mean anode potential of the various stages, beginning with *V*2 and progressing toward the output, may now be adjusted to the appropriate level. In the first three amplifying stages this is accomplished by varying the grid bias on the cathode load valves by means of the potentiometers *R*9, *R*14, and *R*21 and in the case of the later stages by means of the potentiometers *R*57 and *R*103 (see Fig. 4). The latter enables the output provided by *V*27 to be adjusted to approximately earth potential. The actual mean anode potential of the amplifying stages in order are 30, 70, 170, 170, 310 v. Having adjusted the mean anode levels, the link *S*6 may now be returned to the common cathode of *V*4 so as to apply mean d.c. level feedback to the grids of *V*2. The mean anode levels may be checked from time to time by means of jacks but should not need adjustment except at relatively long intervals. The adjustment for balance between the two sides of the amplifier should, however, be done each time the amplifier is used. This is quickly done by shunting the anodes of the various stages in turn by means of the switches provided, beginning at the output and working toward the input of the amplifier. Each stage may then be balanced by the potentiometer in the anode or screen circuits so that the trace is brought to the middle of the cathode-ray tube screen each time. When the amplifier has a condenser coupling between the two units the feedback used in the first unit prevents non-linearity in the output even when the differential unbalance is the maximum allowed by the potentiometer *R*4, *R*11, *R*17, and *R*26. In these circumstances the amplifier can be used with condenser coupling without any danger of non-linearity arising from slow drift in the first amplifier unit.

PERFORMANCE

The performance as regards long-term shift of the zero position to be expected from the amplifier is of the order of 100 μv peak-to-peak over a period of 30 min. It is difficult to stabilize the heater current sufficiently to make valve-matching relatively uncritical. In these circumstances the performance will vary from valve to valve within a given type.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 4 APRIL, 1950

Volumetric Plastic Micro Respirometer[*]

P. F. SCHOLANDER
Marine Biological Laboratory, Woods Hole, Massachusetts

(Received September 22, 1949)

A simple plastic micro respirometer is described based on a direct reading volumetric principle. The respiration chamber with CO_2 absorber is balanced against a compensating chamber through a manometer drilled in Lucite. As oxygen is used it is replaced from a syringe so as to maintain balance with the compensating chamber. The oxygen consumed is read directly on the syringe. Two sizes have been made covering a range of oxygen consumption from 10 mm^3 to 10 cc per hour.

A SIMPLE and direct volumetric principle of micro respirometry was introduced by Winterstein, 1913,[1,2] and was later adopted by Tyler and Berg[3] and Dixon.[4] Scholander[5,6] introduced oxygen replacement in the system and the principle in its final form can hence be stated as follows: The respiration chamber with CO_2 absorber is balanced against a compensating chamber through a manometer. As oxygen is used it is replaced from a measuring device so as to maintain balance with the compensating chamber. The oxygen consumed is read directly on the measuring device.

The system offers considerable advantages. The oxygen consumption is read directly in volume units and is independent of the gas content of the apparatus. The only calibrated part is the measuring device for the introduction of oxygen. Each respirometer is compensated and therefore relatively insensitive to external temperature and pressure changes. The oxygen tension does not drop in the respiration chamber which can therefore be kept small with a corresponding gain in sensitivity.

The respirometer to be described consists of a plastic manometer block connected to an oxygen measuring device (syringe) and to a respiration chamber and a compensating chamber. The shape, size and position of these components are not critical and may be varied to suit individual requirements (see Scholander[7]). Two sizes have been made covering a range of oxygen consumption from 10 cubic millimeters to 10 cc per hour. The apparatus are easy to make, they are almost unbreakable and have been used on a large variety of animals and plants in field and laboratory studies.

A. STANDARD SYRINGE APPARATUS

One or several manometers are drilled into a rectangular piece of $\frac{3}{8}$ inch Lucite, using a jig and a long No. 24 drill (Fig. 1A). The openings of the bores are tapered to fit a standard syringe nozzle. To accomplish this a brass taper like the syringe nozzle, but slightly longer, is put on a file handle, heated and pressed into the manometer bore. The taper is cooled under the faucet and removed. Tapered Lucite plugs (D) or plugs drilled out from neoprene stoppers fit the other end of the manometer bore. For student use it is desirable to furnish the manometers with a lower opening (Fig. 1, manometer 2) through which a rod can be introduced to dislodge broken syringe tips stuck in the manometer opening. Screw top or other standard vials make excellent respirometer chambers (Fig. 1B). They are connected to the manometer block by means of neoprene stoppers or pieces of Tygon tubing which fit on Lucite buttons cemented to the block (Fig. 1B). The absorption bucket is made from the bottom portion of a small vial, and is forced into a few loops of stainless steel wire spiral; the other end of the spiral is bent into a V and fits removably into the bore of the Lucite button (Fig. 1B). The manometer block is suspended over the edge of the water-bath window with two brass hooks. 1 cc to 10 cc syringes furnished with arresting clips are used for the oxygen delivery. A wooden or metal thermoregulated tank with Lucite windows makes a satisfactory water-bath.

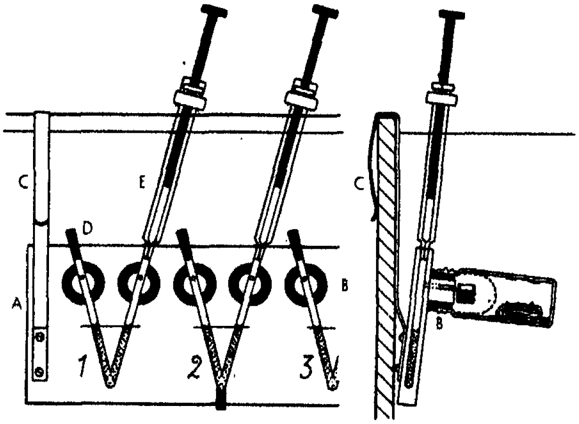

FIG. 1. A—Part of manometer block with two syringe respirometers. B—Neoprene stopper on Lucite button, attaching the respiration chamber. C—Suspension hook. D—Taper plug. E—Syringe for oxygen delivery.

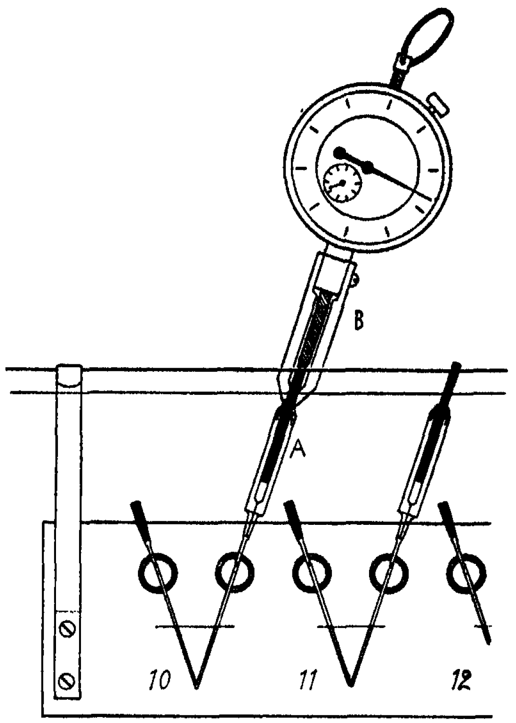

FIG. 2. Part of manometer block showing two complete micro syringe respirometers. A—Plastic micro syringe. B—Dial indicator with plastic sleeve, in measuring position.

Reagents

The manometer fluid consists of methyl-orange colored water containing enough liquid potassium soap to make the solution run easily in the manometer bore. For carbon dioxide absorption 10 percent or stronger KOH solution is used, or, in case of especially high respiratory rates, Ascarite (A. H. Thomas Company, Philadelphia). Syringe tips, taper plugs and plungers of micro syringes are greased lightly with XX heavy Nevastane grease (Keystone Company, Philadelphia).

Operation

The manometers are filled to the mark with manometer fluid. The compensating chambers, wet on the inside, are firmly pressed on to the stoppers. The respiring material is placed in the moist respiration chambers and is, if necessary, kept away from the absorption bucket by means of a screen diaphragm. This is a square of plastic fly-screening cut diagonal to the weave and pushed into the vial (Fig. 1B). KOH solution or Ascarite is placed in the absorption buckets and the respiration chambers are firmly connected to the manometers and placed without delay in the water bath, keeping the chambers completely submerged but the manometer openings dry. In this position the suspension hooks of the manometer block must be clamped securely to the water-bath with a pair of rubber tubing screw clamps. After a short time for thermo equilibration the manometer openings on the compensating side are closed, and the syringes are, one at a time, filled with oxygen from a rubber bladder and immediately inserted into the other end of the manometers. The respirometer bank is now lowered until all the gas-volumes are under water. A drop of glycerine is placed around the syring bearing for tightness. At suitable time intervals the syringes are adjusted and read when the manometer fluid is back to the mark. The difference between two readings gives the volume of oxygen consumed during that time, uncorrected for S.T.P.

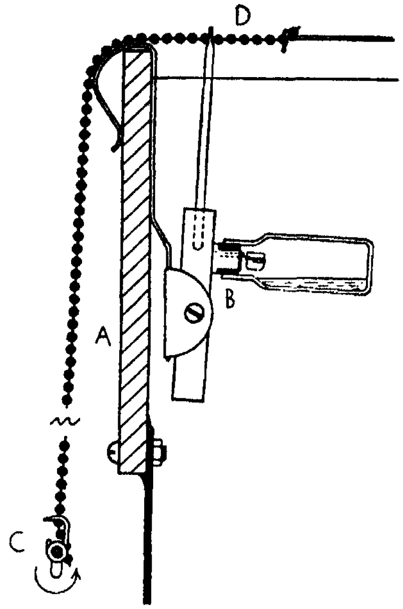

FIG. 3. Shaking device. A—Suspension hook hinged on to manometer block. B—Respiration vial attached by means of Tygon tubing to connecting button on manometer block. D—Ball-chain engaging rocking pin and rubber band. C—Hook engaging ball chain and crank.

Accuracy

With a known calibration of the syringes the sensitivity and accuracy of the apparatus depends mainly upon the capacity of the chambers; small respiration chambers and large compensating chambers increase the sensitivity. For any combination the accuracy (stability) of the apparatus is found by blank runs, i.e., runs without respiratory material. Through a temperature range of 0 to 40 degrees centigrade, using 20 to 25 cc chambers and a 1 cc tuberculin syringe, the method is stable within 10 mm^3, an hour.

B. MICRO SYRINGE APPARATUS

This is essentially a small edition of A, using special plastic micro syringes. These are made from $\frac{1}{4}$ inch Lucite rod (Fig. 2A). The open end of the barrel is machined down to a neck, which tapers to a sharp edge at the opening. A $\frac{1}{8}$-inch Lucite rod selected for size, and with ends machined straight, serves as a plunger.

Air-tightness is obtained by means of a short sleeve of thin-walled Tygon tubing which maintains a slight pressure against the plunger. The ends are cut off straight and paralleled on a brass mandrill which is held in the lathe. The plunger is operated manually by a screw motion and the position measured by means of a dial indicator, introduced by Gilmont.[8] The indicator is provided with a Lucite sleeve (Fig. 2B) which during measurements lightly rests against the straight edge of the plastic sleeve of the syringe. The spring tension is removed from the feeler rod and is substituted by a wire ring for finger control. We have been using Ames model 282 M dial indicator with one inch travel divided into 1000 parts. The plunger position can be manipulated and read within 0.003 inch, where 0.005 inch is equal to 1 cubic millimeter, which is also the stability of the instrument per hour as determined by blank runs using 3–4 cc vials for compensating and respiration chambers.

Rocking Device

A simple hinge device which does not change the described procedure of operation is given in Fig. 3. The lower end of a ball-chain engages adjustably with a crank device. The chain runs in a groove on the suspension hook and is stretched across the water tank by means of a rubber band. The respirometer bank is engaged to the chain by means of the split head of a rod (D), which is loosely stuck into the manometer block. The crank is run by a geared-down motor, e.g., a small electric hand drill, controlled by a Variac.

ACKNOWLEDGMENTS

I wish to express my gratitude to Dr. Laurence Irving, Director of the Arctic Research Laboratory, Point Barrow, Alaska, for encouragement and helpful criticism; and to Mr. Walter Flagg and Dr. R. Wennesland at the same laboratory for assistance in testing of the apparatus, and to Mr. Otto Hebel, Swarthmore College, for suggesting the use of the dial indicator.

Book Reviews

Matrix Analysis of Electric Networks

By P. Le Corbeiller. Pp. 112+xi, Figs. 49. Harvard University Press, Cambridge; John Wiley and Sons, Inc., New York, 1950. Price $3.00.

This book is the first of a series of Harvard Monographs on Applied Science. We are promised that the emphasis in this series will be on the applied *physical* sciences especially "on topics that involve intellectual borrowing among academic disciplines." If the other volumes of this series conform to the standard set in this first volume, the literature in applied science will be significantly enriched.

The aim of this book is to present a simplified version of Gabriel Kron's stationary network analysis. We are told that an understanding of the present work will enable the reader to avail himself without difficulty of the greater amount of information contained in Kron's *Tensor Analysis of Electric Networks* (John Wiley and Sons, Inc., New York, 1939). Due to the rather abstruse nature of the mathematical concepts Kron employs, his work has not as yet received the recognition it deserves among communication engineers and applied physicists. This abstruseness is necessary in Kron's treatment of rotating machinery, but with reference to stationary networks, as Le Corbeiller says, "it should not be necessary to use such a tremendous sledgehammer to crack this rather small nut." The nutcracker Le Corbeiller employs is simple matrix algebra combined with two elementary formulas borrowed from topology, giving the number of independent meshes and node-pairs of a network in terms of the number of nodes, branches, and subnetworks.

Although this monograph may serve as an introduction to Kron's more extensive work, it is actually complete in itself and its mastery will provide the reader with very general and powerful tools for the solution of the most complex networks. Before launching into a description of its contents it should be said at once that this little book is, with a few minor reservations noted below, a masterpiece of pedagogical exposition as well as an intellectual treat. One scarcely knows which to admire the more: the facile clarity of the presentation or the continual delights and surprises found on nearly every page. The author's method is to teach by example and to this end the book is amply supplied with well-chosen illustrations. A number of exercises selected to amplify and illuminate the text are scattered throughout the book.

It is assumed that the reader has a knowledge of elementary algebra including determinants and of elementary alternating current theory. The first chapter entitled "Preliminary Concepts" gives all the extra mathematical background required for an understanding of the later chapters. It consists for the most part of a very clear development of matrix algebra with illustrative examples drawn from simple circuits and from geometry. The chapter concludes with an intuitive proof of the topological results mentioned above.

In Chapter 2 "The Mesh Method of Kron" is described as an extension of the familiar Maxwell mesh method. Kron's extension seems almost trivial at first sight. The final result is a matrix equation giving the branch currents in terms of the series branch e.m.f.s. This equation involves the impedance matrix of the network and also the transformation matrix which operating on the mesh currents transforms them into branch currents. The transformation matrix depends only on the topology of the network and on the choice of the M independent meshes. The full power of the method is realized when there is coupling between two or more of the branches. The Kron method involves no additional complexity even if every branch is coupled with every other, or if the coupling is symmetric (magnetic) or asymmetric (triode). The reader is introduced to the Kron method via an example on the Wheatstone bridge network. Unfortunately, the directions and polarities assumed in the network diagram of this example do not check with the subsequent equations. This is especially a pity since a novice may be tempted by this stumbling block to give up the whole enterprise at the start. Actually, the equations are self-consistent and what needs to be done is to reverse all e.m.f.s. and branch currents in Fig. 14 save those in branch f.

Chapter 3 "The Node-Pair Method" gives Kron's extension of the conventional node-pair method in which the data are given in terms of constant current sources instead of e.m.f.s. The result is again a matrix equation relating the node voltages to the current sources in terms of a transformation matrix and the network admittance matrix.

A truly amazing development is presented in Chapter 4, "The Mixed Method." It is shown here how Kron is able to analyze a network not only with all possible couplings but in which both constant current and constant voltage sources may be connected internally and externally in every possible way. The trick here is to use the external sources to provide sufficient additional meshes to make the transformation matrix non-singular. If there are too few such sources, a number of voltmeters are judiciously added to make up the difference; if too many, the effects of the extra ones can be considered separately. Corresponding to the dual nature of current and voltage there is a second possible treatment making use of node-pairs instead of meshes. This chapter is considerably more difficult to read than the others, doubtless owing to the relative complexity of the networks treated. Still, one cannot help but feel that the discussion in parts of this chapter could be profitably expanded.

There are a number of additional misprints, most of which are obvious and should cause no trouble. In Fig. 46, the two current sources should be interchanged and the direction of current in branch C should be reversed to make this diagram conform to Eqs. 53–1. The physical significance ascribed to the current j^i on p. 85 seems to be incorrect since if all the sources mentioned as contributing to it were absent, it is evident that it would not vanish in general.

Professor Le Corbeiller has done much more than just to enliven a traditionally dull subject. All physicists and electrical engineers owe him a debt of gratitude for this very ingenious, stimulating and useful book.

Vacuum Equipment and Techniques

Edited by A. Guthrie and R. K. Wakerling, Radiation Laboratory, University of California. Pp. 264+xvii, Figs. 102, 23×15 cm. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.50.

This book is one of the National Nuclear Energy Series, being Vol. I of Division I (Electromagnetic Separation Project). It is an outgrowth of the developments carried out at the Radiation Laboratory, University of California, of high vacuum equipment and techniques for use in electromagnetic separation plants. Routine production of high vacuum in large systems on the scale necessary for the electromagnetic separation process never before had been done and, as a consequence, the problems involved were of a magnitude which required considerable amount of pioneering work on both equipment and testing. The results of and the methods used in this work are reported in this volume. The body of the book is divided into five chapters. The chapters have been written by individuals originally connected with the actual work, except Chapter 5 on leak-detection techniques and procedures which was prepared by the authors from existing reports.

Chapter 1, "Fundamental Considerations in Vacuum Practice," by Robert Loevinger (58 pages), presents those parts of the kinetic theory of gases essential to modern industrial and laboratory vacuum practice. The material for the chapter is well selected and prepared. Impedance and conductance of vacuum plumbing, the flow of gases and vapors in the viscous, molecular and transition regions, system speed, pumping speed of vacuum pumps, methods for the measurement of pumping speed, evacuation rate, and pumping speed of cold traps are discussed quite adequately. For example, in the section on molecular flow through pipes, Knudsen's formula is used in the fundamental equation from which the conductance of a long circular pipe and a circular annulus is obtained. The combination of these results in the conductance of a short pipe with aperture. The rectangular duct, the equilaterally triangular duct, the thin slit-like tube, ducts of other shapes, bends and elbows are described as elements of a vacuum system and formulas expressing their conductances are developed. Other sections are treated similarly. Sample calculations are given. An appendix summarizes in tabular form the formulas most frequently used in vacuum design work. These formulas are given in two types of units—the metric laboratory units and the mixed metric and English laboratory units. This table will be found most useful to those engaged in the design of high vacuum systems.

Chapter 2, "Elements of the Vacuum System," by William E. Bush (46 pages), gives material on rotary, oil-sealed mechanical pumps, oil booster pumps, and oil diffusion pumps. Precautions to be observed in the successful operation of vacuum pumps are discussed at some length. The procedure to be followed in the selection of a pumping system where both mechanical and diffusion pumps are involved is outlined. Contamination of mechanical and diffusion pump oils, and oil migration problems are considered. Methods of testing the performance of diffusion pumps are given. Refrigerated traps, a subject which is overlooked in many books on this subject, is given brief consideration at the end of this chapter. In the appendix there are two tables listing mechanical pump oils and diffusion pump oils, and some of their properties. These tables are not complete, but they list several oils which are used as pumping fluids.

Chapter 3, "Vacuum Gauges," by Kenneth M. Simpson (41 pages), includes the usual low pressure gauges that have found extensive use in the laboratory and in production. The McLeod gauge (mercury and oil types), Pirani gauge, thermocouple gauge, Knudsen gauge, and ionization gauge (hot cathode, Phillips, and Alphatron) are the principal ones described. Several control circuits and special designs of these gauges developed at the Radiation Laboratory are reviewed at some length. The question, "What is measured by vacuum gauges?" is asked and an answer given.

Chapter 4, "Vacuum Materials and Equipment," by William E. Bush (44 pages), summarizes in some detail the methods of gasketing and the techniques employed in the flanges used for making high vacuum connections between pumps and vacuum plumbing and other connections within the system. Gasket materials and their properties are set forth in tables and discussed in the text. The methods used by the Radiation Laboratory in adapting standard gate and globe valves for use as vacuum valves is described in a very complete manner, including good illustrations of several types. There are several tables in the appendix listing vacuum greases, cements, solders, and brazing alloys useful in building up and maintaining a vacuum system.

Chapter 5, "Leak Detection Instruments and Techniques," by R. Loevinger, and A. Guthrie (53 pages), is a summarization of the classical techniques and the more recently developed ones. The vacuum analyzer, an instrument which provides information regarding the nature of the gases and vapors inside a vacuum system, and the helium leak detector, the dean of leak detection instruments, are given full discussions. Several pages are devoted to the construction of a helium-type leak detector since it is stated that the cost of these units makes them prohibitive for many laboratories and the simple cold cathode leak detector developed at the Radiation Laboratory can be built by the laboratory personnel. Theories of leak detection and general leak-hunt procedures are included.

The editors have achieved a unified volume. Each chapter may be read independently of the others, which is perhaps an advantage in using the volume as a reference work. Throughout the work abundant reference has been made to the published literature. *Vacuum Equipment and Techniques* is a book to be recommended to those working with vacuum systems to give a better understanding of vacuum processes.

An Introduction to the Luminescence of Solids

By Humboldt W. Leverenz. Pp. 569, Figs. 140. John Wiley and Sons, Inc., New York, 1950. Price $12.00.

This book is written by one of the internationally outstanding experimental investigators in the field of crystal luminescence. It represents a summary of nearly twenty years of continuous and precise work and as a result has a prominent and unquestioned position in the literature of the subject. It should be on the shelves of anyone who has a serious interest in the subject. The hard core of the book centers about the vast work on inorganic phosphors carried out at the RCA laboratories by Leverenz and his associates; however, all material closely related to it is included with careful evaluation. It is precisely within the period of time that Leverenz has been working in the field that luminescent materials have achieved a prominence which makes them an indispensable part of the broader field of electronics. This coincidence is not an accident, for he has been responsible for many of the outstanding advances in development, such as the discovery of the zinc beryllium silicate system, which played a key role in the luminescent lamp industry for a decade.

The first quarter of the book deals with the descriptive and theoretical background of the subject: A survey of atomic and crystalline structure, the processes by which crystals are formed in practice and the imperfections they may contian, the general techniques employed to synthesize phosphors and the energy level diagrams applicable to solid systems. The latter part of this develops the general theory of luminescent systems and is written in a straightforward and unimpassioned way. Leverenz treats the theory as a useful rack or set of pigeonholes for classifying ideas and materials and does not offer a particular viewpoint as a nostrum for curing all ills. The reviewer regards this as an exceedingly healthy outlook since there is a strong tendency on the part of many investigators in the field to make extravagant claims about their own insight into the workings of particular complex systems, whereas the truth seems to be that only one or two simple materials have been studied with sufficient thoroughness to permit even the beginnings of quantitative theoretical analysis.

Chapter V, "Luminescence of Phosphors," which comprises nearly half the volume, represents the heart of the subject. It contains a detailed summary of all of the practically interesting properties of a large number of prominent inorganic materials and a few organic ones that have current interest. Discussed here are such subjects as means of excitation, emission spectra, decay times, stimulation and quenching, absolute and relative efficiency, poisoning agents and the influence of factors such as activator concentration, operating temperature and current density and voltage for cathode-ray operation. This chapter contains about 100 illustrations which summarize important experimental observations.

The remainder of the book represents a general review of special topics that are possibly of more specialized interest than the parts described above, but which should be presented in a book of this type. There is, for example, a chapter in which subjects such as photolysis, "burning" and the effects of milling are discussed, along with sundry other subjects of comparable importance. Finally, there is a chapter on "Uses of Phosphors" which contains a detailed description of the many ways in which luminescent crystals have been used both commercially and in research and the manner in which the existing materials are suited for such application.

In the appendix Leverenz provides additional specialized information including advice on the preparation of the ingredients for sulfide-type materials which require great care if reproducible results are to be obtained.

The bibliography contains at least 1000 entries and should make a similar survey unnecessary for some time to come. I doubt if any contributor to the field can claim that he has been neglected.

The reviewer also noted with some amusement that Leverenz' well-known periodic chart of the elements appears in removable form in a flap in the back cover. This chart contains so much data that I must confess that I become dizzy if I look at it very long. On the other hand, many of my friends find it very useful. In addition it must be admitted that it is tame compared with the nuclear charts that are being evolved at the present time.

FREDERICK SEITZ
University of Illinois

Basic Theories of Physics: Mechanics and Electrodynamics

BY PETER G. BERGMANN. Pp. 280+viii. Prentice-Hall, Inc., New York, 1949. Price $3.75.

This book is an important attempt in presenting the structure of classical theoretical physics in coherent form. It covers the basic theorems of classical mechanics and electrodynamics with special emphasis on presenting results leading to modern theory.

A special feature of this book is the emphasis on the transformation character of all quantities involved. This emphasis leads the author to write all fundamental relations in tensor notation from the very outset, a practice which is very recommendable. Axial vectors like angular momentum, magnetic field, etc., are introduced immediately as second rank tensors which makes a later discussion of the distinction between tensors and tensor densities much simpler.

The first half of this book is devoted to a survey of classical mechanics. After a critical discussion of the point particle concept and of Newton's laws and the associated conservation laws the book gives a brief but concise outline of Hamiltonian dynamics. The generalized dynamics section is written with special regard to demonstrating the relations which led to quantum-mechanical concepts. A section then follows on the mechanics of continua which is one of the most useful parts of the book, since it summarizes in compact notation the basic theorems of hydrodynamics, elasticity and acoustics usually not found in a single place. Again the material is given totally in tensor notation and most of the theorems useful in the section on electricity are developed.

The transition from classical mechanics is made by a discussion of the meaning of a field theory *vs.* action at a distance theory. In this respect this reviewer feels that the author has not done full justice to the basic concepts of a field theory. The author emphasizes the "field" mainly in terms of its continuity properties but does not critically discuss the field concept in terms of cause and effect separation or study the equivalence between action at a distance and field concepts which has so recently become of importance.

Electrostatics is developed in the customary manner from Coulomb's law. The treatment given to the mechanics of continua makes it possible to introduce the Maxwell tensor and similar material in a much easier manner than is usually possible. Polarization, multipoles, etc., are introduced in the usual manner.

The subject of magnetastatics is introduced by the use of magnetic poles. The author's principal points in the introduction of the magnetastatic interaction are: (1) That this is the first time that a velocity dependent interaction is encountered. (2) That Newton's third law is apparently violated. The latter point is unfortunately much confused by the use of the single magnetic pole in describing the interaction. It is true that the magnetic interaction between single moving charges does not obey the third law; this is due to the non-stationary character of the fields and the consequent changes of electromagnetic momentum. In the case of stationary current interactions (including magnetic materials) the third law is always obeyed as can easily be demonstrated. The point is thus an important one but the means of demonstrating it are not too properly chosen. In the section on the general electromagnetic field the magnetic interaction between moving charges is discussed with the correct explanation of the apparent breakdown of the third law. The general electrodynamic equations are introduced in essentially the classical way with an excellent discussion of the conservation laws. The solutions of the equation in terms of retarded and advanced potentials are discussed only briefly and so are the actual radiation fields. A very brief discussion of the basic postulates of special relativity is given and the covariance of Maxwell's equations is demonstrated by direct substitution into the Lorentz transformation.

The book concludes with a general discussion of some of the results of electromagnetic theory in the field of optics. An unusual feature is a good discussion of the eiconal equations and the relation of Fermat's to Hamilton's principle. This chapter will be particularly useful to the student studying the physical foundations of quantum mechanics.

This is an excellent book for the serious student who is interested in the structure of classical theoretical physics rather than principally in its applications. It will acquaint him with the fact that even in classical physics there are many questions of a controversial nature. The book will be found a valuable text in schools where theoretical physics is taught in a single course.

WOLFGANG K. H. PANOFSKY
University of California

Aerials for Metre and Decimetre Wave-lengths

BY R. A. SMITH. Pp. 218, Figs. 125. Cambridge University Press, London, 1949. Price $3.75.

In about 200 pages of relatively easy reading, the author includes a great deal of information of interest to the experimental research man and the design engineer. This has been accomplished by limiting the depth of the book to a scanty framework of simple theory in which the results of experiment and of the more elaborate theories are presented. The scope of the book is necessarily restricted, not only by the wave-length regions specified in its title, but also by the fact that typically microwave antennas are treated in another volume of the series "Modern Radio Technique" (General Editor: J. A. Ratcliffe).

The first two chapters contain a factual statement of the performance characteristics of resonant dipoles and dipole arrays. The next two chapters present a simple theory based on four-terminal network relations and sinusoidal current distributions in linear antennas. In addition, a very instructive graphical comparison is drawn between experimental values for the impedance of center-fed dipoles and the several values predicted by simple sinusoidal theory and by the more sophisticated theories of Schelkunoff, King and others.

Chapter 5 describes the impedance and pattern characteristics of driven elements combined with reflectors and directors. The next two chapters consider the more specialized problems associated with arrays of such units when used as high power transmitting antennas and as receiving antennas for wave-lengths of a few meters. Problems of supporting, insulating, feeding, and switching these antennas are treated.

Chapters 8 through 11 are devoted to several important fields of practical application. The radiation characteristics of long wires are described and are used to predict the performance of terminated wires, V antennas, inverted V antennas, and rhombic antennas. Solutions are offered for the matching, feeding, and switching problems encountered with broadside arrays for 1.5-meter ground radar. The specialized art associated with Yagi antennas is outlined. The aircraft antenna problems in this frequency range are recognized and a number of particular solutions—mainly exposed antennas—are offered.

The principles underlying broad-band antennas and slot antennas are discussed in Chapters 12 and 13, including an exploitation of the Booker-Babinet principle for the interpretation of slot radiation characteristics. In the next chapter these principles find application to antennas for decimeter wave-lengths.

The final chapter makes an interesting analysis of the sources of antenna noise. Directional and frequency factors are considered and related to the noise factor of the receiver.

In considering specialized fields of application, the author largely avoids engineering detail and emphasizes general design techniques. In some cases, as might be expected, the book does not reflect the advance in the art which has occurred since the war. The treatment of many subjects is a bit sketchy, to the extent that the reader will want to turn elsewhere for more complete information. However, this additional information will usually be found in the well-selected original sources to which frequent reference is made.

The author's practical experience is evident in a number of passages noteworthy not because they are startling, but because they are so very true. The reviewer can not refrain from quoting some of these which come closest to his own experience. Past measurement and theory are left on about an equal footing by the following two statements. "In view of the lack of consistent measurements covering a wide range of dipoles a designer who needs a very accurate estimate of the impedance of a half-wave dipole must measure it under the conditions of use." "Summarizing, one may say that in view of the difficulty in realizing the ideal conditions assumed by theory the agreement between theory and experiment is remarkably good, and the difference between Schelkunoff's values and those obtained from the later treatments of Hallen's equation are not very significant in practice. . . . In any case the final adjustments due to the presence of insulators, etc., are likely to be even larger than the discrepancies between theoretical and actual values for the free aerial."

The following statements may seem to be self-evident, but the first has been actively questioned in this country and the second ineffectively applied. "It is much easier to produce a good 'all-round' polar diagram for vertical polarization than for horizontal polarization, . . ." "Moreover, it will be almost essential to decide where such slot aerials are to be placed in the early stages of the design of aircraft in order that the structural design may take account of their presence."

The book is not recommended as a classroom text or for study by one with no previous knowledge of antennas, since basic assumptions and restrictions to simplified developments are not always made clear. It is recommended, however, to the experimentalist and the design engineer as a convenient and helpful reference.

Naval Research Laboratory

Engineering Supersonic Aerodynamics

By E. Arthur Bonney. Pp. 264+xi, Figs. 180. McGraw-Hill Book Company, Inc., New York, 1950. Price $4.00.

Engineering Supersonic Aerodynamics by E. Arthur Bonney is a textbook of applied aerodynamics designed to provide an undergraduate engineer who has already become acquainted with the classical phases of applied aerodynamics with the additional background information needed for the design of supersonic aircraft. Since a wide range of topics is covered and since the mathematical techniques necessary for the theoretical development of these topics is beyond the ability of those students who might use the text, no attempt is made to derive the results from fundamental principles; however, adequate references to the basic literature are included for the use of those who require more complete details.

The first chapter describes the basic phenomena of compressible fluid flow including shock waves, Mach waves, oblique shock waves, expansion waves, and wave interactions. The second chapter covers the one-dimensional steady flow theory of nozzles and diffusers. Chapter three presents the oblique shock and Prandtl-Meyer expansion theory, the approximate two-dimensional linear theory and Busemann's second- and third-order expansion theory. Tables of the results of the oblique shock and Prandtl-Meyer expansion theory which are complete enough for most practical applications are included. Chapter four covers two-dimensional airfoil theory, the theory of the rectangular wing and of delta-wings, and the downwash fields behind finite wings. Chapter five treats bodies of revolution. This chapter could be strengthened by reference to the Stone-Kopal calculations of the lift and drag of cones. Chapter six discusses the design and instrumentation of supersonic wind tunnels. Chapter seven, the last chapter, discusses some of the problems of composite design including interference and performance analysis.

The only important theoretical error noted by the reviewer occurs in the treatment of the rectangular wing (p. 143) where it was assumed that the wave drag of the rectangular wing is reduced from the two-dimensional drag in the same ratio as the lift reduction. The correct theory was given by von Kármán [J. Aero. Sci. 14, 373 (1947)] and shows that the formula given by Bonney is in error by a factor of two (for the zero lift wave drag) at the Mach number where the Mach line from each tip of the leading edge touches the opposite trailing edge tip. In addition the use of the Busemann second-order theory to correct the lift in the tip region of a rectangular wing is of questionable value since the correction has no sound theoretical foundation and cancels out in the two-dimensional region where it is valid and since the final correction so deduced is of a very small magnitude.

There are two items of notation which are, perhaps, unwise. First, the word "characteristics" is used freely in the usual dictionary sense. Since the use of the word in its technical sense applicable to the mathematics of hyperbolic partial differential equations is never mentioned, its use is perfectly correct; however, it may lead to confusion in the minds of immature readers unless there is some comment on the technical use. Second (p. 141), the term acceleration is used to refer to a finite velocity increment. In addition there are several of the minor errors of a proof-reading nature which are inevitable in any new text. Figure 4–13 (the lift/drag ratio of two-dimensional airfoils) is mistitled and improperly referred to in the text. The only other correction worth noting occurs in Fig. 4–61 (the downwash infinitely far behind a delta-wing) where the ordinate scale is cut short so that the downwash behind the wing in the plane of the wing is not shown.

Since the mathematical difficulties of the theories of compressible fluid flow are too great for the vast majority of the undergraduate engineering students, it seems to be impractical to develop completely any extensive portion of this theory in undergraduate courses. On the other hand, the very great importance of compressible flow phenomena in modern aerodynamics makes it essential that some basic education in this field be obtained. The approach used by Mr. Bonney appears to present a reasonable solution of this problem.

Spectra of the Rare Metals and Some Metalloids

By A. Gatterer and J. Junkes. Vol. 3 of the Atlas of Spectral Lines. Vatican Observatory.

Volume 3 of the Atlas of Spectral Lines has been received from the Astrophysical Laboratory of the Vatican Observatory. This handsomely bound and printed volume completes the series on the spectra of the elements assembled to aid in chemical analysis. Volume 1 contained the spectra of 30 chemical elements, Vol. 2 the rare earth metals, and Vol. 3 contains the spectra of As, Au, Be, Br, Cb, Cl, Ga, Ge, Hf, Hg, I, In, Ir, Os, Pd, Pt, Re, Rh, Ru, S, Sb, Se, Ta, Te, and U. There are 42 photographs, 30 x 40 cm in size, of the arc and spark spectra of these elements from 6400-2100A. The same dispersion was used for all the elements and each photograph has six elements adjacent to each other to help in identifying the lines. The normal iron arc or spark spectrum is photographed with the spectrum of each element for comparison. The platinum metals Ru, Rh, Pd, Os, Ir, Pt appear together as do the metalloids Cl, Br, I, S, Se. The other elements are grouped alphabetically with Hf by itself as it was photographed later than the others.

The photographs are enlarged 20 times from the original plates and have a dispersion ranging from 0.80 to 27.28A/mm. The dispersion is given for wave-length ranges of 50A which enables the displacement of lines measured in mm on the photographs to be converted to angstroms.

There are tables giving the wave-lengths of the lines of each element, the wave-lengths of the strong lines (*raies ultimes*) suitable for analysis and the lines of the principal impurities. The tables are accompanied by some text that describes the material used, electrode form, purity, mounting, and general characteristics of the spectrum obtained. The table of intense lines has also been reprinted on heavy paper for more convenient use in analysis. The tables give the state of ionization, the wave-length, and the visual intensity in arc and spark on a scale of 1 to 10 with 15 and 20 for intense lines. The tables are not meant to be exhaustive and no new lines were sought although some of the lines were measured by the authors. Most of the wave-lengths were taken from tables by Kayser-Ritschl, the *M.I.T. Wavelength Tables* of G. R. Harrison, Tables of Exner and Haschek, special tables in Kayser's *Handbuch* and special monographs. New iron standards had to be found in the ultraviolet region 2300–2100A. This Atlas should be a great boon to those doing spectrochemical analysis.

Earth Waves

By L. Don Leet. Pp. 122, Figs. 58. Harvard University Press, Cambridge; John Wiley and Sons, Inc., New York, 1950. Price $3.00.

This book presents selected information concerning elastic waves which are propagated through the earth. It is written for readers with training in the fundamentals of some branch of engineering, physical, or geological science, and deals with first principles with only elementary mathematics. It is not intended for use as a textbook in seismology or seismic prospecting, but rather as a compact summary of the state of our knowledge, for a newcomer in the subjects covered. A relatively large portion of the information provided is taken from material published in periodicals with limited circulation. The book is based on eight lectures of the author on "Application of seismological techniques for engineering problems." This latter title very well describes the content of the book.

The first 38 pages deal with the recording and measurement of elastic waves which have traveled in the earth. It gives an excellent presentation of the principles of recording instruments and the characteristics of the records they write. Diagrams of specific seismographs are well selected.

In the second chapter (20 pages) the known types of earth waves are described. The author considers mainly waves recorded from artificial explosions but he also discusses the types found in seismograms of distant earthquakes and a record written by a field seismograph located near the atomic bomb exploded in New Mexico on July 16, 1945. This is the record in which the author discovered the so-called "hydrodynamic wave," a term not too well chosen, since—except for the form of motion during the passage of the wave—there seems to be no relation to actual hydrodynamic waves.

The third chapter contains a summary of the transmission characteristics of earth waves in seismic prospecting over various wave paths determined by layers having different elastic properties. About 14 pages are devoted to the transmission of elastic waves through the earth, including calculation of the wave velocity in the earth's interior, typical seismograms from various epicentral distances in shallow earthquakes, wave paths through the earth's interior and time-distance curves. The next 18 pages give similar information about seismic prospecting.

In the last chapter (10 pages) the author discusses some aspects of microseisms, or ground unrest, recorded continuously by sufficiently sensitive instruments. He deals mainly with the problem of locating the source of microseismic storms and the direction of travel by the use of three stations, located at the apices of a triangle with separations of approximately one mile. He also discusses possible improvements of this method.

Throughout the book, the author has provided excellent illustrations; most of the 58 figures are derived from his own work.

Giant Brains, or Machines That Think

By Edmund C. Berkeley. Pp. xvi+270, illustrated. John Wiley and Sons, Inc., New York; Chapman and Hall, Ltd., London, 1949. Price $4.00.

The high speed sequence-controlled computing machines such as the ENIAC and the Harvard Mark I, Mark II, and Mark III machines are certainly among the most pregnant and suggestive developments of recent years. It seems clear that their applications will be numerous and significant. In *Giant Brains*, Berkeley has offered a primer of these devices and of their uses, so far as the latter can now be visualized.

It is genuinely a primer. Its prose has been, as the author explains, carefully examined to make sure that the little steps it presents are not too difficult for little feet. He says: "Every word of two or more syllables was continually checked: is it needed? can it be replaced by a shorter word?" One gets the impression that the sentence structure was similarly examined for elaboration and complexity; at any rate, only straightforward and rather short sentences have survived. I found the resulting prose repellent, but the author may have achieved his goal of making understanding easy.

The book deals with a remarkably wide variety of computing mechanisms, including IBM punched-card machinery, the M.I.T. differential analyzers, the Harvard Mark I machine, the ENIAC, the Bell Telephone Laboratories relay calculators, a machine for examining logical propositions, and some remarkable new machines suggested in outline, for illustrative purposes, by the author. It has a chapter on language, and another which explains how the reader can make a simple computer in his basement, provided he can secure the tape-reading mechanism from an old teletype machine.

Berkeley chooses to treat these machines in very considerable detail as concerns coding, information transfer, and the like, while refraining almost altogether from dealing with the devices used to realize the functions of the machine, at least when these grow more complicated than gear trains or relays. This is probably an inescapable choice for one who intends to write for a large public mostly ignorant of electronics, but it has the unfortunate result that it permits no discussion of the ways in which the properties of computer components dictate computer design. Undeniably, the characteristics of the new computing machines now nearing completion in several U. S. and overseas laboratories have been determined at least as much by the strengths and deficiencies of the computer components currently available, as by the wishes of the designers.

A strong anthropomorphic flavor pervades the book. The homemade computer recommended to the reader is called Simon (for Simple Simon), the ENIAC is constantly referred to either as "Eniac" (without the article), or as "he," computing machines are almost always called "mechanical brains," and so on. This confers on the work an air of naivete which is somewhat revolting at best, and misleading at worst. The title, for example, is misleading; the "mechanical brains" we now know how to build are "giant brains" only in the sense of being monstrosities in comparison with physiological brains. The ENIAC, with a million times less complexity than the human central nervous system, occupies a space several thousand times bigger, dissipates a thousand times the power, and is a good deal less reliable.

With its defects, which are probably mostly visible to the scientist, and may not be so objectionable to the lay reader, *Giant Brains* has virtues. It contains a useful bibliography, its descriptions of existing machines probably include some facts unknown to any reader, and the discussions of future possibilities, though incomplete, may be suggestive.

Introduction to Theoretical & Experimental Optics

By Joseph Valasek. Pp. 454+x, Figs. 211. John Wiley and Sons, Inc., New York, 1949. Price $6.50.

This book is a text and laboratory manual for a full year course in optics for advanced undergraduate students. Until now only one comparable modern text, Monk's *Light*, has been available so that the appearance of Professor Valasek's book doubles the number of possible choices for instructors of courses in optics on the intermediate level who wish to use a *single* text for geometrical, physical and radiation optics and an accompanying laboratory course.

The treatment of geometrical optics follows the general pattern used in Drude's classical book. It is clear and concise with sufficient emphasis on basic concepts such as Fermat's principle and the collinear transformation. Particularly clear, though brief, are the chapters on apertures and illumination. One might wish that more subjects had been expanded to the same extent as the optics of the eye, stereoscopy, and the prism spectroscope but it is apparent that the author intends that a reading of the text be supplemented by working the problems. These problems—there are 87 on geometrical optics alone—are excellent and adequately serve to emphasize and amplify principles and methods described only briefly in the text.

In the section on physical optics the principles of interference and diffraction are thoroughly developed from wave theory and diffraction of x-rays in crystals is treated. Mention is made of the limitations of the Fresnel theory when applied to microwaves. Polarization and optical activity are discussed on the basis of electromagnetic theory, which leads to treatments of refraction, dispersion and reflection. The use of advanced calculus is not avoided. A comparison is made between the classical and quantum theory expressions for dispersion.

In the third section on radiation and spectra a wide range of topics including thermal radiation, atomic, molecular, and x-ray spectra, Zeeman, Stark, photoelectric, Kerr and Raman effects, chromaticity, and scattering are condensed into 79 pages. The treatment is necessarily much less thorough and is of a more descriptive nature than that used in the first two sections, but the important equations and relationships are presented and briefly described. Here one could, without detriment to a course in classical optics, omit some chapters on topics which might be more appropriately and extensively treated in an advanced undergraduate course in atomic physics.

The last section of the book describes twenty-four experiments in geometrical and physical optics, spectroscopy, and photometry. Most of these are, of course, similar to those found in Monk or in Taylor's *Manual of Optics*, but included are interesting experiments in spectrochemical analysis, spectrophotometry, x-rays, and a valuable discussion of the photographic process. The principles involved and the use of the apparatus are fully described with frequent references to the body of the text for additional theoretical background, but explicit step-by-step experimental procedure is not usually given. Thus the student must acquire a real understanding of the experiment in order to perform it properly.

The book is carefully written and the numerous excellent line drawings are well thought out. The author's teaching experience has enabled him to introduce new subjects in such a way that salient points are clearly brought forth in a few well-chosen sentences.

California Institute of Technology

Spectroscopic Properties of Uranium Compounds

By G. H. Dieke and A. B. F. Duncan. National Nuclear Energy Series, Manhattan Project Technical Section, Division III, Vol. 2. Pp. xviii+290. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.75.

This book is devoted chiefly to a discussion of the visible and ultraviolet absorption and fluorescence spectra of several dozen uranyl compounds. These compounds have the general formula $M_xUO_2N_y$, where M is a positive ion, usually a monovalent metal, and N a negative ion (halide, nitrate, sulfate, etc.). The spectra were studied in the crystalline state, and were measured with both low and high resolving power, at various temperatures down to 14° K, and in the presence of magnetic fields up to 24,000 oersteds. They are interpreted in detail with respect to the vibrational fine structure and other characteristics of molecular electronic spectra in crystals. In the interpretation frequent use was made of the vibrational isotope effect obtained by substitution of O^{18} for O^{16}. The spectra are summarized in some 40 tables constituting Appendix 1.

In addition the volume contains a chapter on the x-ray crystallography of uranyl compounds and four chapters on various aspects of the chemical preparation of the compounds. An extensive bibliography is included. It is divided into spectroscopic and non-spectroscopic parts, and the references are listed year by year. The reader is warned (in the Preface, however, not at the heading of the Bibliography) that the spectroscopic bibliography includes nothing that was referenced by Nichols and Howe in their 1919 monograph on the fluorescence of uranyl salts, and that the non-spectroscopic part should be regarded as an extension of the literature cited in Part 55 of *Gmelins Handbuch der anorganischen Chemie* (1937). The authors point out that the new elements neptunium and plutonium may have compounds with properties like those of the uranyl compounds. The present volume should be a useful compendium for investigators of the spectra of such new substances.

Richard C. Lord
Massachusetts Institute of Technology

Luminescent Materials

By G. F. J. Garlick. Pp. 254+viii, Figs. 127. Clarendon Press, Oxford, 1949. Price $5.50.

Dr. Garlick has provided a book which will give a reader with prior knowledge of solid state physics an opportunity to become acquainted with some of the main characteristics of luminescence in solid materials together with associated descriptive theory in a minimum of time.

The content of the book is divided into eight chapters. The introductory chapter gives a brief survey of the phenomenon of luminescence together with examples and indicates the main characteristics which must be adequately explained. In Chapter II a review of the fundamental mechanisms that play a role in luminescence are reviewed. These include a brief and somewhat terse presentation of the theory of optical absorption and the luminescent processes based on the Block electron-energy band theory of perfectly periodic crystals together with additional impurity centers and assumed electron traps. The discussion probably indicates that with the present knowledge of the subject it is not possible to give a detailed treatment of the nature of luminescent centers and a quantitative treatment of electron transitions.

Chapter III is quite long and provides in the main a catalog of the luminescence characteristics of impurity-activated phosphors with some attempt to connect them with the theories presented in the previous chapters. Ample examples of these characteristics in various phosphors are given with the help of a large number of illustrative curves.

Chapter IV is devoted largely to the luminescence processes in zinc sulfide. The material presented here is mainly recent and covers more detailed investigations by the author and collaborators done in order to provide information which would establish a more precise theoretical description of phosphorescence and thermoluminescence.

Chapter V contains interesting material on the electrical properties of phosphors associated with luminescence. The principle electrical effects discussed are the electrical conductivity during luminescence, the change in dielectric constant and dielectric loss during luminescence and the production of luminescence when a strong field is applied to some phosphors. One of the most interesting features is the change in dielectric properties from which it is concluded that electron retrapping is negligible in luminescence and that the electron traps have a large effective size.

A description and theory of the effect of infra-red radiation in enhancing and quenching luminescence is given in Chapter VI.

Cathodoluminescence is covered in Chapter VII. The main characteristics of luminescent phosphors when excited by incident, moderately high energy electrons is treated. The theory of this type of excitation is given in a qualitative way which only serves to make one wish for a really quantitative description of the fate of an electron entering the phosphor.

The final chapter covers certain aspects of luminescence from organic molecules. A thorough understanding of the phenomenon in such molecules would go far in providing a basis for understanding certain phenomena in more complicated solids. The reviewer had the mild wish that the subject could have been begun with a comprehensive discussion of this topic as a prelude to the treatment of luminescence in more complex solids.

Lloyd P. Smith
Cornell University

Electrical Engineers' Handbook of Electric Power

Edited by H. Pender and W. A. Del Mar. Fourth edition, pp. 1650+xii. John Wiley and Sons, Inc., New York, 1949. Price $8.50.

Reviewing a book implies that someone has read it. When the book in question happens to be a handbook, and if perchance that the volume contains some 1650 pages, the implication is staggering and in this case untrue. Fortunately, for this reviewer's peace of mind, a handbook is not designed to be read but rather to be used as a reference. When tested in this way, the fourth edition of the now famous Pender-Del Mar *Electrical Engineers' Handbook on Electric Power* comes through with flying colors.

The chief objection to the book is its size. This may not be as much a criticism of the editors and authors as it is of the ever increasing informational demands which our civilization places upon the engineering profession. Still, on leafing through the book, one is struck by the relatively high fraction of the volume occupied by textual matter as contrasted with tables and graphs. One is inclined to suggest that some of this material be omitted or abridged or, if this is not desirable, that the book be enlarged still more and called an encylopedia rather than a handbook.

Some 71 different authors have contributed to the present edition, which in turn is the outgrowth of earlier editions to which still others have contributed. While this procedure insured a degree of competence on the part of the authors of specific sections which could not otherwise have been obtained, some variations in style and level of treatment and some redundancy are evident.

Certain features of the volume stand out and justify special mention. The format of the tables and particularly of the conversion tables is pleasing and convenient. In fact, the format and typography are uniformly excellent. By way of contrast, the paper stock, although of the now favored off-white color, verges on the poor quality side—a few thin and frayed pages being noted in the reviewer's volume as received. The binding is also a bit light for a book intended for hard usage.

Another notable feature is the inclusion of extensive bibliographies at the end of each section. The listing of the references by subjects and in chronological order within sub-divisions rather than alphabetical by authors would seem preferable. As a final feature to be mentioned, one is struck by the all-inclusive nature of the material covered. It is hard to think of any handbook type information that a self-respecting electric power engineer might admit needing that is not contained in the book.

For a reference work of this size, the index is rather small and none too useful, at least as judged by a few simple tests. The rather extensive Table of Contents and the division of the book into sections offsets this deficiency although the use of heavy weight and perhaps colored separators for section headings would be a distinct aid. There appears to be no real difficulty in locating any desired information.

The fourth edition of Pender's handbook is evidently destined to uphold the reputation established by the earlier editions and, accordingly, it deserves a place on the electrical engineer's bookshelf.

A. L. Samuel
International Business Machines Corporation

Acoustic Measurements

By Leo L. Beranek. Pp. 914+vii, Figs. 519. John Wiley and Sons, Inc., New York, 1949. Price $7.00.

This is not only an exceptionally comprehensive book, but one that is very well organized and shows the results of great care in the selection and treatment of the whole range of modern techniques for acoustical measurements. There are many complete circuit diagrams and detailed descriptions of recommended laboratory set-ups for measurements or microphones and loudspeakers and for the use of the audiometer and the sound level meter. Excellent discussions are given of methods for the determination of frequency, the steady-state and transient analysis of sound, articulation tests and the response of systems to noise. Proper emphasis is placed on the importance of devising testing and evaluation methods applicable to a complete acoustical system, and not merely for the measurement of certain components. The work has a fine historical introduction and is to be commended for its clear presentation of recent agreements in the difficult matter of terminology.

Workers in this field will be grateful for the inclusion of a considerable amount of basic acoustical theory needed for a thorough understanding of measurement techniques. There are sections on the attenuation of sound in air under a variety of conditions. Mention is made of the attenuation of sound in water, but here one wishes that more adequate notice had been given of the recent work, both theoretical and experimental, of Eckart and Lieberman relating to Stokes absorption, compressional viscosity effects, and attenuation in chemically active media. It is proper that the work of Eyring on the effects of temperature gradients in "jungle acoustics" is recorded and one can only wish that space had permitted similar mention of the related problems studied by Spitzer, Eckart and many others on the paths of sound waves in the sea. On pp. 103–05 it is gratifying to see reproduced the beautiful but almost completely unknown measurements on diffraction made during the war at Orlando, Florida by the Underwater Sound Reference Laboratories.

Chapter 4 is an excellent piece of writing. Here the reciprocity method of calibration is explained in complete detail. This section of the book should banish any lingering doubts in the minds of workers in acoustics that the reciprocity principle is the primary technique for acoustical calibrations. It includes the important wartime developments in this field not only in air acoustics, but also in underwater sound. The book has a most scholarly treatment of both the Rayleigh disk and the thermophone. For the former the author not only gives a modernized theoretical discussion of this classic device, but also presents a concise summary of recent

British work with this standard, perhaps not generally available in this country. The discussion of the thermophone and especially the clear unraveling of the long controversy between the results obtained with this instrument and those found both by reciprocity and the Rayleigh disk is most enlightening. We are especially indebted to the author for making generally available the results of the beautiful experiments on the thermophone of Geffeken and Keibs.

The chapters dealing with the measurement of acoustic impedance and its relation to acoustical materials are very well done. Here Dr. Beranek writes of a field in which his own contributions have been outstanding. His work, together with that of Morse and Bolt, Hunt and many others, has now nearly if not quite brought this subject to the place where standard specifications and practice for architectural acoustics can be stated in terms of the acoustic impedance of materials rather than in the language of the pioneering days of acoustics.

Workers in all branches of acoustics are indebted to Dr. Beranek for this excellent book, and we may hope that he will be able to revise it as the art progresses so that it will remain an authoritative treatise. The Office of Naval Research is also to be complimented for wisdom and vision in providing support for such a worth while endeavor.

Robert S. Shankland
Case Institute of Technology

Practical Spectroscopy

By C. Candler. Pp. 190+iv, over 100 illustrations. Hilger and Watts Ltd., London, 1949. Price $6.10.

This book is essentially an expanded manual for use with the Hilger wave-length spectrometer, and as such it serves its purpose admirably. The wave-length spectrometer is a well-known and very versatile instrument: in its standard form with a constant deviation glass prism it is suited either for visual observation or for use with a photographic camera. The length of the visible spectrum from 4000 to 7000A is about three inches. With the help of various pieces of auxiliary equipment the instrument can be converted into a grating instrument, an ultraviolet monochromator, an infra-red spectrometer, or can be used with an interferometer or an echelon.

The author describes a considerable number of experiments that can be performed with the instrument which would be appropriate to an elementary laboratory course in spectroscopy or physical optics. The content is as follows: Chapter I. Measurement of wave-length, adjustment of instrument, visual and photographic measurements, lining up of the light source. Chapter II. Qualitative Spectrochemical Analysis: arc, spark, flame, examples. Chapter III. Quantitative Spectrochemical Analysis: visual estimates, photographic method with internal standard, microphotometer, with special emphasis on flame methods. Chapter IV. Absorption Spectra: spectrophotometers, visual and photographic techniques, applications to organic compounds and metallic ions. Chapter V. Infra-red: quartz, fluorite, rocksalt, sylvine prisms; sources; thermopiles and galvanometers; influence of slit width; organic compounds; residual rays. Chapter VI. Raman Spectra. Chapter VII. The Ultraviolet Monochromator. Chapter VIII. The Structure of Line Spectra. Chapter IX. Interferometers: Fabry Pérot etalon, adjustment and use, Lummer plate, echelon grating.

Each chapter contains a general discussion of principles and applications and specific short instructions for the experiments. The treatment is elementary and clear.

For someone interested in an elementary course in practical spectroscopy who has available only the wave-length spectrometer or a similar instrument, this book will be very useful and, in fact, practically indispensable.

According to the publisher's preface, however, this book is also intended to serve as an introduction to general spectroscopy, and as such it is open to a number of criticisms. Since the title is *Practical Spectroscopy*, one might expect it to provide the reader with a general idea of the methods now in use by practical spectroscopists, as apart from what can be accomplished with the use of the Hilger wave-length spectrometer. So long as Mr. Candler confines himself to this one instrument, his treatment is good and convincing. But when he goes beyond these limits, there are some omissions and misleading statements which might leave the student with a wrong impression of the more general aspects of the subject. A few examples may serve to illustrate this. For absorption photometry the visual and photographic methods are treated. The first is of very limited use only, the second cumbersome and not very accurate. Nothing is said in this chapter of the photoelectric spectophotometer which at least in the United States can now be found in every laboratory where absorption measurements are made. Some mention of the photoelectric spectrophotometer would have been particularly easy, since the foundation for it is laid in Chapter VII.

The advances that have been made with infra-red receivers, notably the lead sulfide cell, have revolutionized and simplified the technique in the near infra-red and have made it possible to use many instruments in this region with increased accuracy and sensitivity. One would expect to find some mention of this method in a book published in 1949, but there is none.

At meetings of spectroscopists in this country during the thirties, there were frequent and often quite heated discussions as to the relative merits of grating and prism spectrographs. The arguments were not always marked by great objectivity, but they gradually subsided with the realization that well-designed instruments of either kind are quite equivalent in performance, provided that they have the same resolving power, dispersion and speed, and that the relative advantages and disadvantages are dictated by convenience rather than by any fundamental differences. A statement such as the following by Mr. Candler is, therefore, very surprising: "A major fault of the grating is the low intensity of the spectra produced, in round figures a grating needs an exposure 60 times as long as a prism.—A weak source, such as a helium lamp, produces hardly any lines which are visible, and when the spectrum is photographed the exposure may well stretch to 8 hours." He states further that when a grating is used the necessary exposure times in the photographic infra-red become impossibly long. In general, nothing could be further from the truth. It is, of course, quite possible that Mr. Candler's grating had these properties. If so, he should have thrown it away and obtained a better one.

The chapter on the structure of line spectra also contains some misleading statements. The width of a spectrum line is not usually determined by the Doppler effect as stated on page 160. In all the commonly used light sources, such as arcs, sparks, and ordinary discharge tubes, the width of the line is controlled by pressure or resonance broadening. The mechanism of self-reversal is, therefore, not the one given by the author. On the next page (161) one finds the statement: "Only lines which arise in transitions ending in the ground term appear self-reversed." Anyone can convince himself without too much difficulty that all strong lines, no matter on what state they end, may appear self-reversed.

Shortcomings such as these do not seriously impair the usefulness of the book as a manual for the wave-length spectrometer. They would, however, be serious pitfalls in an introduction to general spectroscopy for the beginning student or for the inexperienced science teacher who would rely chiefly on the information contained in this book.

G. H. Dieke
Johns Hopkins University

Infrared Determination of Organic Structures

By H. M. Randall, R. G. Fowler, N. Fuson, and J. R. Dangl. Pp. 239+v, profusely illustrated. D. Van Nostrand Company, Inc., New York, 1949. Price $10.00.

The title of this book is somewhat misleading in the sense that the work deals largely with related compounds of but one class.

This limitation is pointed out in the preface: ". . . the authors formed one of the . . . research groups . . . whose objective was to determine the structure of penicillin. . . . In order to become sufficiently oriented for effective work, it was necessary to study spectra of many compounds, not all directly related to the penicillin molecule in structure, but largely all of [a] common family. . . . Because of this trend in the choice of compounds, no claim is made to a complete treatment of the present status of infra-red spectroscopy, *even in its application to molecular structure.*" (Reviewer's italics.)

Chapter I is a short account of the application of infra-red spectroscopy to chemical analysis. The reviewer was surprised to find the unqualified intimation that optical isomers could be identified by usual infra-red techniques. The discussions of the interpretation and recognition of specific structure groups in Chapter II are largely confined to the functional groups of acids and acid derivatives (amides, imides). The treatment for these groups is empirical and based on a large number of compounds; here is given a detailed account of the position of the absorption maxima to be expected from the carbonyl ($C=O$) group when it is flanked by OH, OC, or NH groups. The phenyl group and conjugation effects, in general, are also treated.

Chapters III and IV contain most of the meat of the book. Here are included a chart of positions of absorption regions for various structure groupings causing the absorption, a detailed table (over 600 entries) of various groups which cause absorption in the "double bond" region (4.8–6.9 microns) and a catalog of absorbing groups occurring in 135 "theoretically analyzed" molecules. Chapter V cites several specific (practice) examples of the application of the infra-red method to qualitative analysis. Chapter VI on "Instruments and Experimental Techniques" confines itself largely to a very detailed description and performance characteristics of the University of Michigan spectrometers which were used to obtain the spectra reproduced in Chapter VII. In this last chapter (VII) are presented the spectra (original records) of 355 compounds. It is unfortunate that no indication of purity is given for any. About 200 of the compounds are acid and acid derivatives, the remainder are spread among alcohols, ketones, ethers, organic salts, thiazoles, and miscellaneous.

An error of fact has been pointed out to the reviewer by R. A. Friedel and D. S. McKinney. The spectra for liquid morpholine (Plate 257) is actually that for liquid nitromethane (Plate 247). Thus the discussion (p. 7) of hydrogen bonding in morpholine based on Plate 257 is not applicable.

Related to the restriction of the discussions to "amide type" compounds is the further restriction of the text to that portion of the spectrum between 2.8 and 7.8 microns. In view of the trend (by spectroscopists) in reporting measurements as frequencies (wave numbers), it is encouraging to find that, while wave-lengths are used exclusively in the text, the important tables do have both the frequencies and wave-lengths entered.

The book itself is quite handsome, made of high quality paper and the print is large and clear. The content should be very useful to those working with the class of compounds described here and to a larger group for the catalog of spectra of the 355 compounds.

American Petroleum Institute

Theory of Oscillations

By A. A. Andronow and C. E. Chaikin. Pp. 358+ix, Figs. 313. Princeton University Press, Princeton, New Jersey, 1949. Price $7.50.

This is an introductory text to what is commonly known as non-linear mechanics. The original, of which this is an abbreviated version, appeared in Russian in 1937. Translation and editing was done by a group directed by S. Lefschetz in Princeton. The authors of this volume are outstanding members of the Moscow Institute of Oscillations founded by Mandelstam in the early 1930's. The American public has become familiarized with the now famous work in mathematical physics of this school by the well-known treatise of Minorski.

The book will greatly appeal and can most heartily be commended to all those who wish to become familiar with non-linear mechanics, but do not care to be burdened with very elaborate analytical machinery. The mathematical tools have been carefully limited; they go nowhere beyond calculus of real variables and some simple theorems in ordinary differential equations. The book does not presuppose much knowledge of conventional mechanics of linear system, rather it builds the subject up from the beginning by means of an approach adapted to the later developments. The general principles are introduced at a leisurely pace and each step is illustrated by several concrete examples that are always analyzed in detail and are profusely illustrated. As a consequence of this, relatively little space is taken up in the book by the general theorems and their proofs, but this in no way diminishes continuity and logical organization. The methods are mostly those of analytical geometry that aim at finding graphically the trajectories of the system. Only the last chapter, IX, is devoted to some purely analytical methods. Most research on non-linear oscillations has been on systems of one degree of freedom, and so the book and its technique is restricted to these, with the notable exception of coupled relaxation oscillations (flip-flop circuits) which also can be treated by the standard methods developed. The exposition culminates (Chapter V) in the theorem, due mainly to Poincaré, that the only steady regimes of systems of one degree of freedom are equilibria (stationary currents) or limit cycles (self-sustained oscillations) and the main objective of the analysis is the development of criteria for the existence and stability of these particular solutions. The practical examples taken from pure mechanics are few and not the most significant; but the fundamental types of non-linear electric oscillations are thoroughly covered, including grid-tuned oscillators, arcs, multivibrators, trigger circuits, parasitic oscillations in generators, and others.

Given the broad nature of the treatment, the matter covered inevitably had to be limited. The major restriction is that to systems called "autonomous," i.e., the omission of all forced oscillations, non-linear resonance, etc. The editor's preface states, moreover, that a great simplification of the original has been achieved by cutting out most of the general analytical theory while retaining the examples. The result is gratifying and attractive. Furthermore, one never has the feeling that the mathematical authors "talk down" to the engineer or are not conversant with the somewhat more practical aspects of circuitry. The book would have gained by the inclusion of an up-to-date selected bibliography, replacing the rather poor "reading list" given; this seems to be the only major flaw of an otherwise consistently excellent job of the American editors. Might some economy in the illustrations have substantially reduced the price of the book?

W. M. Elsasser
University of Pennsylvania

Elementary Modern Physics

By Gordon Ferrie Hull. Pp. 503+xvi, Figs. 243. The Macmillan Company, New York, 1949. Price $4.25.

Elementary Modern Physics, a revision of *An Elementary Survey of Modern Physics*, has an all-inclusive title which allows the author to range widely over the developments of the last 60 years. The historical method is used in which discoveries are traced chronologically from the early experiments. No chance is missed to emphasize the drama of the action which is done even in the style of a reporter, especially in connection with the work in which the author had a hand. This makes for some interesting reading. In addition to atomic and nuclear physics there is an extensive chapter leading to the modern developments in electronics which include military applications to radar and the proximity fuse. Another application of wartime developments is a stimulating account of cosmic-ray experiments with VII rockets.

Subjects are discussed from several points of view with stress on the fundamental idea, thereby giving the students a broad understanding. The ideas are illustrated by up-to-date examples from the student's experience or by simple situations which he can visualize. A can of molecules is thrown off a cliff. The random motion is not increased until they hit the bottom. The Edison effect is illustrated by an experiment with a 50-watt lamp. In discussing a subject the author does not lose sight of other topics with which it is connected or which obey similar laws. The equation $I = I_0e^{-\lambda t}$ applies to light, radioactivity, and the law of atmospheres. The author has given considerable thought to simple derivations. Some of these derivations are admittedly crude but stress the possibility of their being understood rather than the rigor they achieve. The more complicated ones are relegated to appendices. Many equations are stated without derivation, an unfortunate situation that faces any author of an elementary modern physics text but one about which he must make his own compromise.

The historical approach and emphasis on the broad connections of the subject also have their pitfalls. In trying to analyze the confusing picture that certain developments leave in the mind of the reader, it seems as though the author with his vast background and experience has a tendency to include many sidelights, related items, and links with other phenomena which interrupt the argument and confuse the issue for the uninitiated. For example, into the middle of a section on the scattering cross section for neutrons are put three lines on the scattering cross section for electrons. More continuity could be gained by finishing up one topic without interrupting the train of thought and then comparing it with other phenomena after the first point has been thoroughly grasped.

A second confusing feature of the broad historical approach is that it leaves the reader wondering what exactly is accepted gospel at present and what is apocryphal. The present status of the ether is vague as is also the value of h. For the student of 1950 with a crowded curriculum, it is a question of whether pumpkins and parabolas are worth the time their discussion requires, even if it makes a fascinating story of the structure of the atom and the measurement of its mass. Elliptic orbits, Bragg x-ray doublets, hydrogen introduced through the walls of x-ray tubes, and Maxwell's distribution of electron velocities in metals are among the delicacies offered to titilate the intellectual appetite, whose omission would cause no undernourishment of the mind. The chronological presentation is cluttered up with historical errors in the pursuit of knowledge.

Elementary Modern Physics by Gordon Ferrie Hull with its many interesting illustrations from the experience of the author will be of most use to those interested in the historical approach to modern physics.

University of Pennsylvania

Ionization Chambers and Counters

BY BRUNO B. ROSSI AND HANS H. STAUB. National Nuclear Energy Series. Pp. 243+xviii, Figs. 113. McGraw-Hill Book Company, Inc., New York, 1949. Price $2.25.

At the end of the war the Manhattan Project and Atomic Energy Commission laid plans for the writing of no less than 60 volumes of declassified technical material for publication. This huge work was to make available as much as possible of the specialized scientific knowledge gained in the numerous laboratories concerned with the wartime development of atomic energy. While the intentions are still good, the writing has evidently progressed slowly, as might have been expected, knowing how anxious most of the scientists were to turn their minds to other kinds of work, and knowing the tediousness of the declassification process. The amount of effort involved in the latter process is indicated by the display of prefaces and forewords in the volume we are about to discuss—seven in all. But whatever the effort required, the authors of these books perform an extremely valuable service in making knowledge available which would otherwise have to be rediscovered at the cost of much time and money. *Ionization Chambers and Counters: Experimental Techniques* by Bruno Rossi and Hans H. Staub has just been published as one of a set of three volumes on experimental techniques. Of the two others, *Electronics* by Elmore and Sands, and *Miscellaneous Physical and Chemical Techniques* by Graves *et al.*, the first has appeared and the second is to appear during the coming year.

Ionization Chambers and Counters should perhaps have been titled *Ionization Chambers and Proportional Counters*, to be more accurately descriptive of its content. The first three chapters (71 pages) give a thorough treatment of the problem of ion production and collection in ionization chambers when there is no multiplication by collision. The theoretical derivations of the drift of electrons and ions through gases under an electric field are followed by numerous experimental curves of the drift velocities, mean agitation energies and electron attachment in the particular gases and mixtures of gases which are of interest in fast ionization chamber work. The next part of the discussion leads into the consideration of the time variation of the ionization chamber current under the condition of transient or pulsed ionization, which is of course the condition which is of most interest when individual particles are to be counted. Here, again, experimental curves and data are given which have been obtained at Los Alamos and at other laboratories.

Following the discussion of ion collection a chapter (28 pages) is devoted to gas multiplication, consisting mostly of the presentation and discussion of experimental curves and data. A number of different gases and gas mixtures, and different geometrical conditions, are considered, with attention paid to transient effects. Many of the data will be new to those who were not members of the wartime project. In the remaining 140 pages the application of the ionization chamber and proportional counter to special problems—alpha-, beta-, gamma-, and fission counting—is taken up. Drawings of a great many of the counters which were built in the Manhattan Project laboratories are reproduced, together with experimental data on their performance. The volume is replete with practical drawings, curves, and data, and should prove to be of great value to all who are working with ionization chambers and proportional counters.

University of Michigan

Elements of Sound Recording

BY JOHN G. FRAYNE AND HALLEY WOLFE. Pp. 686+vii, profusely illustrated. John Wiley and Sons, Inc., New York, 1949. Price $8.50.

The authors have, in their own words, directed their efforts "to writing a book that will give useful information on basic sound problems to the practical designer, operating engineer, or technician," a book that will be "useful to the practising sound engineer as well as the student in college or vocational school." In one sense, their efforts have been extremely successful: the resulting volume should serve as an excellent text for students of engineering who wish to learn the details of sound recording theory and practice, with particular emphasis on film recording. For the practising sound engineer, this book will prove useful in many ways, although the well-informed engineer in this field should already be familiar with much of the material included. It will still serve him as a convenient compilation of the current literature in his field. The physicist will find this volume an impressive account of intricate engineering problems and the ingenuity with which they have been solved.

The first 12 chapters provide the student with a speaking acquaintance with the tools of the craft: sound waves and hearing, electronic components and circuits, recording systems, and electrical measurements. It might be argued that the material presented in these chapters is already available in standard journals, texts, and handbooks, but the student will be grateful to the authors for providing so useful and brief a compilation and for their careful documentation of original sources. The utility of the material to the student is enhanced by the inclusion of numerical examples to illustrate the application of various design formulas.

Despite their brevity, the chapters on disk and magnetic recording are reasonably comprehensive, and a considerable number of references are provided from which the student may obtain more detailed information. It is perhaps unfortunate that these references do not include any of the several bibliographies currently available in these fields [Alfred Jorysz, "Bibliography of Disk Recording," Tele Tech (June, 1947). N. M. Haynes, "Bibliography of Magnetic Recording," Audio Engineering (October, 1947)], but the references provided are probably adequate for the authors' immediate purposes.

The degree of specialization of this text may be deduced from the relative number of chapters devoted to each of the several recording media: disk recording is treated, for the most part, in two chapters, and magnetic recording in one chapter, while film recording methods and systems provide material for the greater part of fourteen chapters. The less specialized reader may find this degree of emphasis on film recording somewhat unexpected, but it is amply justified by the authors' professional experience and by the circumstances under which the material was originally compiled. Over a period of years, the authors have been intimately connected with the film industry and its problems, to the solution of which they have made outstanding personal contributions.

The treatment of film recording is comprehensive and carefully documented. Five chapters are devoted to a discussion of the principles and techniques of variable-density and variable-area recording. Measurement techniques, drive mechanisms, production processes, and reproducing systems are the subjects of other chapters, some of which are applicable to disk and magnetic recordings as well as to film. The authors conclude with brief but useful discussions of loudspeakers, room acoustics, and stereophonic recording.

Engineers engaged in sound recording will welcome this volume as a survey of current practice and literature, while the student of sound engineering should find it a helpful and stimulating guide.

Histopathology of Irradiation from External and Internal Sources

By William Bloom. Pp. 808, Figs. 516. McGraw-Hill Book Company, Inc., New York, 1948. Price $8.00.

This book is a systematic study of the effects of radioactive elements administered to animals, as compared to the well-known effects of x-ray treatment. The lesions due to radioactive bombardment are illustrated by hundreds of remarkable photographs, while numerous autoradiographs make it possible to visualize the localization of the radio-element. Knowing the sites of origin of the radioactive particles, it becomes possible to deduce whether the lesions are the results of a local bombardment rather than a generalized, unspecific effect. Besides this ambitious aim, the authors had the more practical purpose of recognizing the type of lesions due to radio-elements with the view of eventually giving them medical attention, since the work was started during the war at a time when the possibility of an atomic war was looming in the near future.

The authors set out to achieve these goals by a considerable series of experiments. The immediate goal of describing the pathology of the organs is very well done. It is apparent from the outset that the director of the group responsible for this work is an histologist. He is, in fact, the author of the well-known textbook of histology: Maximow and Bloom. After a chapter on the cell, the various organs of the body are examined, one by one, and their response to the various radioactive agents is thoroughly described. Thus, the skin was found to be greatly damaged by external applications of radio-elements but not by internal treatment. The hemoietic organs and gastro-intestinal tract, which are very sensitive to both, showed lesions which are remarkably well illustrated in this book. The chapters on kidney, vascular system and nervous system are among the most original of the volume.

The authors used considerable restraint in the interpretations of the results, a fact which may be somewhat disappointing, in view of the excellent material available. Often, the possible physiological and pharmacological significance of the autographic pictures is not mentioned. Of course, the rather crude autographic method, which had to be used because of the urgency of the work, often made it difficult to assign a precise localization to the radio-elements. Lacking this knowledge, many of the lesions could not be interpreted.

The summary is devoted to the fundamental mechanisms playing a role in the action of radiation on living tissues. Thus, it was emphasized that the effects of irradiation are not unlike those of intoxication with mustard gas and other damaging agents. Furthermore, there were no qualitative differences in the reaction of animals to comparable doses of x-rays, gamma-rays, fast and slow neutrons and (for the skin) external beta-rays. These various agents at approximately the $LD_{50}/30$ days cannot be differentiated on the basis of their histological effects. Furthermore, the main difference between radiation from internal and external sources lies in the fact that internal radiation will usually be more prolonged.

In addition, the effects tended to be more localized when the short-ranged alpha-particles were used, while rather diffused responses were obtained with beta-emitters. This is partly due to the fact that the biological beta-emitters, such as Na_{24}, C_{14} and P_{32}, are fairly widely disseminated in the body. Therefore, the effects of such substances will be quite similar to those of an external source, irradiating the whole body.

At the other extreme are a few isotopes, such as $Ba_{140} - La_{140}$, Sr_{89}, Y_{11} and Ra_{229} which produce obvious damage only to those radio-sensitive organs in which they localize.

A stimulating discussion of radio resistance and the causes of radio-sensitivity (primitiveness of cells, mitosis, acquired resistance, etc.) supplies many new points of view on the matter.

Presumably, much of the future work on the subject will be inspired by this book. As it is, it is indispensable, not only to those concerned with the damaging effects of radio-elements, but also to those who are applying radio-elements to the solution of physiological problems and must constantly be careful to avoid the use of harmful doses.

Laboratory and Shop Notes

Tungsten Helical Spring Balance

Samuel L. Madorsky
National Bureau of Standards, Washington, D. C.

November 15, 1949

A SIMPLE tungsten helical spring balance has been developed in connection with a study of rates of thermal decomposition of polymers in a vacuum. This balance was designed for a range 0 to 100 mg, exclusive of a platinum bucket weighing 368.3 mg. It was found to give reproducible results within ±2μ of elongation of the spring which is equivalent to about ±0.013 mg of weight. Previously quartz springs have been used in connection with vacuum work; for example, in the McBain-Bakr sorption balance.[1] However, quartz springs are very fragile and involve loss of time in calibration due to frequent breakage.

A diagrammatic view of the tungsten spring balance is shown in Fig. 1. The spring *A* is made from 3-mil annealed tungsten wire and consists of 45 turns, each turn having an outside diameter of 6 mm. The total weight of the spring including extensions at both ends is about 100 mg. The spring is enclosed in a Pyrex tube and is suspended from a Pyrex rod attached to a ball joint at the top of the tube. The ball joint serves to center the spring in the Pyrex tube *H*. A platinum crucible *G*, weighing 368.2 mg, is suspended from the lower extension of the spring. The spring proper, when hanging free, i.e., without the crucible, is 4 cm long, but with the crucible suspended from it, it is 9.5 cm long. Friction clasps, *B*, serve to hold the spring in place and stretched to its normal length (9.5 cm) when the balance is moved around or when the crucible is removed. The clasps consist of two small brass plates, B^1, padded on the surfaces facing the tungsten wire with thin sheets of rubber. The clasps are attached to brass rods held rigidly in ball joints *C* by means of hard Apiezon wax. By keeping the clasps in a vertical position and sliding the ball joints in opposite directions in a horizontal plane, the spring can be either clasped or released. Crossline *E* consists of 1-mil phosphor bronze wire held to the tungsten extension wire by means of a drop of hard Apiezon wax. The lower part of the glass housing, *K*, is held to the upper part, *H*, by means of a waxed ground joint *F*. A sensitive cathetometer reading to 1μ and provided with a microscope capable of moving in a vertical and horizontal direction was used in connection with the tungsten spring balance.

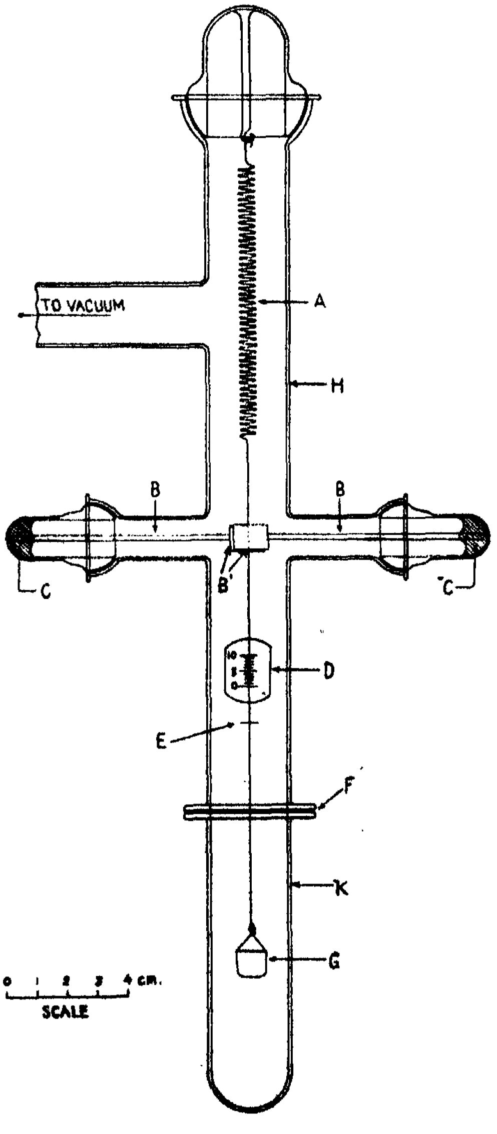

FIG. 1. Tungsten helical spring balance.

Unless the balance is operated in a constant temperature room, the problem of the effect of temperature changes on the tungsten spring balance requires careful consideration. A maximum variation of 10°C will be assumed in this discussion. This variation will affect, in the first place, the rigidity of the spring. The thermal coefficient of modulus of rigidity of tungsten is -6.6×10^{-6} per 1°C.[2] For a 10° change the modulus will change by -6.6×10^{-4}, i.e., by about 0.07 percent, which is negligible. The problem of thermal expansion is more complicated. Here the thermal effect not only on the spring but on the housing of the spring, if the balance is to be used in a vacuum, and on the cathetometer, should be considered. The most suitable material for construction of a housing for the spring is Pyrex glass. It so happens that the linear coefficient of expansion of Pyrex is about the same as that of tungsten:

Tungsten	4.3×10^{-6} per °C[3]
Pyrex	3.6×10^{-6} per °C.[4]

In view of this the position of the crossline *E* will not change appreciably with respect to any reference point on the glass tube *H* because of thermal expansion. However, differences in the linear thermal expansion of the cathetometer and balance housing supports will affect the position of crossline *E* on the tungsten spring with respect to the cross hair in the cathetometer and will introduce appreciable errors in the readings. This source of error is eliminated in this balance by fastening a micro-scale *D* to the inside of the glass tube *H* back of the tungsten extension wire at about the level of the crossline *E*, with the crucible suspended from the spring. This scale is made of glass and consists of 1 cm divided into 0.1-mm unit. By measuring the vertical distance of the crossline *E* to some point on the scale *D* before or after reading the position of this crossline with respect to the cross hair and scale of the cathetometer, any error due to thermal expansion of the cathetometer and balance housing supports will be reduced. The microscope can be focused alternately on the scale *D* or on the crossline *E*.

In order to determine the amount of elongation of the spring per unit weight, calibrated weights of 25, 35, 50, 70, and 100 mg were placed in the platinum crucible and the elongation was noted in each case after 5 min. from the time the weight was put on and after 24 hours. Elongation in microns per mg, on the 5-min readings, varied from 152μ for the 25-mg weight to 151μ for the 100-mg weight. The additional elongation, or elastic creep, during the interval between 5 min. and 24 hours after the start of weighing, was 0.4 percent of the original elongation. Beyond the 24-hour period the creep was very small.

A suspended spring is sensitive to all kinds of vibrations which will interfere with the reading of a reference point on it. In a vacuum the only damping force is the internal friction or viscosity of the material of the spring. In this respect, tungsten with a coefficient of internal viscosity of about 10^{10} poises is by far superior to fused quartz with a coefficient of internal viscosity of only about 10^{6} poises. In a test in a vacuum of about 10^{-6} mm of Hg, the tungsten spring came to rest, after disturbance, in about 10–20 min., while a similar quartz spring, under similar conditions, continued to swing for several hours.

A New Porcelain Rod Leak

H. D. Hagstrum and H. W. Weinhart
Bell Telephone Laboratories, Murray Hill, New Jersey

March 6, 1950

FOR a number of years we have been using in this laboratory a porcelain leak of the type first described by Smythe.[1] As shown at (A) in Fig. 1 it is made entirely of glass and porcelain and incorporates the side mercury by-pass tube, suggested by Bazzoni,[2] for indicating the mercury level inside the porcelain tube. We have found it an excellent leak for our purposes but at best a difficult one to make. The main difficulty arises in the necessity of shrinking the glass into intimate contact with the porcelain tube over the lengths demanded for a reasonably slow leak.

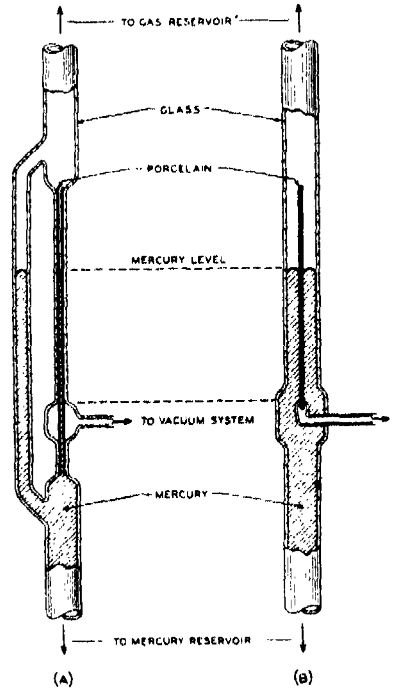

FIG. 1.

The purpose of this note is to present a new form of porcelain leak, shown at (B) in the figure, which, although its principle of operation is the same as the old, possesses several advantages over the old. Here the porous member through which the gas leaks is in the form of a rod rather than a tube.[3] The mercury column surrounds the rod as shown. The leak may be shut off by raising the mercury above the top end of the porcelain and the leak rate increased by increasing the distance of the mercury level below the top of the porcelain as before.

The advantages of this new arrangement are: (1) The glass need be wetted to the porcelain over only a very short length; (2) no side tubing is needed to indicate the mercury level; (3) the porcelain to glass seal is not exposed to the outside thus making it less likely that the seal will crack due to thermal shock if the leak is torched; (4) the glass connection to the vacuum system, which may be subject to strain, here connects to the glass wall of a strong tube and thus cannot transmit strain to the porcelain-glass seal as in the old form. There thus appears to be definite advantages both as regards fabrication and use of the new leak. The rod leak has been used with gas reservoirs filled to 400-mm pressure.

[1] W. R. Smythe, Rev. Sci. Inst. 7, 435 (1936).

[2] C. B. Bazzoni, Rev. Sci. Inst. 8, 171 (1937).

[3] The rod used in this leak is No. 1646 standard refractory ceramic, 0.050 in.–0.060 in. in diameter and 5 in. long, obtained from Stupakoff Ceramic and Manufacturing Company, Latrobe, Pennsylvania. The porcelain is *sealed to a very short section of No. 542 Blue Glass which in turn is sealed to* the standard No. 774 EJ Pyrex.

Data on Porcelain Rod Leak

J. P. Molnar and C. D. Hartman
Bell Telephone Laboratories, Murray Hill, New Jersey

March 6, 1950

WE have found the porcelain rod type of leak described in the preceding note to work very satisfactorily in the arrangement shown in Fig. 1. The lower Y cut-off permits pumping out the connecting tubing between the gas bottle and leak before the break-off tip is shattered. The upper Y cut-off permits a sudden shut-off of gas flow from the leak. If the flow is shut off only by covering the porcelain rod completely with mercury, the gas which is still trapped in the rod will continue to flow for several minutes longer.

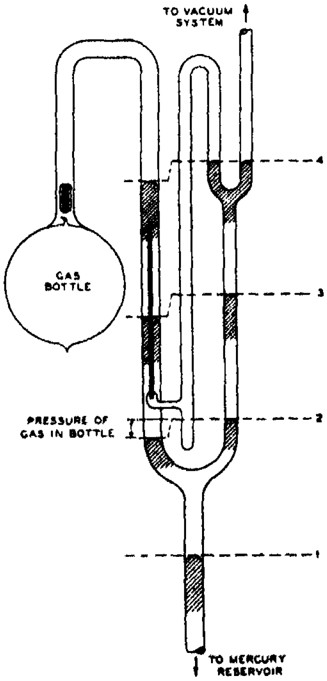

FIG. 1.

Four levels are indicated for the mercury column. The height of the mercury reservoir is so adjusted that when the reservoir is at atmospheric pressure the mercury column rises to level 2. During the bake-out and exhaust of the leak and connecting tube, the mercury is pumped down to level 1. When the leak is in use, pressure is applied to the reservoir (by means of a squeeze-bulb of the kind used in a physician's blood pressure-measuring equipment) to raise the mercury to some level as indicated by 3. Level 4 indicates the condition of cut-off. With this arrangement, if the applied pressure is inadvertently removed, say by a leak in a stopcock, the gas cannot be lost through the lower Y cut-off.

The resistance offered to gas flow by this leak is proportional to the length, l, of the porcelain rod wetted by the mercury and glass seal at the bottom of the rod. For a rod 0.055 in. in diameter we measured a leak rate of (1.0×10^{18}) p/l molecules per second for nitrogen gas, where l is expressed in cm and p is the pressure in millimeters of mercury in the gas bottle. (The pressure on the other end of the leak is, of course, negligible in comparison with p.) Our porcelain rods are 13.1 cm long (max. value of l), while the length of the glass seal is 0.33 cm (min. value of l). Thus we have a controllable range of 40 to 1 in leak rate with our units.

Rubber Tubing Pump*

John W. Weigl† and Donald W. Stallings
Radiation Laboratory, University of California, Berkeley, California

January 30, 1950

ALTHOUGH rubber tubing pumps appear to be used for gas circulation in a number of laboratories, it seems that each group has had to invent one for itself. For this reason, a brief description of a useful model is presented here.

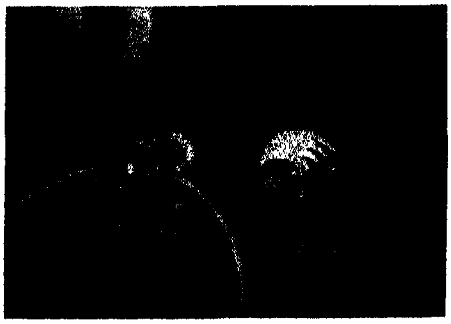

FIG. 1a.

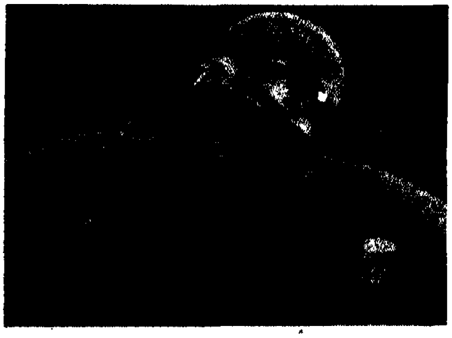

FIG. 1b.

Its mode of operation may be recognized from Fig. 1. One after another, the four rollers at the corners of the square rotor compress a piece of rubber suction tubing, pushing the gas ahead of them, each roller blocking a new gas pocket before the last has been lifted off. The speed may be controlled from about 100–1500 cc/min. by means of a set of step pulleys, as well as by adjustment of the hinged tubing race, and by changing the size of tubing used. If the rollers run smoothly, a piece of amber pure gum suction tubing outlasts between ten and thirty hours of operation.

The main virtues of this type of circulating pump are the smooth flow and negligible hold-up, the lack of metal parts and lubricant in contact with the gas, its rugged construction and ability to withstand evacuation without leakage around shafts and bearings. It may be used for pushing or re-cyling gas, or for the well-controlled evacuation of a closed system to less than one millimeter pressure.

Scintillation Counter for Neutrons

Kuan-Han Sun and W. E. Shoupp
Westinghouse Electric Corporation Research Laboratories, East Pittsburgh, Pennsylvania

January 30, 1950

DURING the development of the scintillation counter for α-, β- and γ-particles at these Laboratories, it was immediately apparent that the scintillation counter may be used for detecting neutrons in the same manner, though not with the same efficiency, as is used for α-particles provided that certain materials which intercept neutrons to yield energetically charged particles are introduced into the phosphor. The first qualitative test was carried out in April, 1947 by using a powdered mixture of Patterson D, ZnS phosphor and anhydrous B_2O_3 mixed in polystyrene dope and painted on a 931A photo-multiplier tube. The neutron pulses observed were about the same order as those of α-particles from uranium on the same phosphor. In the subsequent experiments, a powdered mixture of ThO_2 and ZnS phosphor, or $UO_2(NO_3)_2 6H_2O$ and ZnS phosphor painted on the surface of a 931A photo-multiplier tube was used to observe the scintillations due to fission by neutrons. The photo-multiplier was operated with a circuit similar to that used by Coltman.[1] Visual observation on an oscilloscope indicated that fission pulses due to fast neutrons from the cyclotron deuterons (15 Mev) on a thick Cu target, were several times higher than those due to α-particles from uranium, and somewhat higher than the highest pulses from proton recoils from the polystyrene

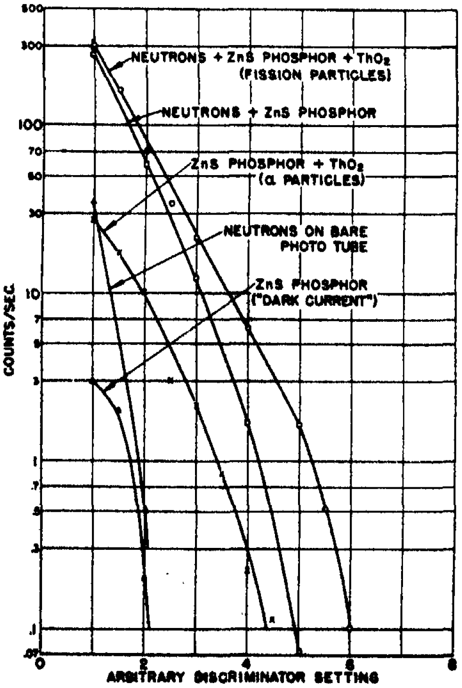

FIG. 1. Pulses from scintillation counter for fast neutrons.

dope and protons and α-particles produced in the phosphor (without fissionable components) by the fast neutrons. In observing fission pulses, it was found necessary to set the gain of the amplifier below the saturation limit. The gradual decrease of light transmission with increasing thickness of powdered phosphor, however, results in a continuous distribution of the pulses. These are shown in Fig. 1 which indicates that the number of counts decreases continuously with the raise of negative bias voltage or discriminator settings. Figure 1, however does reveal that (1) fission pulses can be distinguished from proton recoils or protons and α-particles formed due to fast neutrons on ZnS phosphor or carbon; (2) ZnS phosphor with hydrogeneous materials (polystyrene dope) also may be used for detecting fast neutrons. Knowing the number of α-counts per unit weight of ThO_2 used through other experiments, it was possible to deduce the "effective" weight of Th in the phosphor by measuring its total number of α-pulses. By assuming a fission cross section, 0.15 barn for Th by fast neutrons based on data by Ladenburg *et al.*[2] and Agens *et al.*,[3] it was found that the neutron flux at 181 cm in the forward direction from the Cu target by 15-Mev deuteron bombardment was 1.5×10^4 and 7.5×10^4 neutrons/cm²/sec./μa deuteron for arbitrary discriminator settings 3 to 1 respectively (Fig. 1). A corresponding value of the neutron flux deduced from the $S^{32}(n,p)P^{32}$ neutron threshold detector of a later date[4] gave 1×10^4/cm²/sec./μa deuterons. The agreement is favorable considering the complexities involved in the response of Th and S threshold detectors for various energies of fast neutrons and also in the different schemes of detection. The scintillation counter for detecting neutrons has low efficiency because of the poor light transmission of the powdered ZnS phosphors. The above work, however, indicates that a quantitative counter, perhaps using a thin layer of ZnS with U^{235} or Pu^{239}, may be constructed without any interference from background due to intense γ-rays, or other energetic charged particles.

The authors would like to express their appreciation to Dr. J. W. Coltman for his constructive criticisms and to Dr. A. J. Allen for the use of the University of Pittsburgh cyclotron.

A Device for Measuring the High Voltage for a Photo-Multiplier Tube

INGVAR NILSSON
Laboratory for Nuclear Chemistry, Chalmers Institute of Technology, Göteborg, Sweden

February 13, 1950

WHEN using a photo-multiplier tube as a scintillation counter, it is necessary to hold the high voltage constant within 1 volt. This can be accomplished by using an electronic voltage regulator. It is, however, of great importance that the voltage can be measured with the same accuracy.

It is possible to construct a device fulfilling this requirement by comparing the unknown voltage with the voltage from a RCA 5651 voltage reference tube. This tube is guaranteed to hold the voltage constant within ±0.1 volt. By this method it is possible to subdivide the interesting interval, say 500–1000 volts, in intervals of for instance 100 volts, each interval giving full scale deflection on a meter. The error introduced by the uncertainty in the reference voltage will be of the order 0.1 percent, e.g., 1 volt at 1000 volts.

In order not to overload the meter, it is necessary to know the voltage approximately and to set the voltage selector for the meter at a correct position. This difficulty may be overcome by combining the selector with the voltage control.

The basic circuit is shown in Fig. 1. The values of the components R_1, R_2 and R_3 may be obtained from the equations

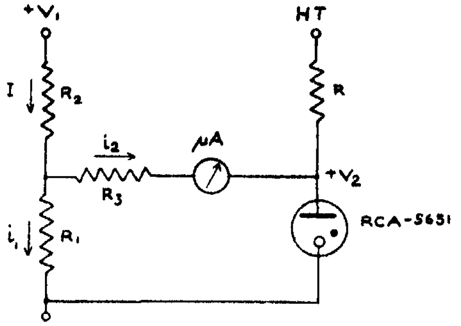

FIG. 1.

$$V_2=R_1i_1-R_3i_2 \qquad (1)$$

$$V_1=[R_2+R_3((R_2/R_1)+1)]i_2+V_2(1+(R_2/R_1)). \qquad (2)$$

In Eq. (1) R_1 may be chosen so that $i_2=0$. Then $R_1=V_2/i_1$, where i_1 is given a suitable value. The values of R_2 and R_3 are obtained from Eq. (2) by requiring that for a certain value of V_1 the meter should read zero, and for a voltage a certain amount higher the meter should have full scale deflection.

As an example a voltmeter using a 100 μa meter and covering the range 600–1100 volts is given in Fig. 2.

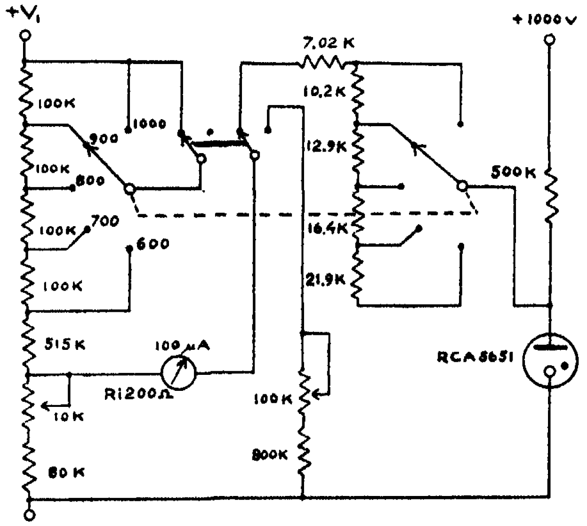

FIG. 2.

The work was performed under the auspices of Atomkommittén, Stockholm.

Further Techniques in Single-Crystal X-Ray Diffraction Studies at Low Temperatures*

S. C. ABRAHAMS, R. L. COLLIN,† W. N. LIPSCOMB, AND T. B. REED
School of Chemistry, University of Minnesota, Minneapolis, Minnesota

January 23, 1950

IN the course of some recent studies of the structure of a series of crystals melting in the range 0° to −40°C, it became necessary to extend the techniques already in use.[1] The resulting methods have enabled us to grow rapidly good single crystals, and to preserve them for sufficient lengths of time to record nearly all the possible (hkl) reflections.

The general method is very similar to that described by Kaufman and Fankuchen. The liquid to be examined is sealed into a glass capillary and maintained solid by blowing a stream of cold air over it. We have now applied this method for use both with Weissenberg and Buerger precession cameras. The capillaries are of uniformly drawn out Pyrex tubing less than 1 mm in cross section with wall thickness about 0.05 mm. The liquids are introduced into the capillaries either by direct distillation from a vacuum line, or by immersing the whole capillary, which is about 1 cm long and has one end previously sealed off, and which has a longer and very fine capillary tube inserted into it, in the liquid. It now readily fills, and then the other end is sealed after cooling the remainder of the capillary tube in a block of dry ice.

The cooling air is taken directly from a compressed air line, passed through a series of drying agents, and then passed through a copper spiral tube immersed in a dry ice-sec. butyl alcohol mixture. It is then led to the capillary through a vacuum jacketed glass tube, as shown in Fig. 1. The pressure of air just before entering the heat exchanger is about 1 cm Hg, and this arrangement permits a steady stream of cold air to be delivered without further attention for periods up to ten hours. A uniform temperature is maintained close to the specimen by mounting the capillary at the apex of a 120° cone, which is made from a Plexiglas block: this holder is readily attachable to the goniometer head. The thermocouple junction is placed about 2 mm from the tip of the specimen, to obtain an accurate measure of its temperature.

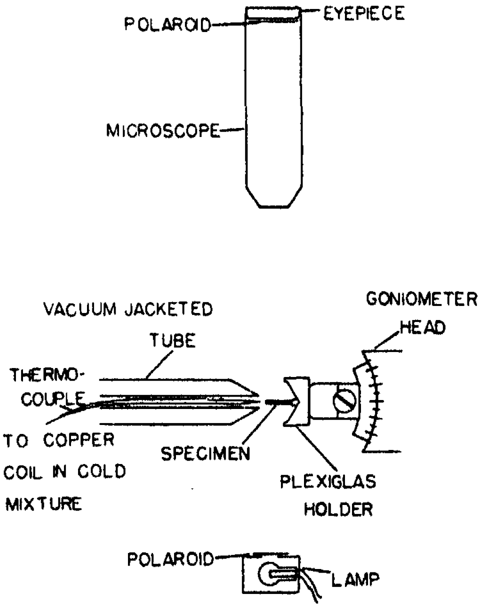

FIG. 1. Low temperature single crystal arrangements.

The crystal is grown by the following procedure, in which the progress of crystal growth may be continuously viewed through a simple polarizing microscope, of about 6–10 magnifications. The specimen may sometimes be solidified by lowering the temperature to about 5° below its melting point, but frequently the liquid supercools to such an extent that a thermal-shock must be applied, either by touching the side of the tube with a piece of dry ice, or even by pouring liquid nitrogen over the specimen. The temperature is then raised to just beneath the melting point, and the solid in the tip of the capillary is then melted by directing a fine controllable jet of dry warm air on to it. On removing this local source of heat, crystal growth will occur until the tip is again solid, and if the temperature is adjusted so that the rate of growth is only just discernible, it is very likely that the newly grown portion will consist of several single crystal fragments. The remainder of the microcrystalline solid is then melted in the same manner with growth now originating from the tip. This often gives rise to a good single crystal immediately, but if not, the procedure is repeated by again melting the tip, followed by fresh growth from the resulting crystal. In this manner, a good single crystal will usually be obtained in a matter of minutes.

To avoid condensation of ice on the capillary, the room in which this work was carried out was dehumidified, so that the vapor pressure of water was about 5 mm. With this condition satisfied, temperatures as low as −55°C have been maintained for extended periods, with a very small amount of ice formation, and this could readily be brushed away, thus doing away with the use of troublesome shields. This technique was developed in conjunction with a Buerger precession camera, which has the advantages that the specimen is very easily accessible, and that once a single crystal is obtained, a large volume of the reciprocal sphere is readily explorable, using MoK_α radiation. With the present cooling arrangement, the precession angle has a maximum of about 23°, corresponding to about $\sin\theta = 0.4$. It is found advantageous to obtain preliminary unit cell and space group data in this way, and then to regrow the crystal on, or transfer to, a Weissenberg camera for a more complete record of the reciprocal lattice. The camera we used is similar to that described by Buerger,[2] for which it was found necessary to construct a new film holder of radius about 4.5 cm, and with a portion subtending about 70° cut out of the back reflection area on the lower side of the holder, so that it could be slipped over the glass vacuum jacket without having to disturb the crystal.

These methods have been successfully applied to hydrazine, hydrogen peroxide, and thiophene, and their crystal structures will be published in detail elsewhere.

The present cooling system may readily be adapted to give a supply of air at temperatures down to −120°C by the use of a second cooling coil immersed in liquid nitrogen. At such temperatures, some shielding device becomes necessary to prevent ice formation on the specimen. It appears possible to construct a set of thin cellulose acetate shields which could be easily removed and so retain access to the capillary. At least certain convenient developments of low temperature techniques appear to lie in such directions, and also in increasing the present precession angle of the Buerger camera, so as to obtain the maximum range from this instrument.

An Instrument for Mechanically Differentiating Curves

ARNOLD H. SCOTT
National Bureau of Standards, Washington, D. C.
November 17, 1949

DURING the late war, a group at the National Bureau of Standards, working on the internal ballistics of guns, differentiated displacement-time curves to get velocities and then differentiated the velocity-time curves to get accelerations. These differentiations were made using a protractor to measure slopes, obtaining the tangents of the angles, multiplying by their proper factor, and plotting the results. In an effort to eliminate a large part of this work, a Coradi integraph[1] was modified by the writer so that it could be reversed to differentiate curves and plot the derivative ordinates directly on graph paper.

The modification consisted in removing the pen (*A*) (Fig. 1) and attaching to the pen holder (*B*) a frame (*I*) which had an index glass taken from a slide rule attached to its feet. A short line was ruled perpendicular to the long line to indicate the point of

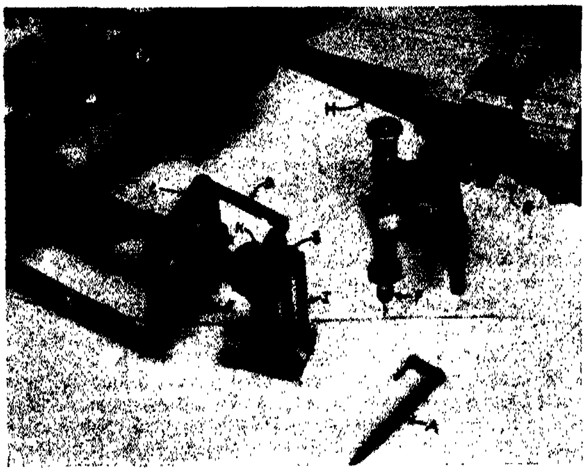

FIG. 1.

measurement. The index frame is rotated with the guide wheel frame (*C*) by means of the link (*D*) so that the long line on the index glass is always parallel to the plane of the guide wheel (*E*). Its angular position is controlled by the position of the pointer (*F*) and the position of the clamp (*G*) on the graduated arm (*H*).

To differentiate a curve the instrument is adjusted so that it rolls parallel to the abscissa of the curve, the guide wheel (*E*) being held off the paper by the lifting screw. With the carriage of the graduated arm (*H*) locked in its zero position the pointer is adjusted to zero and the index frame is adjusted until the long line is parallel to the abscissa. The carriage is then released and the instrument and carriage are moved until the intersection of the index lines is at the point where the differentiation is desired. The pointer is then moved until the long index line is parallel to the curve as viewed through the pen opening (*K*). The pointer is then pressed into the paper to constitute one point of the plot.

The distance (*X*) along the graduated arm at which the clamp (*G*) should be set is computed from

$$X=Q/PR,$$

where P is the value per unit distance of ordinate for the derivative curve, and Q and R are the values per unit distance of ordinate and of abscissa respectively of the curve being differentiated. Since the scale on the graph paper may be slightly different from that on the instrument the setting should be checked by setting the pointer on an ordinate value equal to X. If the long index line is not parallel to a line having a slope of 45° then adjustment of the setting of the clamp (*G*) on the graduated arm must be made.

To test the accuracy of this method a selected curve was integrated using the Coradi instrument as an integraph. The resulting integral curve was then differentiated using both the present reversed-integraph method and the previously mentioned protractor method. The error was assumed to be the difference between the original curve and the derivative curve. This included the errors of integrating the original curve. The average error was 2.10 percent for the reversed-integraph method and was 3.08 percent for the protractor method. The main error is probably in setting the index line tangent to the curve and this problem is common to both methods.

The advantage of the reversed-integraph method is that it is much faster than the protractor method. A disadvantage is that the slope which it can differentiate is limited to about 66 degrees and that range can only be obtained if the clamp is set at eleven cm or less. The most practical range for the clamp setting is between 15 and 25 cm. If the clamp is set at 25 cm the maximum slope is 45 degrees.

High Power Pulsed Magnetron with Replaceable Cathode

M. F. AMSTERDAM AND W. E. DANFORTH
Bartol Research Foundation of The Franklin Institute, Swarthmore, Pennsylvania

January 16, 1950

A NEED has been felt for some time in this laboratory for a magnetron whose cathode would be readily replaceable. The specific type of magnetron involved is the 4J32, a 12-vane high power pulsed tube of 10-cm wave-length, a tube which is normally supplied with a radial cathode mounting.

In order to achieve cathode demountability it seemed that an axial mounting would be more practical and Fig. 1 shows the general plan of our first attempt in this direction. Having secured encouraging performance with the present design, future effort will be directed toward greater compactness which will probably call for a permanent magnet rather than the present cumbersome electromagnet.

The cathode is of the thoria sleeve type with tungsten heating coil inside the sleeve. Heater power is brought in axially by a rod and concentric pipe which go through one pole-piece and also serve to support the cathode. The tube is continuously pumped through one of the holes in the anode block originally intended for a radial cathode lead.

Pole pieces are brazed to the anode block, and the cathode assembly is passed through the hole bored in the pole-piece, the seal being made with a rubber gasket.

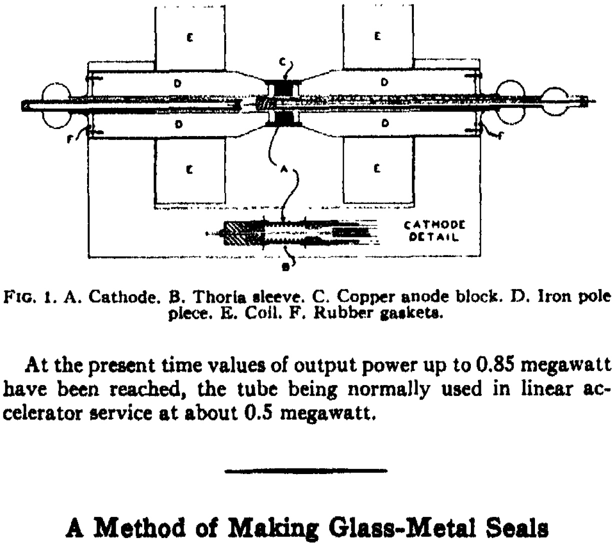

FIG. 1. A. Cathode. B. Thoria sleeve. C. Copper anode block. D. Iron pole piece. E. Coil. F. Rubber gaskets.

At the present time values of output power up to 0.85 megawatt have been reached, the tube being normally used in linear accelerator service at about 0.5 megawatt.

A Method of Making Glass-Metal Seals

N. A. ECKSTEIN, J. W. FITZGERALD, AND C. A. BOYD
The University of Wisconsin, Naval Research Laboratory, Department of Chemistry, Madison, Wisconsin

February 13, 1950

GLASS to metal seals have been made at this laboratory by an electroforming process. These seals have been found to be vacuum tight and reasonably insensitive to thermal shock.

The essential features of the method are illustrated in Fig. 1 which shows the steps involved in making a joint between a Pyrex glass tube and a copper tube.

In Step 1 the glass tube is coated on one end with a ceramic type silver paint.[1] This is then fired on the tube to produce a strong glass-silver bond and to make the coat conducting.

In Step 2 a wax form is inserted in the coated end of the tube. This form will determine the shape of the connecting copper tube.

The wax form is then made electrically conducting[2] as illustrated in Step 3, and then a layer of copper is electro-plated over the entire surface. The current density is adjusted so as to produce a smooth surface and the thickness of the copper tubing so formed is

---

[1] Manufactured by G. Coradi, Zurich, Switzerland.

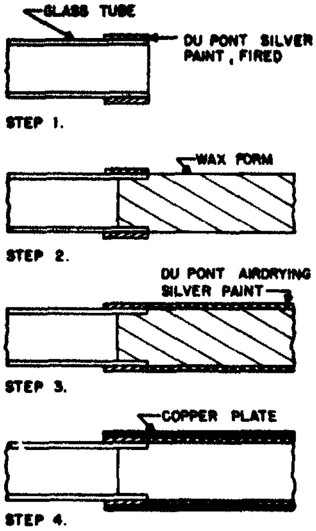

FIG. 1. Steps involved in making a glass-copper joint.

determined by the plating time. The net result after this treatment is illustrated in Step 4. The wax form can then be removed by heating the copper-glass joint which melts the wax.

Joints between Pyrex and copper tubing made in this manner have been heated up to 300°C without breaking. They have also been found to be vacuum tight.

This same general method has been used successfully to electroform quartz crystal electrodes and mounts for ultrasonic apparatus and to seal glass windows on metal cells. Joints between quartz tubing and Pyrex tubing have also been made by electroforming a short copper tube between the two.

---

[1] Obtainable from the E. I. du Pont de Nemours and Company, Inc., Electrochemicals Department, Wilmington 90, Delaware as Ceramic Silver Paint No. 4666.

[2] This may be accomplished in several different ways. However, it has been found convenient to use an air-drying conducting silver paint obtainable from the du Pont Company.

Improved Double-Crystal Spectrometer for Small Angle Scattering Measurements

LEO BROUSSARD
Esso Laboratories, Esso Standard Oil Company (Louisiana Division), Baton Rouge, Louisiana

November 3, 1949

IN experiments dealing with small angle scattering of x-rays the important measurement to be made is the determination of the resulting angular spread of intensity of a monochromatic beam of x-rays after this beam traverses the specimen. The field of interest in this type of work is usually less than 2 degrees on each side of the central undeviated beam. In using an ordinary double-crystal spectrometer for this work, one crystal is fixed in position to produce a monochromatic beam which is directed through the specimen. The angular divergence of x-rays produced by the sample is then determined by rotating the second (or analyzing) crystal through the range of angles required to allow these divergent rays to strike the second crystal at the proper angle of incidence to produce reflection. The reflected x-rays are usually detected with a Geiger-Müller counter. Because of the small angles involved, the counter is sometimes fixed in a permanent position and sometimes moved through twice the angle through which the analyzing crystal is rotated. It is the purpose of this paper to indicate a simple method for overcoming the disadvantages of the present methods.

It is important to remember the difference between the type of reflection occurring when x-rays are reflected by crystals and that of ordinary light reflecting from a plane mirror. In the case of light reflecting from a plane mirror, reflection occurs at all angles of incidence in such a way that the angle of incidence equals the angle of reflection. For monochromatic x-rays reflecting from one set of crystal planes, the angle of incidence still equals the angle of reflection, but reflection will take place for only one particular angle of incidence for a first-order reflection. This fixes the angle of reflection for a given wave-length and a given set of crystal planes, so that the counter tube should be rigidly attached to the crystal in order to maintain a constant angle of reflection between crystal and counter. In this manner the counter is always at the proper position to receive reflected radiation provided the crystal is oriented at the proper angle of incidence for the particular divergent ray being measured.

Reference to Fig. 1 indicates in an exaggerated way the manner in which reflections from the second crystal take place. *MO* represents the main undeviated beam striking the second crystal at its axis of rotation *O*. Another ray *MA* scattered by the specimen strikes the crystal at *A* and does not reflect because the angle of incidence is not correct. Rotating the crystal to the new position (dotted) allows ray *MA* to strike the crystal at *B* making the proper angle of incidence and reflecting to the counter along *BC*. As shown the counter should be coupled directly to the crystal. Now it can be seen that the ray *MOC* does not reflect from the same region of the crystal as ray *MBC*. This displacement requires that the surface characteristics of the crystal be taken into consideration. Also, this displacement can cause the reflected ray *BC* to strike a portion of the counter tube which is different from that portion struck by reflected ray *OC*. This effect can give rise to erroneous readings of intensity since the sensitivity of counter tubes is affected by the point of incidence and the direction of the x-ray beam striking the counter.

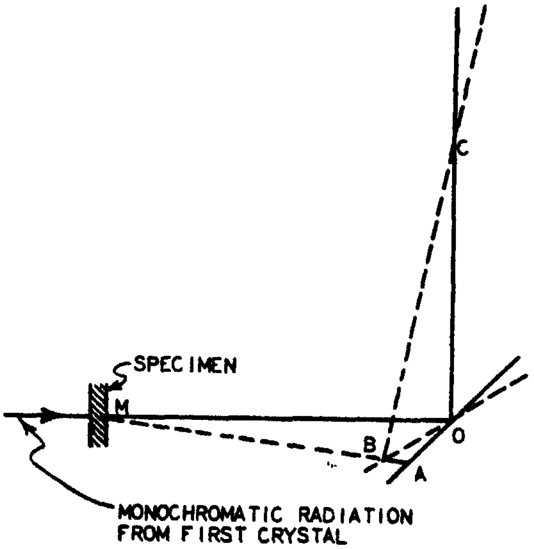

FIG. 1. Reflections from second crystal.

In order to eliminate these difficulties the second crystal is rotated about *M*, the center of the specimen, instead of about *O*. In this way the ray *MA* will strike point *O* when the crystal is brought around to the proper position for optimum angle of incidence. The same portion of the analyzing crystal is used for measurements of all rays and all the reflected rays strike the same portion of the counter.

This improved instrument consists of these main parts. A first crystal is used to produce a monochromatic beam of x-rays. A

Geiger counter is permanently coupled to the second crystal at the proper angle of reflection for this monochromatic radiation. The second crystal and the Geiger counter, as a unit, rotate about the center of the specimen in order to analyze the angular divergence of x-rays emerging from the specimen.

Apparatus and Method for Testing Radium or Thorium Capsule Seals

R. J. Beal

Health Radiation Branch, National Research Council, Atomic Energy Project, Chalk River, Ontario

February 6, 1950

SEALED radium capsules, after equilibrium has been reached, contain radon and radon decay products. Similarly, thorium capsules contain thoron and thoron decay products when equilibrium conditions have been established. In both cases the decay products or active deposits are solids which attach themselves to dust particles. The active deposits are strongly alpha-active, the radium active deposit having a half-life of about 50 minutes and the thorium deposit a half-life of 10.5 hours.

The method here described depends upon the fact that the source capsule while under test, will expel a part of the emanation and accompanying decay products, if the seal is faulty. The expulsion of the emanation is achieved by heating the capsule by a steam jacket to about 100°C. It has proved convenient to collect the active deposit by carrying out the heating with the source placed in the collecting volume of an electrostatic precipitator. The particulate activity precipitates on the inner surface of a removable cylinder, which forms the outer electrode of this precipitator assembly. The activity could no doubt be collected by the long established method of collection on an electrode charged negatively to a few hundred volts. Counting has been done by making the collecting cylinder the outer electrode of a methane-filled cylindrical proportional counter. A very high counting efficiency is thus secured.

The apparatus, as shown in Fig. 1, consists of a cylindrical precipitator with a central electrode at 10 kv positive potential relative to the collecting cylinder. The source under investigation is placed in a cup which slides into position at the base of the cylinder. The complete precipitator and source assembly is surrounded and supported in a steam jacket. The steam jacket is carefully sealed from the precipitator assembly to ensure that moisture does not interfere with precipitation.

The first step in the procedure consists of placing the source in the source cup which is then elevated and locked in position in the precipitator base. Then the steam is turned on and allowed to circulate during the entire time of the test. High tension is applied to the h.t. electrode for 90 minutes. The equipment described above requires about 30 minutes to reach operating temperature of 90°–100°C and a total testing time of 90 minutes is used so that an hour of precipitation occurs at maximum temperature of the test. The collector as used fits into a methane proportional chamber for counting.

Some typical results secured with the method outlined above are given.

(*a*) *A radium-beryllium source of 200-mc nominal value.*—This source gave a precipitation which counted 1500 alpha-c.p.m. It is interesting to note that when this source was held in the apparatus at 10 kv for 24 hours *at room temperature*, only 30 c.p.m. were collected on the tube.

(*b*) *A radium needle of 1-mc nominal value.*—This source gave a precipitation which counted 77 alpha-c.p.m.

(*c*) *Sources ranging in value from 1 mg to 1.2 g.*—A number of sources, ranging in value from 1 mg to 1.2 g, were checked and most of these, when subjected to the test, gave counts within 10 c.p.m. of the normal background of the counter, indicating a satisfactory source seal.

(*d*) *Effect of radium contamination on the exterior of the capsule.*—Monel metal cylinders approximately the same size as a source capsule were prepared with surfaces varying from a high polish to an extremely rough, pitted surface. These monel cylinders were heavily contaminated with radium sulfate. On precipitation only the cylinder with the roughest surface gave any appreciable counts above the normal background, namely 5 c.p.m. Thus, it would appear that surface contamination under normal capsule conditions has little or no appreciable effect on the results of the test.

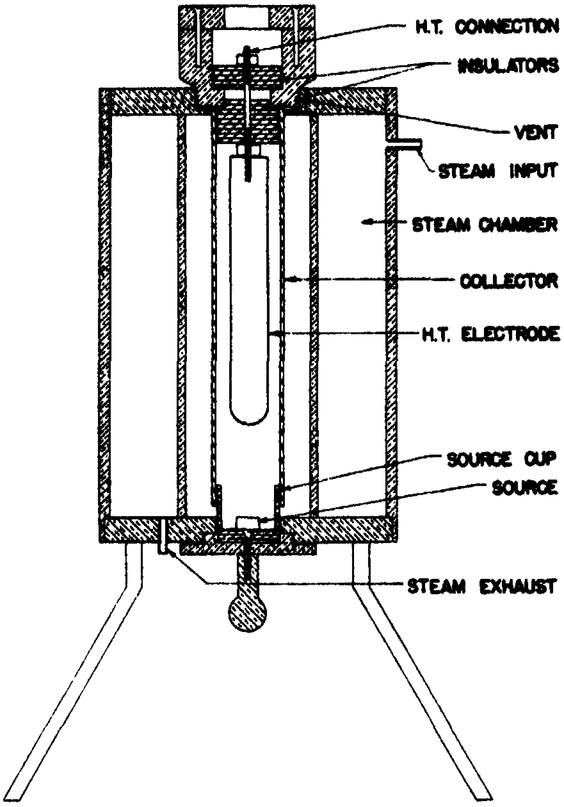

FIG. 1. Radium and thorium capsule seal tester.

Automatic Level Controller for Liquid Nitrogen

E. H. Quinnel and A. H. Futch

Naval Research Laboratory, Washington, D. C.

January 30, 1950

ON many occasions there is a need for an automatic level controller in cryogenic research involving low temperature liquid baths. It is desirable that such a device be simple in construction, positive in operation, occupy as little space as possible, and in case of malfunction, will be fail-safe.

Level controllers utilizing floats,[1] vacuum systems,[2] or vapor pressure thermometers[3] as the sensitive elements have been developed but space requirements limit the application of these devices. The controller to be described uses a resistor as the sensitive element and, therefore, has nominal space requirements.

The controller utilizes the difference in heat dissipation of a liquid and its vapor to establish a large change in the temperature of a resistor dissipating power when its environment changes from liquid nitrogen to the gaseous nitrogen immediately above the liquid. With a five-watt input to a small copper coil, the temperature change for the conditions described above results in a resistance change of a factor of about six. This resistance change is sufficient to operate a low resistance relay in a constant voltage circuit.

The circuit diagram for the controller is given in Fig. 1. The sensitive element C, a coil of approximately 24 feet of A.W.G. 40 copper wire, is connected in series with a six-volt storage battery E and a normally closed relay R. When the sensitive element C is above the level of the liquid nitrogen in Dewar D_2, the resistance of C is large (order 18 ohms) and the current in the circuit is too small to actuate the relay R. Thus, the relay contact completes the 110-volt circuit, supplying power to the heater H[4] and closing valve V. Pressure builds up in the Dewar D_1, and liquid nitrogen is transferred to Dewar D_2.

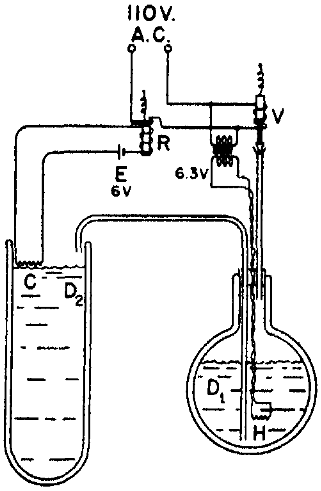

FIG. 1.

When sufficient liquid nitrogen has been transferred to immerse the sensitive coil C, the resistance of C becomes small (order 3 ohms) and the current in the circuit is now sufficient to actuate the relay R. Actuation of the relay breaks the 110 volt circuit thus cutting off the power to heater H and opening valve V. The pressure in Dewar D_1, is reduced and transfer of the liquid ceases until the liquid level again falls below coil C. If it is desired to protect the controller against an accidental opening of the battery circuit, a minimum current relay controlling the 110-volt power input to the system can be installed.

The level controller as built has operated satisfactorily for periods of 48 hours and maintains the desired level of the liquid nitrogen to within ±3 millimeters.

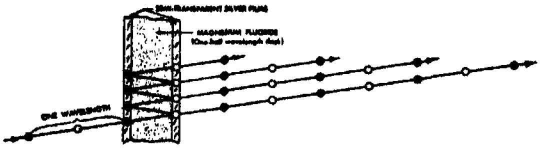
New Instruments

W. A. Wildhack: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

These descriptions are based on information supplied by the manufacturer and in some cases from independent sources. THE REVIEW *assumes no responsibility for their correctness.*

Interference Color Filter

Wide application in the fields of color television, photography, refractometry, and astronomy are foreseen for this new development. The filter consists of two semi-



SEMI-TRANSPARENT SILVER FILMS
MAGNESIUM FLUORIDE (One-half wavelength thick)
ONE WAVELENGTH

TRANSMISSION TYPE INTERFERENCE FILTER

transparent, silver films separated by a magnesium fluoride film of a given thickness. As a light ray passes through the filter, part of it is reflected back and forth between the silver films with some of it emerging at each reflection. Wave-lengths equal to twice the thickness of the magnesium fluoride film emerge in phase, and therefore maximum transmission occurs for that particular wave-length; at the same time interference occurs for other wave-lengths and effectively monochromatic transmission is obtained. The color transmitted is determined by the distance the multiple reflections must travel which, in turn, is determined by the thickness of the fluoride film and the angle of incidence of the light. Both transmitting and reflecting type filters are available.—BAUSCH & LOMB OPTICAL COMPANY, *Rochester 2, New York.*

Improved Ultra-Sensitive D.C. Amplifier

This new and improved d.c. amplifier of the General Motors breaker type offers many advantages in the measurement of d.c. and low frequency a.c. voltages in the microvolt and fractional level thermocouple voltages, infra-red detectors, photovoltaic cells and the like. It can be used to replace suspension galvanometer systems.

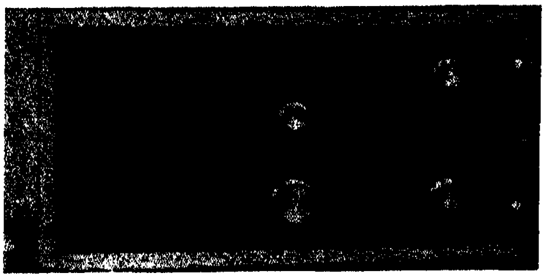
This new amplifier (Model 10) features very high immunity to the effects of a.c. pick-up in the input circuit. The discrimination ratio against 60-cycle pick-up is over 1000. It has an improved life breaker. Convenient and accurate coarse and fine gain controls, zero position controls and calibration signals are provided.

This instrument has a zero stability of better than 0.005 μv per day after warm-up. The noise level approaches the limit imposed by the Johnson noise of the external circuit. This amplifier is available for operation with input circuits from 0 to 1 megohm. The d.c. output of the amplifier is sufficient to operate standard recorders, milliamperemeters and d.c. relays. For 110 volts, 60-cycle operation. Price $580.00.—LISTON-FOLB, *Department M, Box 1334, Stamford, Connecticut.*

Ultra-Low Frequency Oscillator

A new, wide range, ultra-low frequency oscillator Model 410-A combines the sub-audio with the normal audiofrequencies and provides both sine and square wave outputs over the entire frequency range from 0.02 to 20,000 c.p.s. Six frequency bands are provided, each covering a full decade, with continuous control of frequency. A single, 11-in., illuminated, direct reading logarithmic scale is used on all bands.

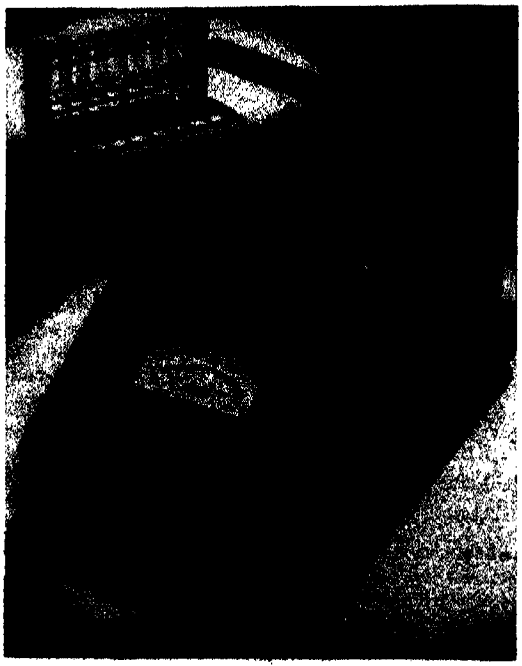
The sub-audio range of frequencies makes the unit especially useful for design and test of servomechanisms, control instruments and feed-back amplifiers, for vibration checks and medical research, and in conjunction with timing and production controls. The square wave output is useful for low frequency switching and triggering operations and for checking the frequency or transient response of audio circuits.



This instrument features low distortion and hum level, constant output impedance, excellent frequency stability and amplitude constancy over the entire frequency range. An important feature of a sub-audio electronic oscillator is its ability to recovery quickly from band-switching and similar disturbances. The sine wave output of the 410-A recovers to 90 percent of its steady-state amplitude in less than two cycles of the dial frequency.—Krohn-Hite Instrument Company, *580 Massachusetts Avenue, Cambridge 39, Massachusetts.*

Industrial Rouy-Photrometer

Designed to speed routine processing analyses, the new Industrial Rouy-Photrometer provides the highest accuracy obtainable in colorimetric absorption analysis. This greatly improved type of photoelectric colorimeter gives concentration readings in which inherent functional error is cut to within 0.1 percent. Such a high degree of accuracy is made possible for the first time by careful matching of the photoelectric cell and the microammeter, which results in strict linearity of current *vs.* light energy.



Operation of the Rouy-Photrometer is rapid and simple, with a single control for all adjustments, and once calibrations have been set up, no special skill or calculation is required of the operator.

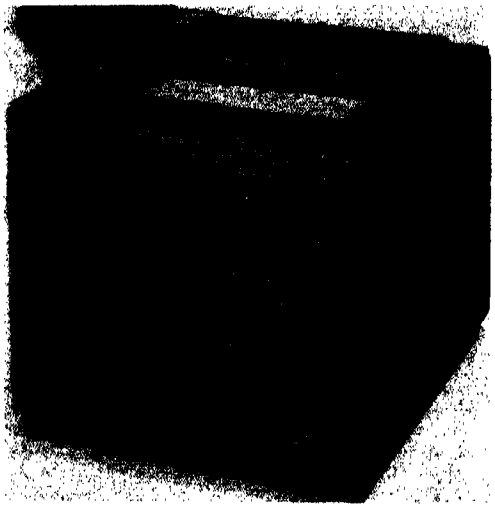
Maximum reproducibility, so important in efficient process control, is assured for identical readings on the same specimen can be obtained by different workers, even on different Photrometers.

Highest selectivity over the entire visible spectrum is another outstanding Photrometer advantage. Each instrument is equipped with a set of ten compound compensating glass filters. The filters are mounted in one rotating plastic disk which rotates within the Photrometer. Two blank spaces are provided for filters required in special work. Each filter and filter element is controlled in production and matched to produce identical transmission curves.

The Rouy-Photrometer is a single cell, line-operated instrument. On special order, it is adaptable to 6-volt d.c. operation. It is available complete with four absorption cells, one sealed H_2O absorption cell, plastic insert, dust cover, and handbook.—E. Leitz, Inc., *304 Hudson Street, New York 13, New York.*

Variplotter

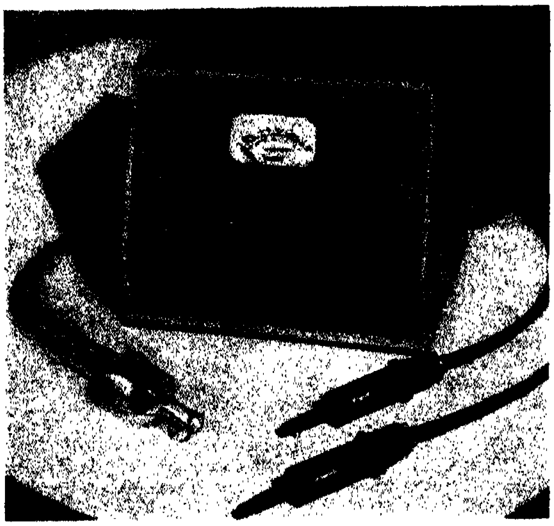
The Model 205 variplotter is designed to record one variable as opposed to another in any application where the functions may be represented by varying d.c. voltages, such as electron tube characteristics, temperature-pressure curves, wind-tunnel data, industrial processes, etc. The plotting surface is a back-lighted, 30-in. glass square over which the plotting paper is positioned.



Sensitivity is 50 mv/in. with other ranges also available, and the pen can traverse the board in either X or Y direction within three seconds. Accuracy is 0.05 percent of full scale at a temperature of 68°F for static conditions and 0.1 percent for dynamic conditions. —Electronic Associates, Inc., *Long Branch, New Jersey.*

Thermocouple and Ionization Type Vacuum Gauge

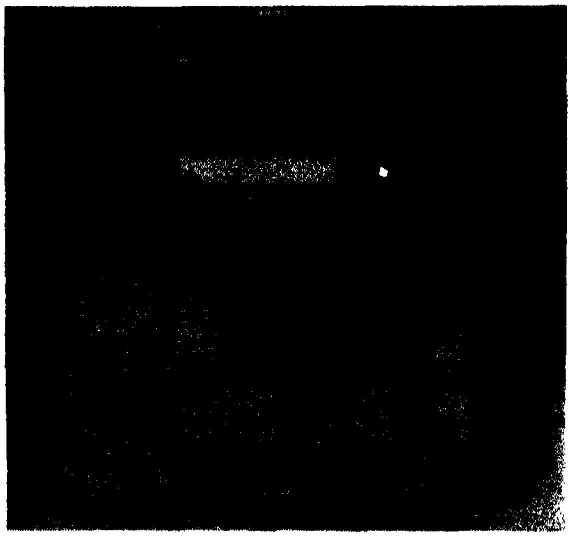
Designed to fill all the needs of the laboratory or plant high vacuum installation, this new instrument has two thermocouples for the range from 1 mm Hg abs. to 10^{-3} mm and an ionization head for five ranges covering pressures between 5×10^{-3} and 10^{-8} mm Hg abs. Outstanding features of this instrument include a specially designed, low leakage, shielded connecting cable which eliminates errors at pressures below 10^{-6} mm where the ionization currents are less than 10^{-4} ma, and a protective relay with very short time delay which automatically turns off the ionization gauge filament when the pressure in the system exceeds 1½ times the full-scale



pressure for which it is set; in preliminary tests gauges have survived more than 100 instantaneous pressure bursts from 10^{-3} mm to atmospheric pressure. In addition, the filament emission is automatically regulated at 1, 5, or 10 ma at the operator's choice; the indication of small pressure changes without readjustment of emission is particularly useful for leak detection.—NATIONAL RESEARCH CORPORATION, *70 Memorial Drive, Cambridge, Massachusetts.*

Earth Resistivity Apparatus

Intended for use by contractors, engineers, and students, who require data on sub-surface conditions at comparatively shallow depths, 300 ft. or less, the Type LLR earth resistivity apparatus is a modification of the Gish-Rooney instrument, but is considerably less expensive. It is a moderately priced, compact apparatus which measures earth resistivities by the Wenner four-electrode method. Certain types of rock, ores, sand, and gravel have characteristic resistances, and by applying the principles of the Wenner method of data evaluation, it is comparatively simple to determine the depth at which such deposits occur as well as their horizontal and vertical extent.—GEOPHYSICAL INSTRUMENT COMPANY, *Arlington, Virginia.*

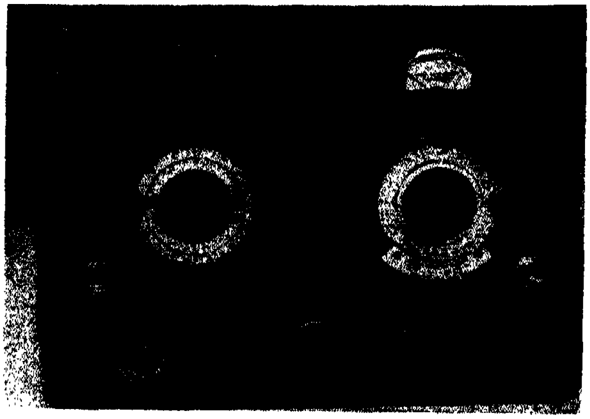


F-M Signal Generator and Amplitude Modulator

The Type 1022-A f-m standard signal generator (illustrated) is designed specifically for testing f-m broadcast receivers. Carrier frequency range is 88 to 108 Mc and I-F range 10 to 11.5 Mc. The r-f oscillator is modulated directly by a reactance tube, thus eliminating the difficulties caused by spurious beats or "birdies" that occur in beat-type systems. Modulation system is flat from 20 cycles to 15 kc, and internal modulating frequencies of 60 and 400 cycles are provided. Deviation range is 0 to 200 kc, with less than five percent incidental amplitude modulation. Open circuit output voltage is continuously variable from below 0.1 μv to more than one volt. Leakage is completely negligible. Output impedance is 50 ohms and is practically constant over the operating range.

The Type 1023-A amplitude modulator is designed for use with the f-m signal generator as well as with other signal generators for receiver tests where amplitude modulation is desired with negligible incidental f-m. It modulates the signal generator output after attenuation, so that reaction on the oscillator frequency, which produces f-m, is eliminated.

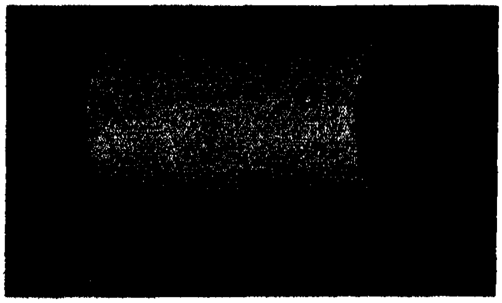
Modulation up to 80 percent at 60 cycles, is provided internally. External modulating frequencies between 20 cycles and 15 kc can be used. Input and output impedances are 50 ohms.



Radiofrequency range is 10 to 150 Mc with a gain of 0.1 and 10.1 to 11.3 Mc with a gain of 10.—GENERAL RADIO COMPANY, *275 Massachusetts Avenue, Cambridge 39, Massachusetts.*

D.C. Integrator Motor

An integrator motor is now available for applications requiring the time integral of a d.c. voltage. Speed of the motor is proportional, within half of one percent, to applied voltages between −15 and +15 volts. Speed is actually proportional within a quarter of one percent through all of the range except near zero voltage, or reversal point. Angular shaft displacement over any given period, therefore, is proportional to the integral of applied voltage during that period. The output shaft may be geared or directly coupled to an indicator or other



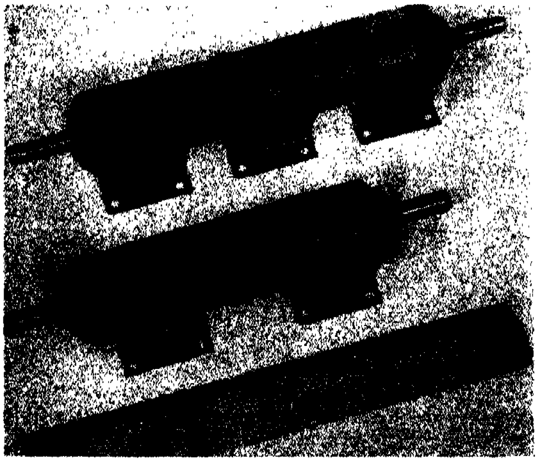
instrument load. In the model illustrated, the armature is geared to a single output shaft at a ratio of 500 to 1. An alternate model can be supplied with the armature geared to two output shafts, at ratios of 100 to 1 and 1000 to 1.

Unique design, precision workmanship, and jewel bearings provide the extremely high torque-to-inertia ratio of 400,000 to 1 at 1 volt applied. The integrator motor consistently starts and runs on the energy supplied by a photo-cell exposed to sunlight. Weight of the motor is 12 ounces, and the greatest over-all dimension is 3¾ in.—Specialties, Inc., *Skunks Misery Road, Syosset, New York.*

Miniature Speed Changes

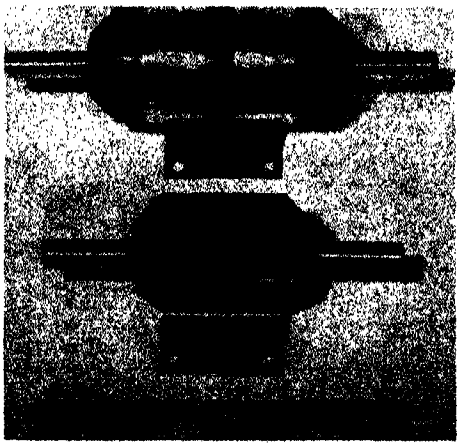
Gear reductions as high as 750,000 to 1 are now practical and available. These special units are made up by adding one or two additional gearing sections to the standard 3-section units having ratios up to 3375 to 1. This provides several hundred ratios between 1000:1 and 750,000:1 in addition to (500 or more) standard 1-, 2-, and 3-section units.

Input speeds as high as 50,000 r.p.m., and output torques up to 2 lb.-in. are permissible. Weights of 4- and 5-section units are approximately 6 and 7 ounces, respectively. Body diameter is 1.050 in.; body lengths are 3$\frac{15}{16}$ in. for 4-section unit and 4⅝ in. for 5-section units.



The addition of still another section with a maximum ratio of over *11 million to 1* is structurally practical, but so far no application for such extremely high gear reduction has been found.

▶ Very high ratios in hobbed gears and "zero backlash" construction can be furnished at reduced torque rating. Zero backlash is obtained by the use of a torsional spring and two parallel gear trains built into each gear section. One gear train is spring loaded against the other so that backlash is taken up continuously. Torsion spring is initially wound up to provide a zero backlash output torque of 1 lb.-in. in either direction, but may be unwound to any extent desired.—Metron Instrument Company, *432 Lincoln Street, Denver 9, Colorado.*



Logarithmic Attenuator

The new Kay-Lab logarithmic attenuator, Model 511, has internal thermostatic control to maintain temperature at 100°F. This feature eliminates temperature dependence of non-linear circuits in the attenuator and permits use at temperatures from freezing up to 100°F.

The non-linear circuit elements are adjusted to give an output which is accurately proportional to the logarithm of input voltage. A.c. Logatens operate on both halves of the wave and are substantially flat from d.c. to 100 kc. Both a.c. and d.c. Logatens are available, and it is recommended that d.c. Logatens be used for d.c. applications, due to contact potential and other effects. D.c. Logatens are half-wave devices which have been adjusted for a specific polarity.

Suggested applications for the use of a Logaten are in a decibel meter, in dynamic compression, in electronic computing and control amplifiers, and in acoustic studies. Plug-in units with either octal plug or banana terminals are available.—Kalbfell Laboratories, Inc., *1076 Morena Boulevard, San Diego 10, California.*

Model F-1 Oscillograph

The complete instrument consists of an amplifier and strip chart recorder which are also available separately. The amplifier has a 2000 to 1 maximum gain in four stages with a single 6V6 final stage. Its frequency response is flat from ½ to 100 c.p.s. and allowable input voltages range from 0.010 to 275 volts. Impedances are 10 megohms input and 50 ohms output. The recorder has a magnetic pen drive with a sensitivity of 1.1 mm/volt and 1.5 mm/ma with a 3-in. pen, and the frequency

response is flat from ½ to 70 c.p.s. The ink well may be refilled through an opening in the top of the case, and a Plexiglas door provides access to the chart so immediate notations may be made on the chart paper while the instrument is in operation. Dimensions of both instruments are 15×7×7 in.—PHOTRON INSTRUMENT COMPANY, *6516 Detroit Avenue, Cleveland 2, Ohio.*

Manufacturers' Literature

Titrilog—4-page illustrated bulletin on new Consolidated Titrilog describes the Titrilog application for the continuous recording of trace quantities of sulfur compounds.—CONSOLIDATED ENGINEERING CORPORATION, *620 North Lake Avenue, Pasadena 4, California.*

Magnetic Storage Systems—8-page brochure describes magnetic storage systems for use in computing inventory and automatic control systems to replace storage relays, stepping switches, punched tape and other bulky forms of storage.—ENGINEERING RESEARCH ASSOCIATES, INC., *1902 West Minnehaha Avenue, St. Paul, Minnesota.*

Tracerlog—No. 24, February, 1950, 12-page house organ, features a description of the SC-13 radioactive ore analyzer. Included also are revised data on LKB mechanical register and an index of Tracerlog articles for the year 1949.—TRACERLAB, *130 High Street, Boston 10, Massachusetts.*

The Oscillographer—Vol. 12, No. 1, 24-page house organ, includes a discussion of the new Type 292 cathode-ray oscillograph and an article entitled, "Transducers—A review of the design and applications of transducers for oscillography."—ALLEN B. DUMONT LABORATORIES, INC., INSTRUMENT DIVISION, *1000 Main Avenue, Clifton, New Jersey.*

Magnetic Counter—Leaflet describing small, lightweight three- or four-digit precision counter, one inch high. The additive or subtractive counter wheels record a maximum of 1200 counts per minute on 24 or 110-volt a.c. or d.c.—ABRAMS INSTRUMENT CORPORATION, *Lansing 1, Michigan.*

The Chronotest—(Electronic millisecond timer), 4-page illustrated folder on Chronotest, a British instrument for measuring short-time intervals between 0.1 and 10,000 msec. with an accuracy of one to two percent, useful in measuring the operating times of relays, fuses, switchgear and overloads, for timing chemical, physical and biological reactions, for testing camera shutters and for making psychological investigations. —HERMAN H. STICHT COMPANY, INC., *27 Park Place, New York, New York.*

New Materials

Forest K. Harris: Associate Editor
in Charge of this Section
National Bureau of Standards, Washington, D. C.

Mercury Filter

The Type "F" gold adhesion mercury filter consists of a reservoir with a discharge aperture at the bottom. A gold ring surrounds the aperture and constitutes the filter element. Mercury wets the ring, forming a metallic bond which results in a seal against anything that is not soluble in the mercury. The walls of the container are not wet by the mercury, so that liquids and fine particles of solids are drawn downward along the interface between the mercury and the wall by capillary action and agitation, but are stopped upon reaching the wetted ring. The filter allows a rapid flow of mercury and filters out dirt, oxide scums, oil, water, and acid, delivering dry mercury. It does not remove fine gold in suspension, or dissolved metals. These are usually removed by distillation. The seal is a noble alloy of gold which is more durable than pure gold and will last for several months of active operation. It is in the form of an easily replaceable disk. All other metal parts of the apparatus which come into contact with mercury are of stainless steel and are resistant to nitric acid.—BURRELL CORPORATION, *1942 Fifth Avenue, Pittsburgh 19, Pennsylvania.*

Teflon Gaskets

Chemiseal Snap-on Teflon (tetrafluorethylene) molded gaskets are designed to seal connections in glass pipe assemblies. Gaskets are stocked to fit Corning Pyrex conical-end pipe measuring 1, 1½, 2, 3, and 4 in. inside diameter. An annular ring construction insures correct centering and provides an efficient seal that is not subject to attack by any known chemical, and that will not contaminate any fluid being handled. The gasket compensates for misalignment and does not restrict the flow area at the pipe joint.—UNITED STATES GASKET COMPANY, *610 North 10th Street, Camden, New Jersey.*

Synthetic Mica

Synthetic mica, with essentially the properties of natural mica but able to withstand much higher temperatures, has been crystallized successfully at the National Bureau of Standards by Insley, Van Valkenburg, and Pike. The synthesis was carried out at atmospheric pressure with the aid of a fluorosilicate as a crystallizing agent. The other raw materials needed are quartz, magnesite, and bauxite. The mixture is placed in a platinum crucible and melted in an electric furnace at about 1400°C. As the furnace cools, mica crystals grow from a seed at the bottom of the crucible. The most satisfactory synthetic mica developed so far has the formula $K_4Mg_{12}Al_4Si_{12}O_{40}F_8$ and is equivalent to a form of natural mica in which the hydroxyl radical has been replaced by fluorine. Its physical properties compare favorably with those of natural mica. The largest crystals grown so far have a surface area of four square inches.

Satisfactory synthesis depends largely on the crucible lining. Ceramic linings are badly corroded by a fluorine-bearing melt. Carbon and silicon carbide crucibles are better but fluorine escapes through the porous walls and fine carbon particles become imbedded throughout the mica. Crucibles lined with platinum foil give the best results. The shape of the crucible is also important. Flat-bottomed crucibles are undesirable since they offer a large surface for formation of seed crystals which grow in different directions and limit the development of large crystals. If a crucible with a cone-shaped bottom is used the number of seed crystals is reduced and the direction of growth tends to be upward. Experiments are in progress to find ways of predetermining crystal growth more closely.—NATIONAL BUREAU OF STANDARDS, *Washington 25, D. C.*

Aluminum Thermal Insulation

Infra Type 6 consists of three aluminum sheets spaced 1½ in. apart by fiber partitions which are stated to be flame, mold, and vermin proof. Thus six reflective surfaces (two external and four internal), having emissivity and absorption of only three percent, are made active by fully effective reflective spaces. Permeability to water vapor is zero, and the material will not support or store condensation. It is installed in a single operation requiring no special skill, at a speed of 2000 sq. ft. per day. It may be installed in floors or ceilings, over or under radiant heating panels, concrete slabs, etc.

A 44-page brochure entitled "Simplified Physics of Thermal Insulation," containing descriptions and data on aluminum and mass insulation, is available on request from the manufacturer.—INFRA INSULATION, INC., *10 Murray Street, New York, New York.*

Glass Building Blocks

PC "55" glass blocks consist of seven new types designed to permit a more uniform panel appearance and better brightness control. Functional features include opal glass fused into the block junction to diffuse light which would otherwise be directly transmitted through the block edge, fibrous glass inserts to further diffuse light transmitted by the block and special prisms on interior faces of certain patterns. These features are combined in accordance with the use for which the specific block has been designated. Some are designed for south elevations, others for north elevations. Light-directing and light-diffusing blocks are available for these special applications. The blocks with fibrous glass inserts increase light diffusion on extremely sunny exposures. In addition to functional qualities the blocks have a new face pattern which permits easy cleaning.—PITTSBURGH CORNING CORPORATION, *307 Fourth Avenue, Pittsburgh 22, Pennsylvania.*

Some Properties of the Parallel Plate Spark Counter II

LEON MADANSKY[*] AND R. W. PIDD[†]
Brookhaven National Laboratory, Upton, New York

(Received September 2, 1949)

The delay error distribution of the parallel plate spark counter has been measured and the average delay is found to be 6×10^{-9} sec. The counters are, therefore, applicable to the measurement of lifetimes as short as 10^{-9} sec. Auxiliary circuits, including a fast synchroscope, for short time interval measurements are described, and the resolution limitations of the counters and circuits are discussed.

INTRODUCTION

A PARALLEL plate spark counter has been developed[1] which is satisfactory for coincidence counting, and the time resolution of a coincidence detecting system has been measured. The time resolution concerns the accuracy with which time intervals can be measured, while the maximum counting rate of the system, limited by a 0.001-sec. counter quench time, determines how quickly data may be accumulated. The resolution in time interval measurements is determined by the random delay errors in the counters and errors introduced by the recorder.

The delay error distribution for a counter is defined as the distribution of the time delays between the passage of a detected particle through the counter and the appearance of the counter pulse. In practice, the time at which the particle passed through the counter is detected by a second counter which will also have a delay error. Thus the measured distribution is the combined delays of the two counters. Constant delays are not important, since they can always be balanced by delay lines. However, the random delays introduce an error into time measurements. The shape and half-width of the delay distribution function present one of the limiting factors in the shortness of time intervals which can be measured by counters. For example, it can be shown that for a Gaussian delay distribution the shortest lifetimes which can be measured with counters in coincidence is of the order of 0.2 the width at half-value of the delay error curve.

The parallel plate counters were developed in order to obtain shorter delays than are observed in the cylindrical Geiger counter. The reason for the parallel plate design is that, since the electric field is uniform and the discharge is a spark, the initiation and propagation of the gas discharge should occur much more quickly than in the Geiger counter. It will be shown that the half-width of the delay error distribution is 6×10^{-9} sec.

THE EXPERIMENTAL METHOD

In the following experiments, beta-particles from a P^{32} source traverse two parallel plate counters. The counters have 98 percent efficiency for detecting beta-rays and operated with 0.001-sec. quench time. Figure 1 shows the experimental arrangements. The particles pass through the copper foil electrodes of each counter, producing an instantaneous coincidence. The solid angles are such that half the counting volume of counter *I* and all of counter *II* is utilized. The voltage pulse from counter *II* triggers a blocking oscillator which provides a brightening pulse for the scope. The same pulse is also delayed through 50-ohm coaxial cables and fed to one of the vertical deflection plates. The pulse from counter *I* is delayed and then triggers a sweep circuit. This delay amounts to about 3×10^{-8} sec. The pulse from counter *I* is also delayed in another channel and appears on the other vertical deflection plate. The vertical delays are adjusted to have the pulses from counter *I* and counter *II* appear displaced from one another on the sweep. The pulses are easily distinguished since they appear with opposite polarity. The time between these pulses is fixed so that the

[1] The technique of preparing the counters has been improved since the publication of Part I, Phys. Rev. 75, 1175 (1949). The details will be described elsewhere.

"tail" on the first pulse does not overlap the rise of the second. This arrangement provides that only pulses which occur within the sweep time will appear on the scope as a "coincidence." Events of this sort are photographed with a camera having continuously moving film. With a suitable calibration of the sweep one can measure the time delays between pulses and plot the distribution. A typical trace is reproduced in Fig. 2 together with a calibration which was a 106-Mc/sec. signal.

DESCRIPTION OF APPARATUS

The construction and preparation of the foil counters are described elsewhere.[1] The counters are shown in Fig. 3. It is important to shield the counters from one another, since the ultraviolet from the spark discharge in one counter can cause a discharge in the other. These spurious coincidences can be observed by their characteristically long time delay (~0.1 μsec.). A copper box is constructed around each counter, shielding it optically in order to avoid this effect. By placing a lead wall between the counters, thus preventing true coincidences, one could look for spurious coincidences. It was found that the shield was entirely effective and no spurious coincidences existed.

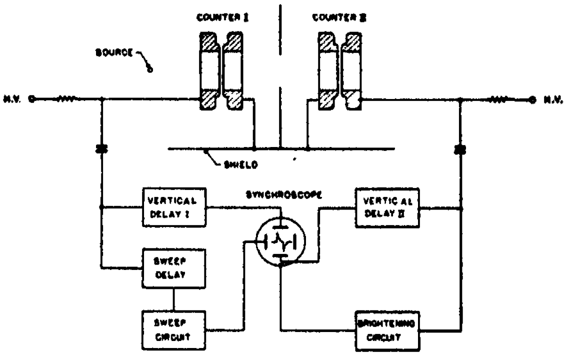

FIG. 1. Schematic diagram of experimental arrangement.

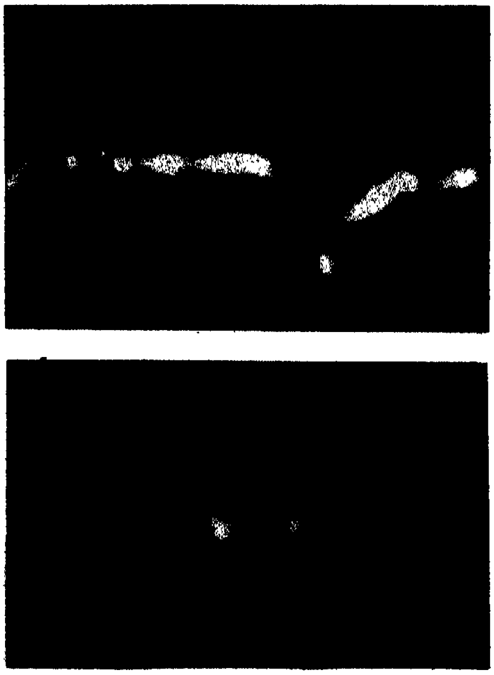

FIG. 2. A typical oscilloscope trace showing a coincidence. Lower figure is 106 Mc/sec. calibration signal.

FIG. 3. Photograph of foil counters.

The signals from the counters that are used to trigger circuits (about 200 volts) are coupled into 50-ohm coaxial cables, which act as delay lines, by 50-μμf condensers. The signals for the vertical pulses are coupled with 10-μμf condensers. The cables are matched at both ends to avoid reflections in the lines. Both counters are supplied with negative 4000 volts through 88-megohm resistors, which act as the quenching resistors.

The brightening circuit is a blocking oscillator having a pulse of 0.2 μsec. duration. The sweep signal is produced by charging a 50-μμf capacitor through an 807 tube that has been brought up to conduction from cut-off. The positive pulse that supplies the 807 grid comes from a blocking oscillator similar to the brightening circuit. The sweep has a duration of 5×10^{-8} sec. and occupies 3 inches of the scope face. All the voltages for these circuits are regulated to minimize random delays in starting times. The variation in starting time of the sweep circuit is about 1×10^{-9} sec. However, measurements are made on the intervals between the pulses from each counter, avoiding this error. The scope tube is a Dumont 5RP11 operated with 35-kv accelerating potential. A typical coincidence trace and the accompanying calibration is shown in Fig. 2.

The sweep is recorded on linagraph pan film with the use of a special Schmidt optics camera. The Schmidt mirror and lens system was obtained from the Edmund Salvage Company. The Schmidt camera has a f. 0.9 optical system and is provided with a continuously moving film feed. The line width of a typical trace with such a recording system is 5×10^{-10} sec. so that intervals of 10^{-9} sec. are clearly distinguishable.

ERRORS

The precision with which one can determine the delay errors are limited by two factors. First of all, the accuracy of the determination of the "break" of the pulse from the sweep base line is limited by the inherent curvature of the initial part of the spark pulse. Although the shape of the pulse is fairly constant, small changes in the slope and initial curvature do exist and produce small errors in determining the position of the pulse on the sweep. With these counters this error is $\pm 5\times 10^{-10}$ sec. The shape of the pulse is a function of counter spacing[2] and the resulting error must be determined for each particular design.

Since the sweep is non-linear, equal space intervals on the sweep trace represent different time intervals, depending on where in the sweep the intervals occur.

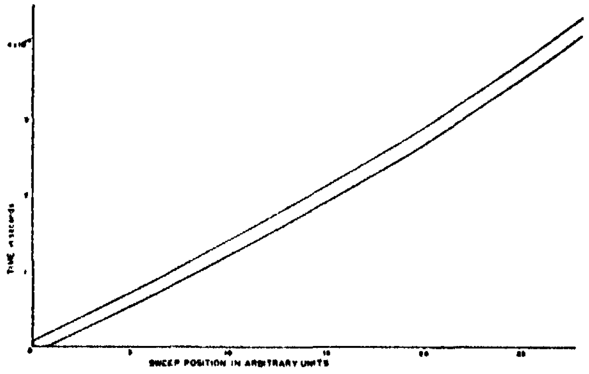

FIG. 4. Limits of calibration curves of sweep.

A curve can be plotted from which time intervals can be read as a function of the position of two pulses on the sweep. This curve is obtained by calibrating the sweep with a known signal (106 Mc/sec. in our case) on the vertical plates. The shape of the sweep signal, or the non-linearity, varies somewhat from sweep to sweep, so that the measured time intervals are uncertain by a small amount. Figure 4 shows two curves which represent the limits of any sweep calibration. About 90 percent of the sweeps fall well within these limits. At most, errors introduced by changes in the shape of the sweep signal amount to no more than $\pm 10^{-9}$ sec. The measured distributions of delay errors include the inherent counter delays as well as the effect of sweep error.

DISCUSSION OF THE RESULTS

The random time lags are measured as deviations of the time between pulses on the sweep from a fixed time interval, which represents true zero. This true zero time is measured by having a pulse from a single counter feed all four channels. The delay error distributions were obtained for several values of overvoltage. Some typical delay error curves are plotted in Fig. 5. These are for operation at 300 volts, and 1000 volts above the threshold for sparking. The width of the curves at half-value decreases with overvoltage until at 1000 volts one obtains a value of 6×10^{-9} sec. These results are in good agreement with the values of delay errors given by J. W. Keuffel.[3] The long delays that he describes ($>10^{-8}$ sec.) are probably due to sparking at the edges where the field is not uniform.[4] This was absent in our case, since the edges of the counters were well shielded by a collimator. In each of the cases the delay error distributions show a negligible probability for a pulse after a certain time. This cut-off is a true one, since no pulses were ever observed beyond this point in a total of 5000 counts. The curves are symmetrical, indicating that the counters are indeed alike with respect to time lag in spark initiation.

CONCLUSIONS

The results of these measurements may be analyzed in terms of the measurement of a lifetime of an excited state and time of flight of an elementary particle. A lifetime measurement involves first the detection of a particle that has left the nucleus in the excited state we wish to observe, and second, the emitted particle from the decay of this state. In many cases the first particle is the electron from beta-decay and the second is the internal conversion electron from the transition to the next lower state. Let $P(t)dt$ be the probability that the pulses from each counter will appear a time t apart on the sweep. We assume here that the delays of the cables and circuits have been subtracted out and that t is measured from a zero time. Thus, for simultaneous coincidences $P(t)$ is the delay distribution. This function is important in that it places a limit on the smallest life-

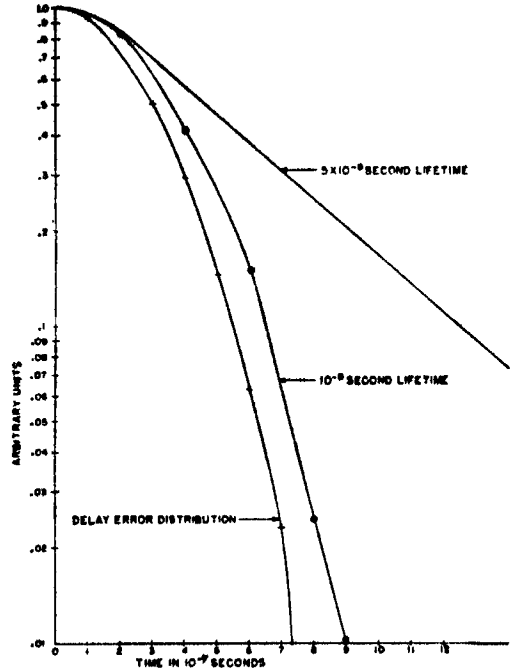

FIG. 6. Expected lifetime distributions for a delay error distribution with 6×10^{-9} sec. width at half-value.

times one can measure. It is easy to find the effect on this function $P(t)$ if the coincidences are not simultaneous but are a result of a true delay distribution in the source itself due to a short lived excited state. Figure 6 shows a typical random delay distribution curve for an experiment with the P^{32} source and counters operated at 1000 volts overvoltage. Additional curves illustrate the distributions one expects for states whose lifetimes are 10^{-9} and 5×10^{-9} sec. The fact that the delay error curves do cut off at a fixed limit allows one to consider the exponential tail on the observed distribution to be due to a lifetime and not to long time delay errors in the counters. It is clear that with 1000 volts overvoltage one can measure a lifetime of 10^{-9} sec. without much difficulty.

A second example is the measurement of times of flight. It may be assumed that the error in detecting a time delay is equal to the half-width of the delay error distribution. At beta $=0.75$ the time of flight of a particle between two counters spaced 10 meters apart is 4.45×10^{-8} sec. An error of 5×10^{-9} sec. in the time interval measurement would introduce a 13 percent error in the measurement of beta. In terms of a μ-meson the energy of a 50-Mev particle could be measured with an 8 percent error. The use of more than 2 counters in coincidence would sharpen the combined delay distribution and make an experiment of this sort more accurate.

There are two indications that improvement in the time resolution of spark counters may be obtained. Time lags of the order of 1 μsec. have been observed in the initiation of a spark at overvoltages of 5 volts.[5] Our data show that an increase in overvoltage from 300 to 1000 volts reduces the half-value width of the delay error distribution from 1.8×10^{-8} sec. to 6×10^{-9} sec. It would appear then that higher overvoltages would yield better counters. Although it is not practical to operate the present counters at more than 1000 volts above threshold with a 1-msec. recovery time, there may be counter preparation techniques which make it possible to operate at 3000 volts above threshold. Such counters have been made with the same technique of preparation but cannot as yet be systematically duplicated.

A second improvement in the counter resolution can probably be achieved by reducing the electrode spacing. Observations of the structure of the spark pulse displayed on the fast synchroscope show a time lag of 3×10^{-9} sec. in the development of the fast spark pulse when the electrode spacing is 4 mm. This time lag is reduced to 10^{-9} sec. when the electrode spacing is made 1 mm, hence reducing the error in reading the position of the initial rise of the pulse on the sweep. Time lags which are due to inhomogeneities of the electric field can also be reduced by better counter construction. The electric field in our counters was uniform in the counting region to within 1 part in 500. Further improvements in the recording circuits are in progress, with particular emphasis on the reduction of sweep errors.

ACKNOWLEDGMENT

The authors wish to thank Dr. J. B. H. Kuper for the courtesy of his laboratory and to express appreciation to his technical staff for their excellent cooperation. This work was done under the auspices of the U. S. Atomic Energy Commission.

A Differential Analyzer for the Schrödinger Equation*

R. L. Garwin
Department of Physics, University of Chicago, Chicago, Illinois

(Received August 29, 1949)

A rapid differential analyzer of accuracy about 0.5 percent is discussed and its performance reviewed. Extensions to differential equations other than that of Schrödinger are mentioned.

INTRODUCTION

For some time there has been a need for a small, simple differential analyzer. For example, in nuclear physics it is most convenient to have available a rapid method of solution of the one-dimensional Schrödinger equation,

$$(\partial^2\varphi/\partial x^2)+[E-V(x)]\alpha\varphi=0, \qquad (1)$$

for a large variety of functions $V(x)$. The problem undertaken in this research was primarily to design and build a machine capable of solving this equation, and, secondarily, to develop methods to be used in extending the usefulness of the machine to other problems. For most purposes an accuracy of solution of the order of one percent is sufficient, but 0.1 percent is desirable, and, as will be seen, readily achieved.

METHOD OF ATTACK

There are, in general, at least two overlapping classes of computing machines; analog and digital computers. In the Schrödinger problem either type may be used; for instance, a moving needle galvanometer with zero friction and zero restoring torque, the axis of whose coil coincides with the axis of the magnetized needle in the zero position, obeys the Schrödinger equation in the sense that if the current through the coil is made to vary in proportion to $[E-V(t)]$, the angular position of the needle as a function of time will be the solution of the equation

$$(\partial^2\theta/\partial t^2)+(K/I)[E-V(t)]\theta=0$$

over a considerable range of θ. This analog of the Schrödinger particle was not employed as a computer because of its severely limited scope.

A general analog differential analyzer (Bush type) adapted to the problem at hand has the form schematized in Fig. 1. Here a, b, c, and d are variables of the physical form required for the operation of the machine, i.e., shaft rotations, voltages, etc., and b_0, c_0 the initially given or assumed values of b, c. Now, from the nature of the individual units

$$a=db/dx,\quad b=dc/dx;\quad a=d^2c/dx^2$$
$$d=[E-V(x)]\alpha c=a;$$

so:

$$(d^2c/dx^2)+[E-V(x)]\alpha c=0, \qquad (2)$$

which differs from (1) only by a simple change of variable.

In a certain sense, a digital computer is the ideal type for almost any problem, especially if adapted to take data in the form of tables, graphs, or even rough sketches, but in the present state of the subject a small digital computer, though a powerful tool, is not available for this purpose. It should be noted, however, that if, as seems likely, storage mechanisms are improved, a small immensely flexible digital computer would certainly be a possibility.

It was desired to perform the required operations electrically insofar as possible to dispense with the usual gears, shafts, servos, etc. With the electrical methods available, however, a great simplification is achieved by making the independent variable the time, (t). Electrical methods have the advantage of flexibility, accuracy, economy, but suffer from limitations, the most severe of which restricts the most straightforward machine to linear differential equations.

The heart of the analyzer is the integrator unit which is derived from the simple resistance-capacitance integrator of Fig. 2 as follows.

The voltages in this circuit are connected by the relation $dE_0/dt=(Ei-E_0)/\tau$ where $\tau=RC$. Considering the voltages as variables, this network would be a perfect integrator if the term E_0/τ could be removed. Physically this term arises because the junction of the resistor and condenser is not always at ground potential, or in other words, τ is non-infinite. Evidently τ itself cannot be made infinite without losing a large factor in voltage in each integrator, so another method is employed; namely, to keep this junction at ground poten-

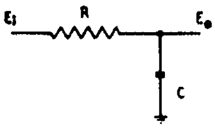

FIG. 2. Prototype electrical integrator.

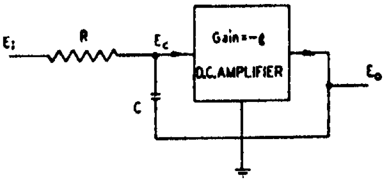

FIG. 3. Basic compensated integrator.

tial by using a feed-back amplifier to vary the potential of the bottom terminal of the condenser (Fig. 3).

Now the continuity equations for current give

$$\frac{E_i-E_c}{R}=\frac{-d(E_0-E_c)C}{dt}=-\frac{d}{dt}\left(\frac{g+1}{g}CE_0\right)$$

and for g large (in our case at least 10^6)

$$\frac{-dE_0}{dt}=\frac{E_i}{RC}+\frac{E_0/g}{RC}\approx\frac{E_i}{RC}.$$

It is to be noted that accuracy of integration depends only on the minimum variational g during the integration period, as well as on unwanted components of E_i, τ.

The major difficulties were three. It was found that most resistors of the value necessary are violently non-linear, but certain sputtered film or deposited carbon resistors afford a convenient solution to the problem.[1] The restriction is really quite stringent since for 0.1 percent accuracy in each integrator and 200 v applied to the resistors, a voltage coefficient of resistance less than 10^{-5}/v is required.

The second problem was non-ideal behavior of the condenser. Most condensers are satisfactory as regards leakage (it is evidently only terminal-to-terminal leakage that counts, since leakage to ground enters only as it affects g), but it is difficult to find a condenser which does not possess some dielectric "soak-in." A quite satisfactory solution to the difficulty was found in polyethylene film condensers[2] with leakage time constants $>10^6$ sec. and dielectric soak-in about 10^{-4}.

The third and by far the most difficult problem was the input behavior of the d.c. amplifier, that is, grid current and grid-cathode potential changes. It was felt that the use of standard receiving tube types was an important advantage worth considerable effort to achieve. Grid current was finally reduced to less than 10^{-9} amp. without tube selection by using a 6AK5 at 100-μa plate current. The grid-cathode potential was stabilized by regulating the average heater power to better than 0.1 percent by the scheme[3] illustrated in Fig. 4. In this circuit the filament of the first diode is operated at such current that the emission is temperature-limited. It is then easily shown that the sensitivity of the space current to heater voltage variation gives about 2 v change in plate potential for 0.1 percent heater voltage change. This error signal is then amplified and applied through the power output tube and transformer so as to maintain constant heater voltage.

After testing many circuit designs, several of which operated with considerable success (cascodes), the amplifier sketched in Fig. 5 was standardized. The amplifier pictured is connected as an integrator by the feed-back

condenser C. An important point to note is that because the non-fed-back gain of the amplifier is greater than 10^6, the grid of the first tube is always within 0.2 mv of ground, for an output voltage of -150 to $+150$ v. This fact allows the use of a simple method of setting initial conditions for integrators: If the input is grounded and the switch S_2 is closed, the output potential of the amplifier must adjust itself so that the first grid potential is zero. This can only be done by seeking a well-defined output potential for each setting of the coarse and fine initial condition potentiometers in the lower left-hand corner. (The initial condition is, of course, set by observing the output potential with the machine's accurate servomechanical d.c. voltmeter and adjusting the potentiometers to give the desired voltage.)

On opening S_2 no potential change larger than 0.1 mv is expected or observed. The switch must, however, be so modified by filing that the grid contact "makes" last and "breaks" first, for obvious reasons.

The properties of the amplifier, in view of its practically infinite gain, can be characterized by the behavior of the input circuit: grid current is always negligible, while grid-cathode potential changes (which may be compensated by varying the $5K$ cathode resistor) are less than 1 mv/hr. after a few minutes warm-up. It may be remarked that a grid potential change of 10 mv would be produced by a leakage resistance to the grid of 5×10^{11} ohms from a 500-v source. The trick is that the grid circuit is entirely separated from points at different potential by a grounded "guard ring," i.e., on S_2 only half the contacts are used, the others being grounded, while all grid wiring is enclosed in shielded cable. Thus the problem is simplified to that of keeping grid-to-ground leakage above 10^6 ohm, which is readily done. The only adjustment needed or possible in the amplifier is the compensation of grid-cathode potential changes by means of the variable first cathode resistor. This is accomplished by setting the input switch to $1M$ with input grounded. Any grid-cathode unbalance E then produces a rate of rise of the output voltage E v/sec. (for a 1-mf condenser) which is to be reduced to zero by varying the cathode resistor. The lack of grid current may be checked by observing that zero drift rate on $1M$ means also zero drift with the input switch at $10M$. Drift rates at high output voltages were checked by observing the output voltage with a 50-mv meter and a bucking battery. This drift rate is equal to that at zero output voltage because of the high amplifier gain.

For the usual integrating period of 30 sec., the amplifier characteristics are such that drift errors are held to 0.1 percent of full scale even on the shortest

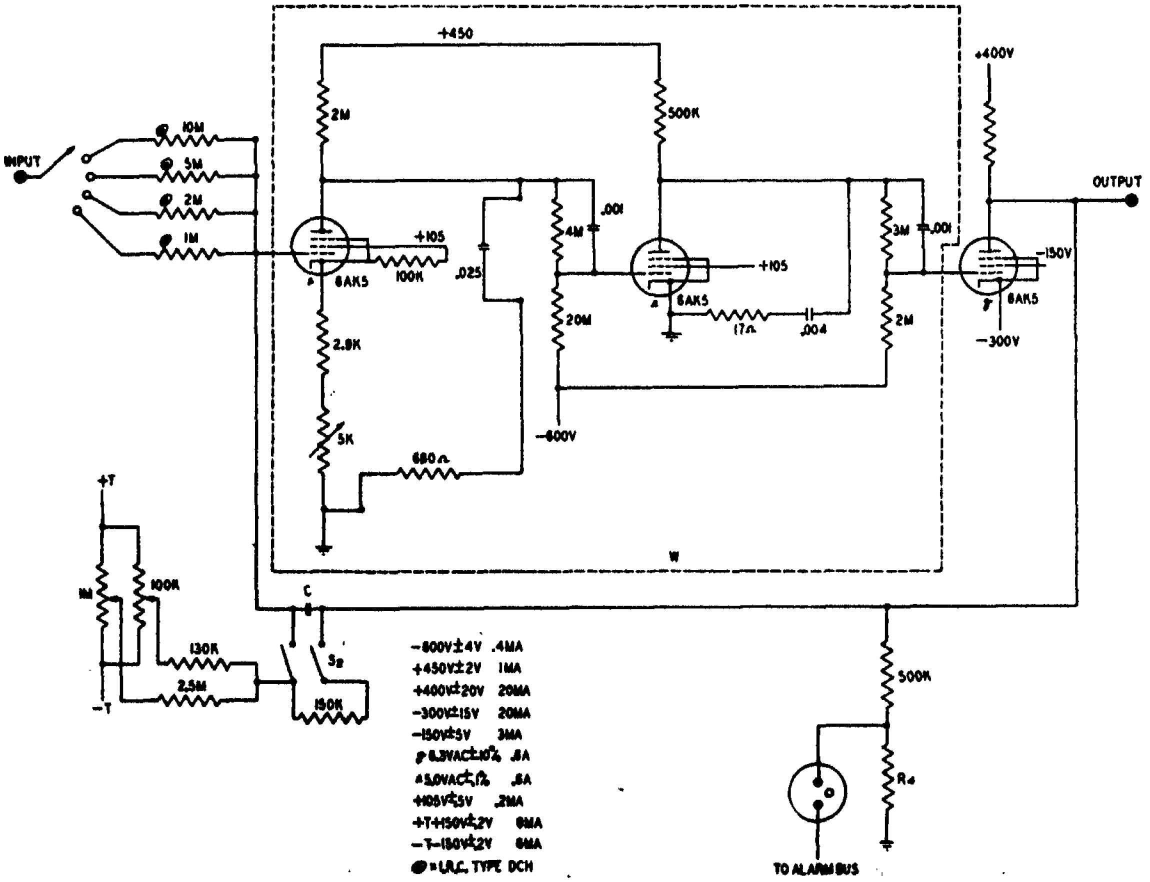

FIG. 5. Standardized d.c. feed-back amplifier.

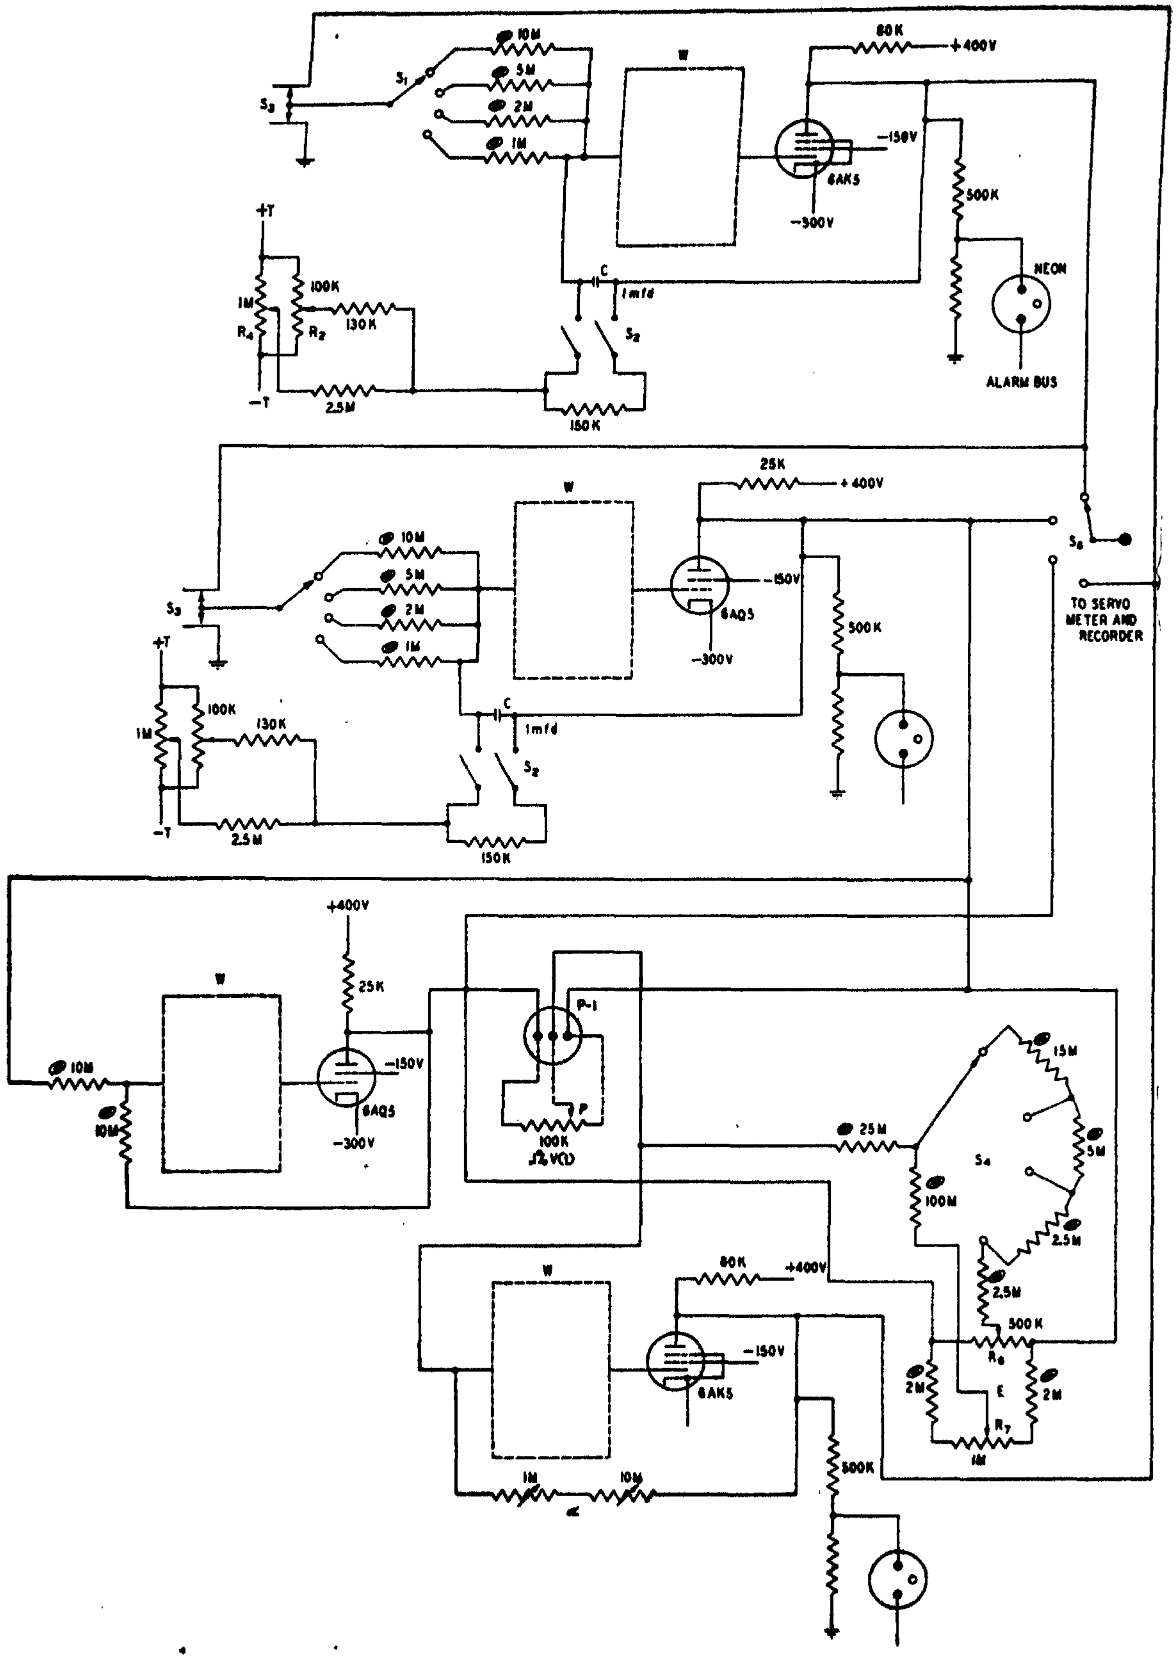

Fig. 6. Computing section.

time constant. The networks between first and second and between the second and third stages serve to stabilize the amplifier against high frequency oscillations, while low impedance (non-regulated) and separate power supplies for the first two and last stages serve to prevent low frequency instability. A power supply yielding many voltages was chosen rather than a more complicated integrator since the power supply may be used for a much larger differential analyzer without undue current requirements. With the proper output tube (6AQ5) and plate resistor, the amplifier is capable of an output voltage range of plus 150 to minus 150 v into a 10,000-ohm load, with, of course, negligible effective output impedance. Relays between units maintain isolation until the desired instant, and an overload signal is available from the neon lamp. The same amplifier may be used with a feed-back resistor in place of the integrating condenser to give an inverting amplifier, impedance changer, etc.

The overloading of any amplifier automatically turns off the multivibrator-controlled relays S_3 (Fig. 6), thus allowing the operator to adjust the various multiplying factors and initial conditions so as to keep the variables within range. This multivibrator is operable also from a start-stop foot switch and from contacts bearing on pencil lines marked on the graph carrying the potential function, allowing precise control of the integrating period. The scheme of the entire machine except for power supply and servos is shown in Fig. 6. Not shown in Fig. 6 are 20-mmf condensers across the feed-back resistors in the amplifier and multiplier sections. These, together with parallel combinations of 2200-ohm resistors and 0.01-mf condensers in the cathode of each of the four output tubes, effectively stabilize the system against phase shift oscillations caused by the capacitance to ground in shielded cables.

The machine thus consists of four "package" amplifiers identical except that two have polyethylene condensers as the feed-back elements, while two have linear resistances. The purpose of the integrators is seen from Fig. 1. The third unit is used as a phase inverter to give a voltage equal to and of polarity opposite from that appearing at the output of the second integrator. These two equal and opposite voltages are then added in varying proportion by means of the linear potentiometer P and the stable potentiometers R_6 and R_7. Thus if y is the voltage appearing at the output of the second integrator, $-y$ appears at the output of the phase inverter and $[E-V(x)]y$ at the input to the fourth unit. This fourth amplifier is really an impedance changer, its output completing the differential analyzer feed-back loop by being connected to the input of the first integrator.

During operation the finger of the linear potentiometer (P) is constrained, by hand or with a photo-cell +servo system, to follow the graph of $V(X)$ carried on a rotating drum, while another linear potentiometer and servo record the solution $\varphi(t)$ on a synchronously rotating cylinder.

PERFORMANCE

In order to find an eigenvalue and eigenfunction of a given Schrödinger potential, a trial E is chosen and a solution computed on the machine, with convenient initial conditions. By node counting and interpolation, a better trial value is found and the process repeated until the desired accuracy is achieved. Usually five repetitions (30 sec. per integration, 10 min. total) suffice for 0.1 percent accuracy in E.

Three identical brass scales are used with the machine: one on the servo output meter (equipped also with a switch increasing the sensitivity ten times), one on the pointer connected to the linear potentiometer P, and one for use in drawing input potential functions. The first step in the solution is to draw the potential function as large as will allow it to fit on the input graph, and to any convenient abscissa $x(t)$.

Next, one has to adjust the individual sections of the machine. This is done by throwing relays S_3 into the "rest" position by means of the foot switch and varying the cathode resistor in the first integrator until no drift is apparent. Evidently the switch S_1 should be set at $1M$ for this purpose. The same is done for the second integrator. Now with the output of the second integrator at zero potential the cathode resistor in the inverter is adjusted to give zero output voltage. With the output of the second integrator (and thus the inverter output) held at zero, the cathode resistor of the fourth unit is now adjusted until its output is zero. The only remaining adjustment consists of choosing the free oscillation period of the machine so as to make the analog "mass" of the analyzer equal to that of the Schrödinger particle. The mass of the particle is entirely fixed by wave-length at some energy E_0. The input potentiometer P is thus set at E_0 on the graph and the switches S_1 adjusted to give approximately the right period. The machine is then allowed to make an oscillation at this frequency, and the wave-length is measured. Any discrepancy between the Schrödinger wave-length and the period of the machine is then removed by changing the multiplying factor α in proportion to the square of the ratio of the wave-lengths. This also can be done without calibrated dials by using the servo voltmeter.

After this has been accomplished the physical analogy is complete and one can search for eigenvalues without the necessity of readjustment except at intervals of some hours.

A very rough estimate of the desired eigenvalue is made. The machine is then allowed to perform its solution of the differential equation for this trial eigenvalue. If, for instance, the ground state is desired, one counts the number of nodes in the trial solution. If the trial solution has a node a lower trial eigenvalue is selected and the solution drawn by the machine. By a simple process of extrapolation a better trial eigenvalue is found, two more trial solutions usually being sufficient to give 0.1 percent sensitivity in the eigenvalue.

The machine may be relied upon, when used properly, to give solutions of absolute accuracy 0.2 percent in not unfavorable cases. Of course, the machine solution must often be supplemented by asymptotic analytic solutions, especially at infinities in the potential.

This differential analyzer is also immediately suited to the solution of the paraxial equations for the path of charged particles in cylindrically symmetric magnetic fields and affords a considerable saving in time. Indeed, any second-order differential equation $y''+X_1y'+X_2y=0$ may be solved on this machine after first making the substitution $y=u\exp(-\frac{1}{2}\int X_1dx)$ to give $u''+[X_2-\frac{1}{2}X_1-\frac{1}{4}X_1^2]u=0$.

It is hoped to use the analyzer for the computation of nuclear potentials for nuclear shells. By adding two more input graphs the present model may be adapted to the solution of the relativistic Dirac equation where its main purpose may well be to provide experience and intuition as to the behavior of the solutions.

By the use of magnetic clutches[4] or hydraulic servo mechanisms operating on control powers of only a watt or so, it should be possible to perform multiplication, and hence all processes necessary to solve non-linear differential equations with linear circuits and potentiometers. Because of the use of linear elements, these solutions should be accurate to perhaps 0.1 percent with care.

ACKNOWLEDGMENT

The writer takes this opportunity to thank Professor E. Fermi for much help and encouragement in the prosecution of this project.

THE REVIEW OF SCIENTIFIC INSTRUMENTS VOLUME 21, NUMBER 5 MAY, 1950

Design and Operation of Liquid Nitrogen-Cooled Solenoid Magnets*

JAMES J. FRITZ[1] AND HERRICK L. JOHNSTON
Cryogenic Laboratory and Department of Chemistry, Ohio State University, Columbus, Ohio

(Received December 20, 1949)

This paper describes the design and construction of compact iron-free solenoid magnets cooled by immersion in liquid nitrogen. Construction details and performance data are given for two such magnets, which produce a magnetic field of 4000 gauss with a power expenditure of 2.7 to 3.3 kw. Heat transfer coefficients between copper wire and boiling liquid nitrogen have been measured for temperature differences between the wire and the liquid of 2 to 11°K.

FOR many types of magnetic measurements, it is desirable to obtain large magnetic fields by use of an iron-free solenoid. This is particularly true for measurements at the temperatures of liquid helium, where differential magnetic susceptibilities are often required. If such measurements are to be made precisely, hysteresis in the magnet must be eliminated, and the interaction between the magnet and small measuring fields must be reduced to a minimum. These conditions are best met by the use of a magnet which contains no ferromagnetic material.

TABLE I. Design requirements for liquid nitrogen-cooled magnets.

Magnetic field at full power	4000 to 5000 gauss
Variation of magnetic field along axis	No more than one percent over 1 cm from center
Maximum power expenditure	4 kw
Maximum consumption of liquid nitrogen	1200 cm^3/min.
Available voltage	190 v
Maximum current (for convenience)	30 amp.
Inside diameter	3 in.
Maximum outside diameter	6 in.

In designing a solenoid magnet, it is desirable to obtain as large a magnetic field as possible for a given amount of power under given conditions of working space and homogeneity. To achieve this, the magnet should be constructed from wire of as low resistivity as possible. It should be as compact in size as other conditions permit, and the space enclosed by the windings should be filled, insofar as possible, by the wire itself. Adequate provisions must be made for electrical insulation and for the removal of heat produced during operation. Wire size, total resistance, and the nature of electrical connections depend mainly upon the current or voltage characteristics desired, and do not greatly affect the power expenditure.

For most installations, these conditions can be met by a multilayer winding of relatively large wire, preferably of square or rectangular cross section, with spacings between turns and layers smaller than the wire size. Cooling can be accomplished by circulation of a non-polar liquid of low viscosity.

[1] Now at Pennsylvania State College.

DESIGN OF A LIQUID NITROGEN-COOLED MAGNET

It is obvious that the power consumption of a solenoid magnet can be reduced if the resistivity of the metal is lowered by cooling it to low temperatures. If this is done by immersion of the coil in a refrigerant such as liquid nitrogen, certain other advantages are gained. In the first place, the electrical energy can be removed by boiling the refrigerant. The rate at which liquid coolant must be supplied is considerably reduced, in comparison with that required for an ordinary cooling cycle. If a sizable reservoir of refrigerant is used, this will automatically supply the amounts required and needs only to be refilled periodically. Furthermore, heat transfer to a boiling liquid is excellent, and the viscosity of the liquid is at a minimum. Because of these factors, the area required for heat transfer and the spacing needed for liquid circulation are minimized.

The use of a magnet cooled by liquid nitrogen proves especially advantageous for work involving liquid helium, since the liquid helium container must be surrounded by liquid nitrogen or liquid air in any event. In a typical installation, a magnet immersed in liquid nitrogen can have an inside diameter of about 3 in., instead of a minimum of about 6 in. required for one operating at room temperature about the same apparatus. This affords a considerable increase in compactness.

Previous operations of solenoid magnets in liquid refrigerants has been reported by de Haas and Westerdijk,[2] who produced fields up to 250,000 gauss for periods of about 0.1 sec. with coils immersed in liquid hydrogen and in liquid helium. They extended methods previously used by Kapitza[3] for production of very large magnetic fields. For continuous operation at smaller magnetic fields, liquid nitrogen would appear to be a more efficient and less costly cooling medium than the lower boiling gases. However, if wire with a sufficiently low residual resistance (e.g., highly purified gold or copper) were used, it would be quite feasible to operate a magnet in liquid helium for moderate periods of time.

DESIGN DATA FOR LIQUID NITROGEN-COOLED MAGNETS

The design requirements set up for the present magnets are given in Table I. The conditions in Table I called for a winding which would produce at least 140 gauss per ampere at the center, and which would have a resistance between 4 and 10 ohms under operating conditions.

The length of the magnet was determined by the requirement for homogeneity of the magnetic field. Table II gives calculated values of the magnetic field per ampere turn per centimeter for several solenoids having dimensions of 7.6 cm (3 in.) I.D. and 14.0 cm (5½ in.) O.D. Values are given for the center of the magnet and for a point along the axis 2 cm from the center.

TABLE II. Field homogeneity for solenoids of various lengths.

Length of solenoid		Magnetic field per amp. turn per cm Gauss cm/amp. turn		Change in field over 2 cm from center
cm	in.	at center	2 cm from center	percent
10	3.9	1.388	1.312	5.5
16	6.3	1.671	1.639	1.9
20	7.9	1.768	1.763	0.3

As is apparent in Table II, a solenoid about 6 in. long produced fields with about the desired degree of homogeneity. Further reduction in length not only reduces the uniformity of the field, but also considerably reduces the current efficiency of the winding.

Commercial copper magnet wire was chosen as the most practical material for the winding. Its resistance was found experimentally to drop by a factor of 8 on cooling from ordinary temperatures to 77°K. This factor was used for design purposes.

It was decided that the turns on each layer should be wound as closely as possible, with spacings between layers to provide for refrigerant circulation. The problem of removing the heat evolved had two aspects. First, there must be sufficient area for heat transfer between the copper and the boiling refrigerant. Second, the spacing between layers must be adequate to provide for exit of nitrogen vapor and entry of fresh liquid.

Heat transfer data for boiling liquid nitrogen were not available. Estimates from the equation of Jakob[4] indicated that the heat transfer coefficient from copper to boiling liquid nitrogen should be about 10 times the corresponding coefficient for water, and should be represented by

$$h=5\times 10^{-2}(\Delta T)^4 \text{ B.t.u. hr.}^{-1}\text{ ft.}^{-2}\ (^\circ\text{F})^{-1}, \tag{1}$$

where ΔT is the temperature difference between the metal and the liquid. On the other hand, Giauque[5] quoted a value of 335 B.t.u. hr.$^{-1}$ ft.$^{-2}$ (°F)$^{-1}$ for liquid oxygen with a ΔT of 3.6°F. This is about 50 times larger than that which would be predicted from Eq. (1). For design calculations Eq. (1) was used, since it certainly gives a very conservative estimate of the heat transfer coefficient for moderate temperature differences.

The heat to be removed at 4 kw power input is 1.4×10^4 B.t.u. hr.$^{-1}$. For wires close-wound on a 6-in. length, the area available for heat transfer would be roughly $A=2\pi nld_{\text{Av}}$, where l is the length of the magnet, n is the number of layers, and d_{Av} is the average diameter. Calculations made with values of h given by

[3] P. Kapitza, Proc. Roy. Soc. (London) **115**, 658–683 (1927).

[4] H. J. Stoever, *Applied Heat Transmission* (McGraw-Hill Book Company, Inc., New York, 1941), p. 63.

[5] W. F. Giauque, Final Report on Liquid Oxygen Trailer Unit, OSRD No. 4141, p. XI-29 (1944).

Eq. (1) showed that the temperature difference required for the dissipation of 4 kw by a single layer coil should be no more than 13°C. For a multilayer coil it would surely be less, and heat transfer to the boiling liquid should present no serious problem.

At high power inputs, however, large amounts of nitrogen gas must be produced inside the windings. Sufficient space had to be allowed for the removal of the gas, since otherwise it might prevent the entry of fresh liquid, with consequent heating of the magnet.

In order to determine the amount of spacing necessary for proper gas and liquid circulation, a small model winding was constructed and tested. This model contained six layers of No. 20 copper wire, close-wound on a 2-in. O.D. form to a length of 3 in.; layers were separated by $\frac{1}{16}$-in. spacers. The coil had a resistance at 77°K of about 0.5 ohm. It was tested with currents up to 26 amp. (325 watts power input). Resistance measurements during operation indicated that the wires heated 1 to 2°K immediately upon application of the maximum current, and did not heat any further. The area of spacing was 18 cm^2; at 325 watts the average velocity of the nitrogen gas must have been about 10 cm sec.^{-1}. From the appearance of the coil under test and the measured resistances, it was concluded that the velocity of the gas could be increased considerably, possibly to as high as 3 meters/sec., without denying the liquid proper access to the windings. Spacings less than $\frac{1}{16}$ in. could probably be used for most solenoids.

For spacings between $\frac{1}{32}$ and $\frac{1}{16}$ in., wire sizes between No. 20 and No. 24 could be used to meet the other specifications. Number 22 was chosen for reasons of convenience.

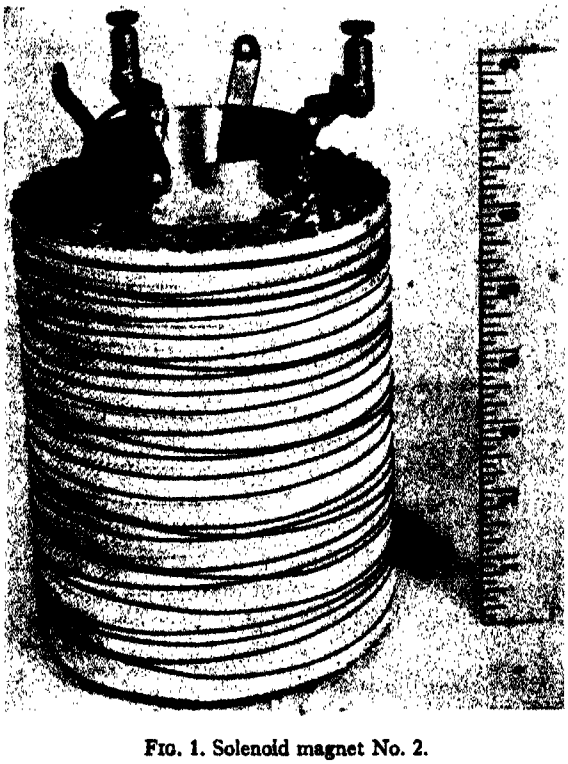

FIG. 1. Solenoid magnet No. 2.

CONSTRUCTION DETAILS AND PERFORMANCE OF LIQUID NITROGEN-COOLED MAGNETS

Two magnets have been constructed and have been operated at nitrogen temperatures. Both were 6 in. long and 3 in. I.D. and were of essentially similar construction. Magnet No. 1 consisted of 17 layers of No. 22 double cotton-covered magnet wire. The wire was wound as closely as possible on each layer; each layer contained 26 turns per inch. The layers were separated by strips of $\frac{1}{16}$-in. glass cord spaced about $\frac{5}{16}$ in. apart. In the process of winding, the strips were flattened somewhat; the average separation between layers was 0.040 in. The cords extended about $\frac{1}{4}$ in. beyond each end of the solenoid and were tightly laced with fish-line for stability. The outside of the solenoid was protected by a wrapping of 1-in. wide glass tape. The over-all outside diameter was $5\frac{1}{2}$ in.

Magnet No. 2 is shown in Fig. 1. It consisted of 16 layers of No. 22 single cotton-covered enameled copper magnet wire, with 30 turns per inch on each layer. In this case the spacers between layers were strips of $\frac{1}{32}$ in. by $\frac{3}{32}$-in. red fiber about $\frac{3}{8}$ in. apart. The average spacing between layers was 0.031 in. As can be seen from the photograph, the strips extended about $\frac{1}{8}$ in. beyond the ends of the solenoid. They were bent outward at the ends almost at right angles, so as to prevent movement of the copper wires. The outside diameter of the solenoid was 5.0 in. The inner brass tube can be seen above the top of the windings. It was 2.99 in. O.D. and $\frac{1}{32}$ in. thick. The tube was insulated by several coats of Formex, and was baked at 150°C after each application of the plastic. The first layer of the solenoid was wound directly on the insulated brass tube.

The details of support and electrical connection can be seen in the photograph. The two ends of the winding are brought to standard brass terminals mounted on brass supports attached to the central tube. They are insulated from the tube by strips of $\frac{1}{8}$-in. red fiber. The four brass strips which extend upward and outward from the top of the central tube permit support of the magnet from above by vertical bars or strips.

The electrical data on the two magnets are given in Table III.

The figures given for power consumption in Table III were calculated by use of the actual resistances of the magnets at currents of 20 to 22 amp. These resistances were slightly higher than the zero-current resistances listed in Table III, due to slight heating of the windings under heavy load. Both magnets have been operated at fields between 4000 and 5000 gauss, and magnet No. 2 has been operated continuously for about 5 hr. at 3700 gauss. No difficulties were encountered. The operation of the magnets was smooth and steady.

Heat transfer and gas liquid circulation in the magnets were extremely good. At 3500 to 3600 watts,

TABLE III. Electrical characteristics of nitrogen-cooled solenoid magnets.

Magnet No.	1	2
Resistance at 300°K	53 ohms	50.4 ohms
Resistance at 77°K	6.4 ohms	6.0 ohms
Gauss/amp. at center	179.5	197.1
Gauss/amp. 1 cm from center	178.5	196.1
Power consumption at 4000 gauss	3340 watts	2720 watts

resistance measurements indicated that the windings heated about 2°K above bath temperature. This pointed to a heat transfer coefficient of about 200 B.t.u. hr.$^{-1}$ ft.$^{-2}$ (°F)$^{-1}$, compared with a value of about 16 predicted by Eq. (1) and that of 335 for boiling liquid oxygen.[5]

The area available for passage of gas upward was about 36 cm^2 in magnet No. 2. At 3600 watts, the total amount of nitrogen evolved was 0.64 mole/sec., or 4100 cm^3/sec. at 77°K. Thus, the average gas velocity over the length of the magnet was about 60 cm/sec. There was no evidence that this was anywhere near the maximum velocity feasible. At high power inputs, the gas streams caused violent agitation of the liquid nitrogen above the magnet. It might be desirable to install a system of baffles or screens in the liquid to absorb the kinetic energy of the escaping gas and thereby reduce the agitation.

The liquid nitrogen was consumed at approximately the rate calculated from the power input, as it should be unless there were serious losses in the transfer system or in the nitrogen Dewar.

HEAT TRANSFER COEFFICIENTS FROM COPPER WIRE TO BOILING LIQUID NITROGEN

As an aid to further design, rough measurements were made of the rate of heat transfer from copper wire to boiling liquid nitrogen. For this purpose, a single layer coil of No. 34 double-enameled copper wire, 2 in. long and 2⅝ in. O.D. was used. The coil was wound on a Dilecto tube ⅛ in. thick, with turns spaced as closely as possible.

The test coil was immersed in liquid nitrogen with its axis vertical. The current flowing through the coil and the voltage drop across it were measured for power inputs from 0.4 to 1200 watts. These measurements were made with multirange meters to a precision of about 0.5 percent. The resistance of the coil between 77° and 90°K was calibrated against a thermocouple in a separate experiment and was thereafter used to determine the temperature of the wire.

Since the wire was wound tightly upon the form, which was a rather good heat insulator, only the outer surface of the copper could be effective for heat transfer. Estimates showed that heat conduction through the form to the inside could at most account for only a few percent of the power dissipated. The area used for calculations was the outside surface of a cylindrical sheet having the dimensions of the coil. Although the outside area of the coil was somewhat larger than this, the portion inside the crevices between turns could hardly be more than slightly effective. The temperature difference used was that between the average temperature of the wire and the bath temperatures, since it could readily be shown that temperature differences inside the wire were negligible, even at the highest power input. The results obtained from a smoothed plot of the data are given in Table IV.

TABLE IV. Heat transfer coefficient from enameled copper wire to boiling liquid nitrogen.

Temperature of bath 77.3°K		Outside area of coil 0.115 ft.^{2} (107 cm^2)	
Temperature difference between coil and bath °K	°F	Heat transfer coefficient (h) B.t.u. hr.$^{-1}$ ft.$^{-2}$ (°F)$^{-1}$	Cal. sec.$^{-1}$ cm^{-2} (°C)$^{-1}$
2.0	3.6	320	0.037
4.0	7.2	780	0.092
6.0	10.8	1350	0.158
8.0	14.4	1675	0.197
10.0	18.0	1880	0.220
11.0	19.8	1915	0.225

As can be seen from Table IV, the heat transfer coefficient was roughly proportional to the temperature head. The value at a temperature difference of 3.6°F was almost identical with that given by Giauque[5] for boiling liquid oxygen.

Certain other observations were made during the experiments. The coil operated quite satisfactorily up to a current of 12.5 amp., but failed suddenly at about 15 amp. The current density at failure was about 5×10^6 amp. cm^{-2}. Later examination of the coil disclosed that in several spots adjacent turns had fused together when failure occurred. On the other hand, the enamel coating elsewhere in the coil showed no evidence of damage either in its appearance or in its electrical properties. It is quite probable that magnets could be operated successfully using enamelled or Formex-covered wire in place of the cloth-insulated wire used in magnets Nos. 1 and 2.

PRECAUTIONS IN THE USE OF LIQUID NITROGEN-COOLED MAGNETS

In the operation of liquid nitrogen-cooled magnets, particularly with high power inputs, it is essential that the liquid nitrogen used contain no appreciable amount of oxygen. Any oxygen present will be concentrated as the refrigerant is boiled off and replaced, and might eventually cause detonation of organic material present in electrical insulation, particularly if a short or a "hot spot" should develop. The fact that in the heat transfer experiments copper was fused in highly purified liquid nitrogen without detonation gives reassurance of the safety of this medium. However, a similar occurrence in refrigerant containing an appreciable amount of oxygen could easily lead to a serious explosion or a bad fire. (It should be noted that the copper fused at a current density about 10 times higher than the maximum used with magnets 1 and 2.) If sufficiently pure nitrogen could not be obtained, it might be necessary to withdraw the refrigerant when the oxygen concentration reached a few percent and replace it with fresh liquid. This hazard could be reduced by keeping the amount of inflammable insulating material to a minimum, but it can hardly be eliminated completely.

It is also essential that provision be made to maintain the nitrogen level safely above the top of the magnet at all times. Safety factors are provided by the large amount of energy required to heat the magnet from nitrogen temperatures even to room temperature and by the large increase of resistance as the temperature increases. In a test run, in which the liquid nitrogen was allowed to boil away completely, no difficulty was encountered so long as the nitrogen made any contact with the coil. However, when the level of the liquid was below the bottom of the magnet, the top heated faster than the bottom and was well above room temperature before the bottom had warmed appreciably.

SUMMARY

The use of boiling liquid nitrogen as a coolant makes possible the design of compact solenoid magnets capable of producing large magnetic fields with relatively moderate expenditures of power. These magnets are especially useful for work involving liquid helium. They can be designed to produce fields of 5000 gauss with currents of 30 amp. or less, so that standard laboratory equipment can be used for control of the electrical circuits. Design and operational data for two such magnets have been presented. As an aid to design, rough values of the heat transfer coefficients from copper wire to boiling liquid nitrogen, have been determined.

We wish to thank Mr. O. D. Gonzales and Mr. L. E. Davis for aid in assembly and test of the magnets and Mr. L. E. Cox for technical assistance in the actual construction.

A Trigonometric Computer with Electrocardiographic Applications

RICHARD McFEE*
Departments of Electrical Engineering and Physics, Syracuse University, Syracuse, New York

(Received October 20, 1949)

An analog computer has been built which determines $(e_1^2+e_2^2)^{\frac{1}{2}}$ and Arc Tane_2/e_1 two thousand times a second with an accuracy of about five percent. Using amplified electrocardiographic voltages proportional to three perpendicular components of the dipole moment of the hearts electric field, a pair of computers of this type will be able to produce other voltages proportional to the magnitude and two directional angles of the dipole. This may simplify considerably the study of fluctuations in the direction of the dipole and the neutralization of the effects of abnormal heart positions.

INTRODUCTION

DURING a study of the character of the electric field of the heart it became apparent that the experimental application of the theory might be considerably simplified if computers of the type described here were available. The practical realization of this possibility required the answers to two questions; first, could apparatus which would meet the specifications be built, and second, what electrode systems on the body would furnish the required voltages? The computer discussed in this paper has answered the first question, but since the answer to the second question is at the moment only partially known, the apparatus cannot be put to immediate practical use. However, it is hoped that its principle of operation and the details of the circuits used, particularly the "baseline clamper," will be of general interest, quite apart from its specific medical application.

The application of a trigonometric computer to electrocardiography stems from an opinion, held by most but not all of those familiar with the situation, that the electric fields set up in the body by the heart may be considered due to a varying electric multipole located at the heart's center of which the dipole moment, or "heart vector" is usually predominant. Unfortunately, this opinion has been of limited practical value, partly because actual calculation of the heart vector is tedious, and partly because the measurement techniques which in actuality define the heart vector were, until recently, specified more or less dogmatically, the result being that its physical significance was debatable. Some recent work in this connection[1] has clarified the situation considerably, and it seems probable that the "best" positions for the electrodes will soon be determined.

The fluctuations of the heart vector are of medical interest chiefly because it is supposed to reflect the vectorial average of all the infinitesmal EMF's generated by the heart, and thus the average direction of the spread of the excitation wave and the relaxation process. At first it might seem that it could be best

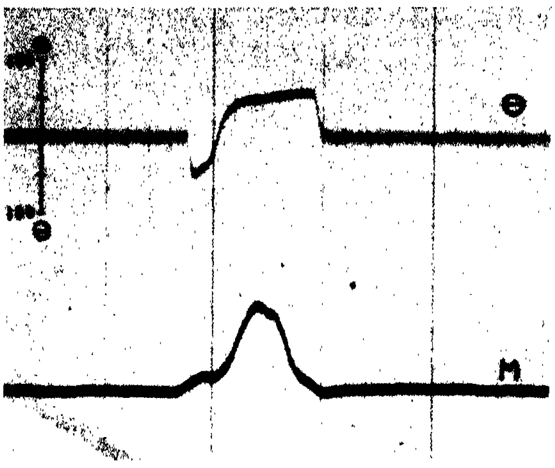

FIG. 1. A typical computer output.

studied in terms of time graphs of voltages proportional to its three components, but unfortunately unimportant changes in the angular position of the heart from individual to individual sometimes completely change the configuration of such records, obscuring other features of its variations which may indicate the presence or absence of heart disease. These "other features" referred to are usually relative angles; for example, the difference between the directions of the dipole during the beginning and end of contraction, or the abrupt changes in the direction of the dipole during the excitation process.

The problem of portraying the fluctuations of the heart vector in a fashion which emphasizes the relative angles has been attacked thus far through the use of the vectorcardiograph.[2] The latter is a cathode-ray tube with one component of the dipole on its vertical plates and another on the horizontal plates. The result is that the spot is displaced from the origin by these voltages and is viewed as a point in a plane, of which the polar coordinates are evident. By obtaining two vectorcardiograms with different pairs of components, it is possible to infer the variations in the direction of the heart vector with considerably less difficulty than with time graphs of the three components.[3] The recent development of the steroscopic cathode-ray tube presentation has enabled considerable extension and refinement of this vectorcardiographic approach.[4, 5]

The application of a trigonometric computer to this problem can now be explained. Such a computer can be used to obtain voltages proportional to the *spherical coordinates* of the heart vector; i.e., to the latitude angle $\phi(-90° < \phi < 90°)$, the longitude angle $\theta(-180° < \theta < 180°)$, and the magnitude M. When recorded on a time graph, these voltages yield information concerning relative angles in a singularly direct fashion. Furthermore, the angle voltages may be applied to the deflection plates of a cathode-ray tube, and the magnitude voltage to the intensity controlling grid, thus producing a simple map-like presentation of the variations of the heart vector throughout the beat.

Such voltages can be obtained with two computers each having two inputs (e_1, e_2) and two outputs (e_θ, e_M) related by the equations

$$\begin{aligned} e_M &= k_M(e_1^2+e_2^2)^{\frac{1}{2}} \\ e_\theta &= k_\theta \operatorname{Arc\,Tan}(e_2/e_1). \end{aligned} \tag{1}$$

The input of the first computer would consist of two amplified components of the heart vector, and the input of the second would use the magnitude output of the first and the third remaining component. The three remaining outputs would be the desired voltages.

A typical record of the output obtained from one computer of this type using only two components of the heart vector is shown in Fig. 1. Since only one computer has been built, similar records showing all three spherical coordinates are not available.

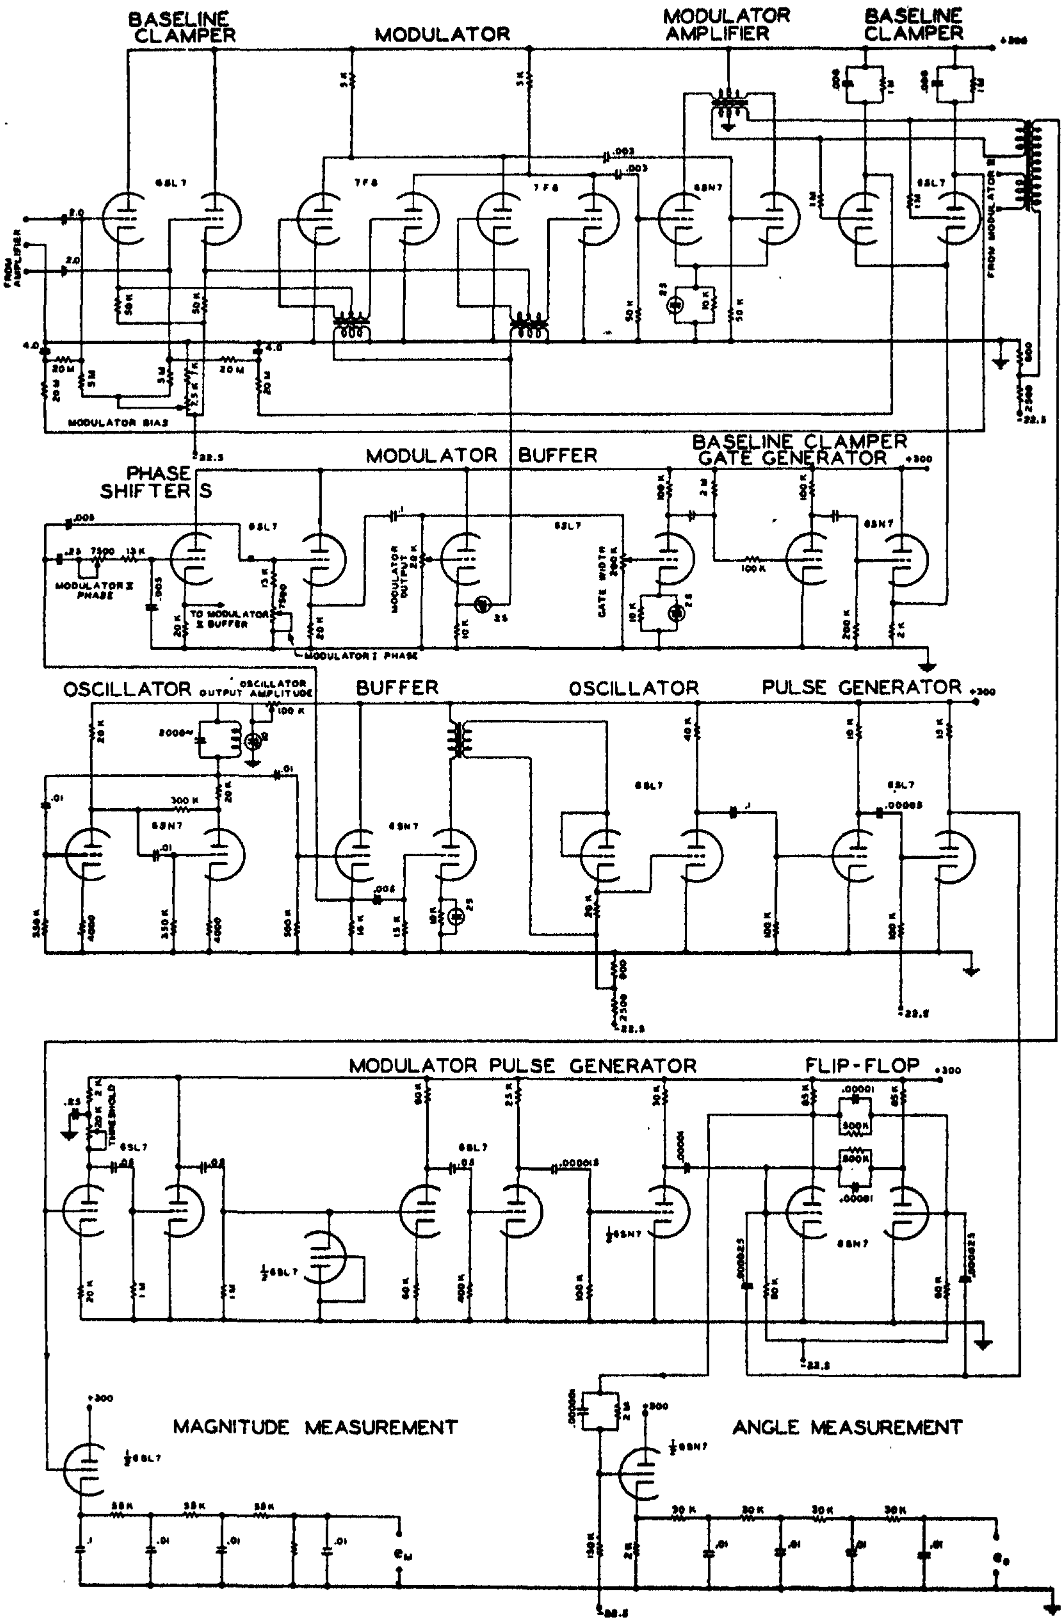

FIG. 3. Circuit diagram (does not show second modulator).

GENERAL DESCRIPTION OF THE COMPUTER

The computer operates by taking advantage of an analog between the equations (1) and the equations giving the phase and magnitude of the sum of two sinusoidal voltages ninety degrees out of phase with each other. In this latter case the well-known result is

$$V_1\underline{/0}+V_2\underline{/90}=(V_1^2+V_2^2)^{\frac{1}{2}}\underline{/\text{Arc}}\,\text{Tan}(V_2/V_1). \quad (2)$$

A similar use of this analog has been made previously in connection with radar ranging apparatus.[6]

In practice the two sinusoidal waves ninety degrees out of phase are obtained from a master oscillator and are separately modulated by the two inputs to the computer. These are added and the amplitude measured by an ordinary detector and the phase determined by comparison with the unmodulated output of the oscillator. A simplified block diagram of the circuits are shown in Fig. 2.

The basic circuits required are two modulators, two pulse generators, two baseline clampers, and an oscillator, a detector, and a phase measuring circuit. The construction of the particular circuits used is shown in the over-all circuit diagram of Fig. 3, and their roles are illustrated in the detailed block diagram, Fig. 4, and the timing diagram, Fig. 5.

The purpose of the baseline clamper is to make the outputs of the modulators zero when their inputs are at the baseline level, which is not necessarily zero. It will be described in more detail shortly. The modulators are more or less conventional, although designed for linearity, small variation in phase, and small harmonic distortion in their output. The harmonic distortion of the oscillator output is also intentionally low. The modulator pulse generator produces a pulse when its sinusoidal input passes through zero going positive, regardless of the amplitude of the latter unless the amplitude is very small, in which case no pulses at all are produced. The oscillator pulse generator produces a pulse when its input passes through zero going negative. The outputs from these pulse generators are applied to the grids of a flip-flop trigger circuit. The pulse from the modulator generator will make the output of this circuit flip up but not down. Oscillator pulses, on the other hand, will cause the output to flip either up or down. When the modulator generator is producing pulses the length of time the output of the trigger circuit is positive is determined by the phase difference between the outputs of the pulse generators. When the modulator generator is not producing pulses, the oscillator derived pulses trigger the flip-flop circuit at half the normal rate and produce a square wave at the output. The average of this square wave is the same as the average of the square wave produced when the magnitude of the heart vector is appreciable (thus causing modulator pulses) and the angle is zero. Thus when the angle is indeterminate, the angle voltage becomes equal to the zero angle value, which is desirable because it thus automatically shows the zero level. The phase measuring method involved here has been described previously.[7]

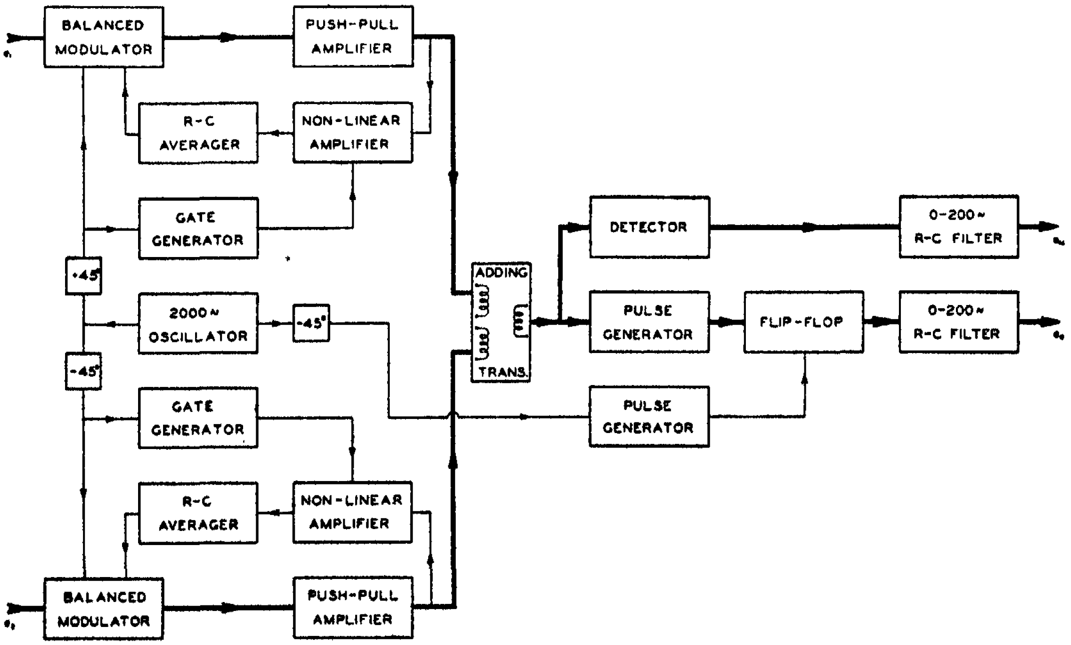

FIG. 4. Detailed block diagram.

[7] Crufts Laboratory Staff (Harvard), *Electronic Circuits and Tubes* (McGraw Hill Book Company, Inc., New York, 1947), first edition, p. 854–855.

The threshold level at which the change-over occurs is adjustable. When it is set too low, small but rapid changes in the baseline level, sixty cycle pick-up and muscle tremor noise will cause large and erratic variations in the angle voltage output. When it is set too high, the angles associated with small magnitudes are not shown. Some compromise between messy records and more complete information is necessary, and this is made manually with the "threshold" control. This is the only control that needs adjustment during actual operation.

An oscillator frequency of 2000 cycles was chosen as a compromise between the greater difficulty in constructing pulsing circuits at higher frequencies and the modulators and filters at lower frequencies.

In order to avoid building the special low frequency pulse generators required to test the accuracy of the computer with the baseline clampers in operation, accuracy tests were made with the latter disconnected.[8] In one test a series of inputs were applied which corresponded to a heart vector of about three-quarters maximum magnitude rotating in discrete steps from −175 to +175 degrees. The error in the output voltage proportional to the angle did not exceed a value equivalent to five degrees, and the magnitude output voltage (which should have been constant) fluctuated about five percent. It is probable that this was due to changes in line voltage while the readings were being taken. The behavior beyond ±178 degrees became erratic, as would be expected, in view of the discontinuity at ±180 degrees. The second test was run keeping the angle constant at +45 and −135 degrees while varying the magnitude. A "compression" amounting to about four or five percent was noticed at maximum magnitudes. The angle voltage stayed constant within ten degrees down to about ten percent of maximum magnitude and within thirty degrees down to about five percent maximum. The error due to the baseline clamper is naturally uncertain, but the close agreement between plotted graphs of θ and M calculated from measured time graphs of the heart vector, and direct $\theta - M$ time graphs obtained from the same persons with the computer indicate that it is not excessive.

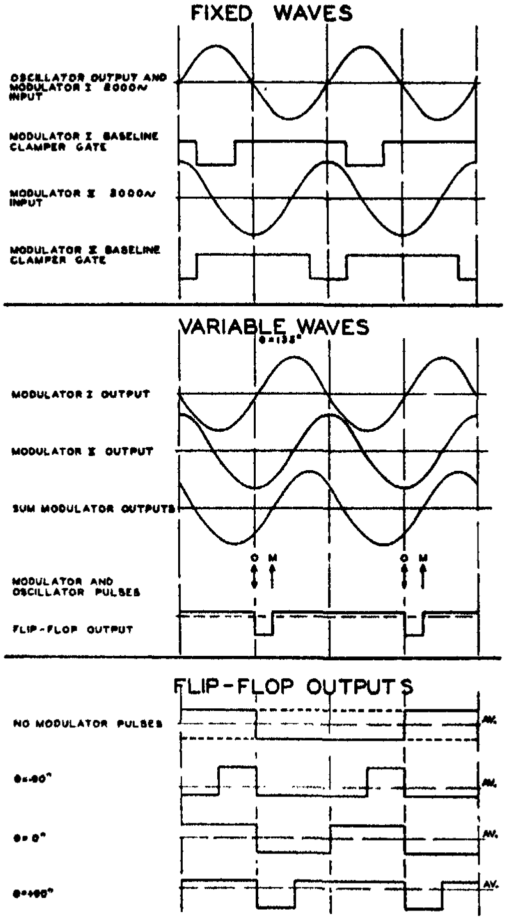

FIG. 5. Timing diagram.

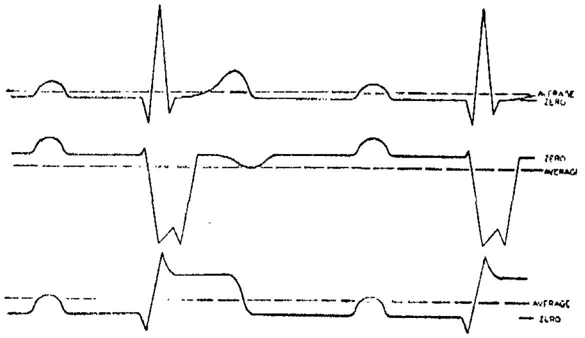

FIG. 6. Baseline and average levels for various electrocardiographic waves.

THE BASELINE CLAMPER

The baseline clamper as used here is a circuit which automatically adjusts the modulator so that its output is zero when its input voltage is at the baseline level. To illustrate what is meant by the baseline it is pointed out in each of the various electrocardiographic wave forms shown in Fig. 6. It has been found experimentally that these voltage levels occur when the heart is electrically inactive and consequently when the components of the heart vector are zero. Thus the baseline clamper circuit insures that the modulator output is zero when it should be.

Such a circuit is necessary because the actual modulator input voltage corresponding to this baseline level is usually *not* zero. Unbalanced electrolytic potential differences at the pickup electrodes produce this effect when d.c. amplifiers are used, and the difference between the average and the baseline levels (also shown in Fig. 6) produce it when low frequency a.c. amplifiers are used.

---

[8] Observation of the modulator output resulting from an amplified electrocardiographic wave applied to the input showed that the automatic adjustment made by the baseline clamper was identical to that which would have been made manually, if it had been necessary. It is difficult to specify any other way for telling whether or not the baseline clamper is "accurate."

Perhaps the simplest way to make the modulator output zero at the baseline level would be to connect an oscilloscope to the modulator output and manually adjust the modulator zero point so that the observed output was zero most of the time. However, such a manual adjustment has obvious disadvantages. Not only does it involve extra equipment and time, it also requires a difficult subjective judgement on the part of the operator. Furthermore, the input wave form will change slightly from one series of cycles to another making frequent and in some cases continuous adjustments necessary. As a result, an automatic adjustment is highly desirable.

The baseline clamper circuit operates by adding to the input voltage a d.c. voltage (which can vary slowly) strongly tending to make the time the modulator output is positive equal to the time it is negative. To see how this property produces the desirable result, consider the output resulting from a modulator input wave having the baseline level *above* the value giving zero output. If the input is at the baseline level for more than half its cycle, then the output will be positive for more than half the time. Similarly, if the baseline level is *below* the zero level, the output will be negative for more than half the time. Thus the baseline clamper will be in equilibrium only when the baseline level and the zero level are equal. The condition that the wave be at the baseline level more than half the cycle is sufficient but not necessary. A more exact statement is that the wave must be at the baseline level longer than the absolute value of the difference between the time it is above and the time it is below that level. This condition is met by nearly all electrocardiographic waves with recognizable baselines.

It is not difficult to construct a feedback circuit having this time equalization property. An amplifier can be gated so that its output is influenced only by the peaks of every other half-cycle of the input and so that it is overdriven by very small signals. Its output will then assume definite but different values for positive and negative (reversed in phase) inputs and its average output, except for a constant factor, will be proportional to the difference between the time its input is positive and the time it is negative. This average value is obtained with an *R-C* low pass filter and is fed back to the input of the modulator so that it tends to reduce itself. The system is essentially an error proportional servomechanism, and its design requires the usual attention to stability conditions. The actual circuit used for the baseline clamper is shown in Fig. 7. The triode amplifiers are gated by negative pulses on their cathodes. The tubes are cut off except during the pulses. During the pulses the large signal on the grid, of the order of fifty volts, either again cuts off the tube or else produces simultaneously grid limiting and plate saturation. The small plate condensers prevent the plate voltage from changing during one or two carrier frequency cycles but are not large enough to interfere with the relatively slow changes associated with variations of the modulator inputs. The *R-C* feedback path has a time constant of about forty seconds. It is felt that about double this value would give some improvement.

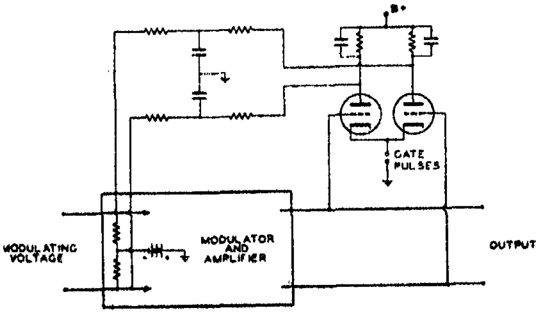

Fig. 7. Baseline clamper circuit.

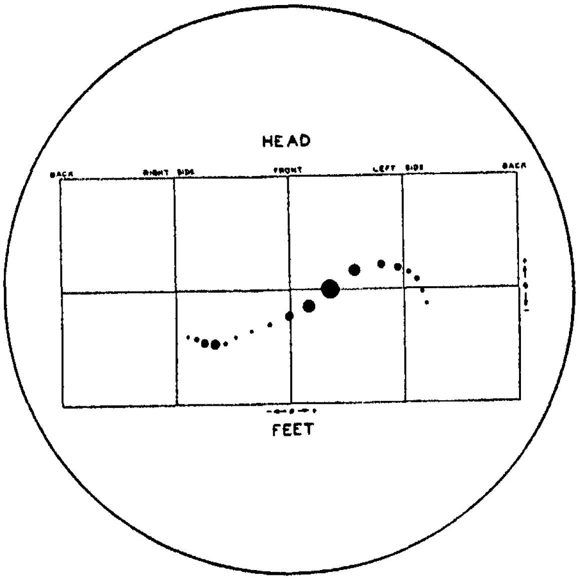

Fig. 8. Hypothetical heart vector map of ventricular excitation.

Even simpler baseline clampers can be constructed to operate with d.c. amplifiers, since they do not require special gating circuits.

THE HEART VECTOR MAP

It is of interest to outline how a maplike display of the three-dimensional heart vector can be achieved, even though this has not yet been done. If two computers are available, they can be interconnected so that one computer determines the magnitude and angle of the projection of the three-dimensional heart vector on one plane, and the second computer uses the "magnitude" output of the first and an additional heart vector component perpendicular to the first plane to determine the three-dimensional magnitude and second angular coordinate. Since the "magnitude" output of the first computer is always positive, the "angle" output of the second never exceeds ±90 degrees.

If the angle coordinate voltages are connected to the vertical and horizontal plates of a C.R.T., and if the magnitude coordinate voltage is used to focus and intensity modulate the spot, the map presentation is attained. To interpret this display we think of the heart as being surrounded by a sphere which is "mapped" onto the face of the cathode-ray tube in such a fashion that the latitude and longitude lines of the sphere form a rectangular grid. The position of the spot on this map corresponds to the place where the heart vector "pierces" the sphere, and the size of the spot corresponds to the magnitude of the heart vector. The spot can be turned on and off regularly, so that the time dependance of the heart vector is also evident. A photograph of the tube taken during the initiation of the contraction of the ventricles would appear similar to the sketch in Fig. 8.

The main purpose of this presentation would be to permit easy compensation for the effects of abnormal heart positions. By rotating the computer reference system it might be possible to reduce most normal map displays to a standard one (normalization). Electrical networks for producing such a rotation are already in use.[5] More careful study of the heart vector could be made by taking time graph records of the three spherical coordinate voltages after it has been normalized with the "map" presentation.

Since it is clear that considerable distortion of the movement of the heart vector would exist near the top and the bottom of the map, the normalization would be made so that the standard trace lay along or near the equator.

OTHER APPLICATIONS

Computers of this type have general application to any situation where Arc Tan(e_2/e_1) and $(e_1^2+e_2^2)^{\frac{1}{2}}$ need be determined rapidly. It is possible that careful design and construction would lead to accuracies within 1 percent for the magnitude output and within 1 degree for angles associated with fairly large magnitudes. The baseline clamper could be used as an automatic centering circuit for vectorcardiographs.

ACKNOWLEDGMENT

I am grateful to the many members of the Departments of Electrical Engineering and Physics at Syracuse University who have helped in the construction of the computer, and in particular to Dr. Wilbur Le Page, whose suggestions and encouragement had much to do with its success. Electrocardiographic tests were made with the space and equipment kindly furnished by Dr. J. S. Robb, of the Syracuse Medical School. The suggestions and criticism of Dr. Franklin Johnston, of the Heart Station at the University Hospital, Ann Arbor, Michigan, were of considerable help in the preparation of this paper.

Vibration Studies: Related to Electron Microscopy

F. A. Hamm and F. C. Snowden
General Aniline and Film Corporation, Central Research Laboratory, Easton, Pennsylvania

(Received December 5, 1949)

This paper describes a convenient scheme for detecting and measuring vibration as related to the performance of an RCA electron microscope (Type EMU). The procedure involves the use of a Webster Model F5P2 phonograph pick-up arm in conjunction with a cathode-ray oscillograph. The cathode-ray oscillograph signal amplitude which represents the vibration of the location being investigated was calibrated by means of a Brush Development Company Type BL-301 vibration pick-up whose voltage output is proportional to the product of the vibration amplitude and the square of the frequency. An audio oscillator was used to calibrate the voltage output of the Webster (rochelle salt) pick-up as a function of frequency. After calibration, these oscillographic measurements may be used to determine absolute mechanical displacements.

Electron micrographs are included to illustrate the image displacements due to several different amplitudes of vibration. Cognizance of vibration is often necessary, especially in high resolution electron microscopy. This scheme may be used as a guide in high resolution electron microscopy.

INTRODUCTION

ELECTRON microscopists are becoming more critical of inherent and accidental instrumental limitations. This is the natural result of several factors—experience, greater interest in high resolution and the instrumentational type of research emanating mostly from the RCA Laboratories,[1] Princeton, New Jersey.

One of the accidental limitations is vibration. In this case the specimen moves, usually with a certain periodicity, with respect to the imaging system of the electron microscope. A resolvable image shift, whose magnitude is dependent upon the instrument magnification and vibration amplitude results.

The electron microscopist may have little choice in the matter of choosing a site for the instrument, thus, the critical investigator should be able to recognize prohibitive specimen vibration and expend some effort to eliminate it.

---

[1] Although many papers have been published, perhaps the one most pertinent to this subject is by James Hillier and E. G. Ramberg, "Magnetic electron microscope objective: Contour phenomena and the attainment of high resolving power," J. App. Phys. 18, 48 (1947).

It is the purpose of this paper to report on a convenient method for *detecting* amd *measuring* vibration as related to the performance of an RCA electron microscope in the hope that the dissemination of this knowledge may aid others. In general, this scheme may be put to the following uses: (1) to identify what combination of machinery is responsible for the vibration in the vicinity of the electron microscope or other instruments adversely affected by vibration, (2) to probe the building for the best location for the electron microscope, preferably before the initial installation, (3) to use as a guide for determining when the vibration amplitude is tolerable, especially when recording high magnification images.

GENERAL DISCUSSION

For several years it has been realized in this laboratory that specimen vibration was periodically prohibitive at high instrument magnification. The trouble was traced to a combination of large vacuum pumps, an air compressor, and a 15-hp air-conditioning unit, all located in the basement almost directly beneath the first floor location of the electron microscope. This service equipment had already been essentially isolated from the building by mounting it on large concrete slabs set in 4-in. cork. Some improvement was effected by remounting the service lines from this equipment to the basement ceiling with commercial vibration shock mounts. These shock mounts consist of rubber in shear bonded to metal.

It was soon realized that the elimination of these floor vibrations was a difficult, if not impossible, task. A careful analysis of the whole vibration problem was then made which revealed: (1) the three principal frequency components were 15, 60, and 300 c.p.s.; (2) the two lower of these components are the more difficult to suppress; (3) the intolerable floor vibrations occurred only periodically, that is, some frequent, but irregularly recurring, combination of heavy laboratory service equipment was responsible for the trouble; (4) the undesirable image shifts were usually observed only at high instrument magnifications above 15,000×.

[a] The Webster F5P2 was placed on top of the deck to the right of the column. In all cases the oscillograph *y*-gain was set at 50 except for Fig. 6 where 40 was used.

[b] This is only approximate because of trace length, but is within five percent of real value.

Several attempts to insulate the electron microscope from the vibrations were unsuccessful. A closer examination of points (1) and (2) above reveals why these attempts failed; the low frequency of the principal components of the vibrations observed makes difficult

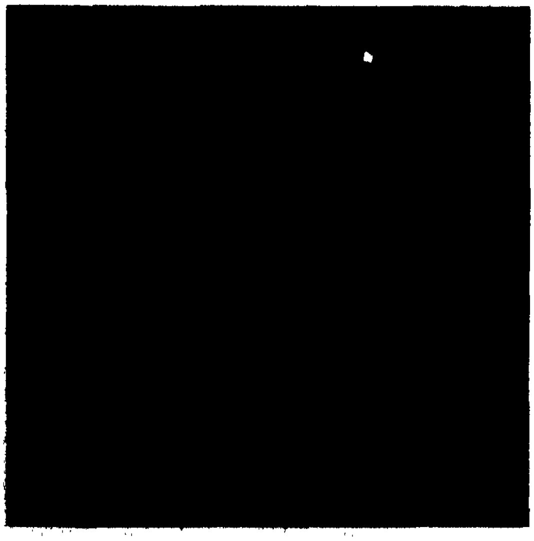

FIG. 1. 80,000×. Diatoms. No significant vibration.

FIG. 2. 80,000×. Camphor carbon black. Forepump on.

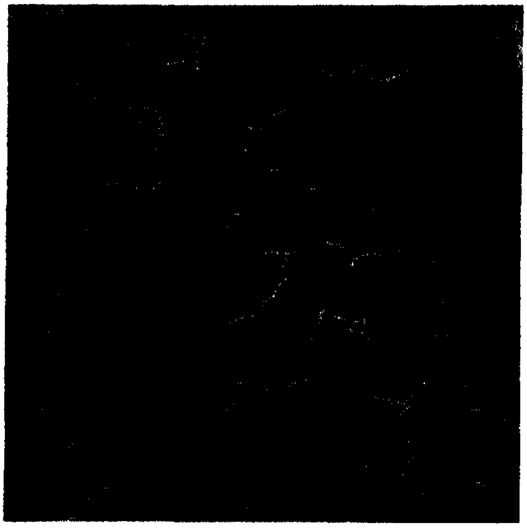

FIG. 3. 80,000×. Same field as Fig. 2. Forepump off.

their effective suppression. This is explained by the fact that for a given material the compression in inches *versus* the load in pounds is a fixed value. Similarly, the natural frequency of an insulating elastomeric mount is an inverse function of the static deflection of the mount under load. Calculations showed that for a 20-fold suppression of the 15 c.p.s. component a vibration mount exhibiting a static deflection of one inch and a natural frequency of 3 c.p.s. had to be found. Such a vibration mount cannot be purchased for a load as light as that of the electron microscope (875 lb.).

It was then decided to devise a technique for continuously measuring these vibrations, using such measurements as a guide for high resolution electron microscopy. It was also decided to move the instrument to a new location within the laboratory, making it necessary to measure floor vibrations at various possible locations. The subsequent section describes the method used. It must be remembered that this scheme does not represent an exhaustive appraisal of the problem, but it does afford a very satisfactory solution from the electron microscopist's point of view. However it is obvious that the data given in Tables I and II cannot be used by other investigators. Unless completely calibrated commercial vibration analyzing equipment is used, the investigator will have to calibrate his own scheme, which may be similar to the one described herein.

OSCILLOGRAPHIC MEASUREMENT OF VIBRATION

The preliminary step taken in the solution of this problem was the probing of the floor area in the vicinity of the electron microscope, and the red deck on the microscope itself, with a Webster Model F5P2 pick-up arm, the output of which was observed on a DuMont Model 208B oscillograph. Three principal frequencies were present in the troublesome vibrations of approximately 15, 60, and 300 c.p.s. The 15 c.p.s. was the envelope for the 60-c.p.s. component, and the 60 c.p.s. the envelope for the 300 component. The same three principal frequencies were observed at various intensities throughout the first floor of the building.

Once the frequencies of the vibrations were known, the horizontal gain control of the oscillograph was depressed to zero facilitating the reading of the maximum and minimum vertical traces. These vertical traces were proportional to vibration amplitude, and it was easily determined in which areas the vibration effects were minimum, and consequently which areas were best suited for the relocation of the microscopy laboratory.

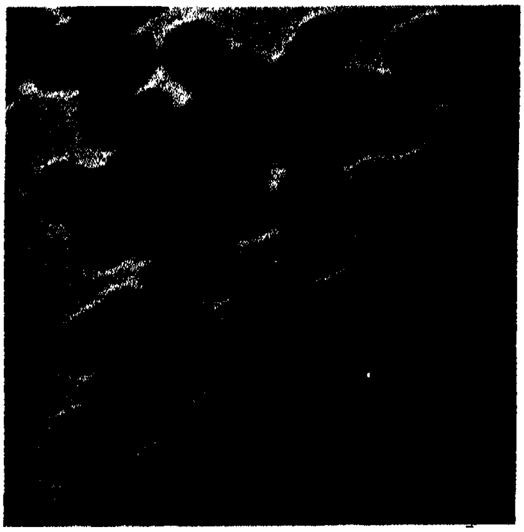

FIG. 4. 120,000×. Camphor carbon black. 200A shift.

However, this data, while useful, gave no information of an absolute nature required for correlation of image quality with actual vibration amplitude and for determining the critical vibration level. Since some indication of this critical amplitude level was desirable, a Brush Type BL-301 pick-up[2] was employed, permitting its calculation.

The Brush BL-301 is an inertia-type pick-up. Such pick-ups generate, piezoelectrically, a voltage which is proportional to the amplitude and the square of the frequency of the vibrations under investigation, when these vibrations are sinusoidal in nature. It was safe to make such an assumption on the basis of the vibration wave-forms as seen on the oscillograph. Thus,

$$e = kaf^2, \qquad (1)$$

where k is some constant of proportionality determined by the pick-up sensitivity. The sensitivity of the BL-301 is given as 30 v (open circuit r.m.s.) per 0.001-in. displacement at 500 c.p.s.[3] Under these conditions

---

[2] Manufactured by the Brush Development Company, 3504 Perkins Avenue, Cleveland 14, Ohio.

[3] This information is given in the manufacturer's data on the pick-up.

Eq. (1) becomes

$$e=0.12af^2. \qquad (2)$$

An investigation into the impedance characteristics of this pick-up reveals that the impedance is very nearly purely capacitative, the capacity of the pick-up at 40°C being 0.0015 μf.[3] This is the value used in subsequent calculations since the calibration measurements were made at ambient temperatures of 34–37°C.

The voltage E_g generated by the pick-up is the vector sum of the internal voltage drop E_i, and the external drop E_0 across the oscillographic input resistance. At the lower frequencies E_0, the actual voltage amplified, will be only a fraction of E_g, the voltage that must be substituted in Eq. (2) for the solution of the amplitude. It must be known, then, what fraction of E_g is represented by E_0 at the pertinent frequencies. These were calculated and found to be 27.8 percent at 15 c.p.s. and 74.5 percent at 60 c.p.s.

Since the Webster F5P2 pick-up is more sensitive at 15 and 60 c.p.s. than the BL-301, it was decided to calibrate the former with the latter. This also permitted the calculation of vibration amplitudes directly from the data already obtained with the Webster. Vibrations of known frequency from an audio oscillator were transferred to a hard table top through a radio speaker. The F5P2 pick-up was calibrated by comparing its output with that of the BL-301. The only assumption made was that the sensitivity provided by the manufacturer for the BL-301 was essentially correct, since we had no means for generating a vibration of known amplitude.

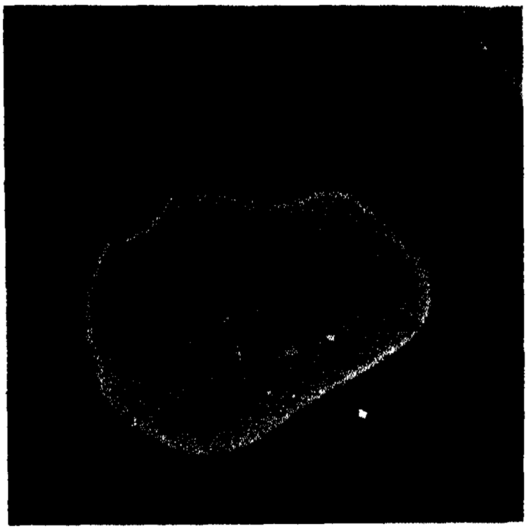

FIG. 5. 120,000×. Diatom. Forepump on.

The results of the calibration showed that at 15 c.p.s. the F5P2 was 4.75 times as sensitive as the BL-301, at 60 c.p.s. 1.72 times as sensitive, but at 300 c.p.s. only 0.33 times as sensitive.

Next the oscillograph sensitivity and amplifier gain were determined by the application of known voltages, first directly to the vertical deflection plates, and then to the amplifier input. The sensitivity was 24 v r.m.s. per 1-in. deflection above and below the normal position. The amplifier gain was 500. From the information now available it is possible to calculate absolute vibration amplitudes, and a list of the results obtained appears in Table I.

From Table I it can be seen that the vibrations are much more severe when a large air conditioner is on. This air conditioner is one floor level below the electron microscope.

It is peculiar to note that the vibration amplitude on the right side of the deck was actually less when the forepump was on than it was when the forepump was off. The authors have no completely satisfactory explanation of this phenomenon. The fact that the vibrations on the microscope deck are considerably greater in amplitude than those on the floor directly beneath it is indicative of the difficulties encountered in any attempt to damp out low frequency vibrations. The vacuum forepump is connected to the microscope valving block. Thus, in general, two sources of vibration must be considered—the forepump and the building vibrations.

Left out of the tables, purposely, were the results obtained for the 300-c.p.s. component present, because under the worst conditions encountered, the amplitude of this frequency was calculated to be only 0.000027 mil, or 0.007 percent of the corresponding 60 c.p.s. component.

Measurements were also made on a Saturday morning with all of the most troublesome machinery turned off. The results showed a spectacular decrease in the amplitude of the vibrations present. No 300-c.p.s. component was noticed at all, and the others were greatly reduced in magnitude. As an example, on the floor in front of

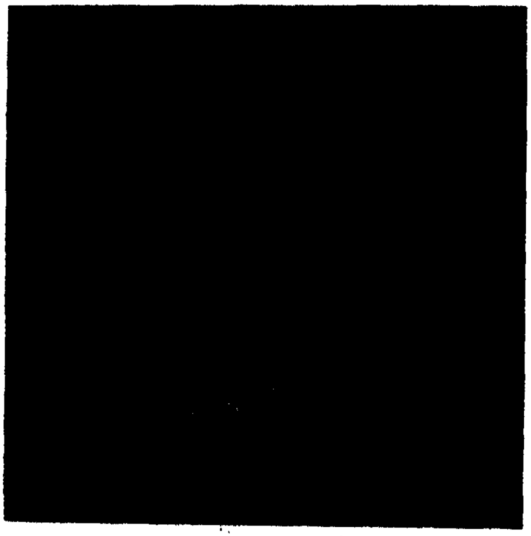

FIG. 6. 120,000×. Same field as Fig. 5. Forepump off.

the diffusion pump column the amplitudes of the 15- and 60-c.p.s. components were only 0.048 and 0.0074 mil, respectively. On the right side of the microscope deck, where the amplitudes always appear to be greatest, the results showed a maximum displacement of only 0.14 mil for 15 c.p.s. and 0.022 mil for 60 c.p.s.

The vacuum forepump (Cenco Hypervac 20) was mounted on thick cork in a coil spring suspension "cradle" bolted to the basement ceiling beneath the microscope. In spite of these precautions prohibitive vibration amplitudes are frequently exhibited by the action of the pump.

Since the detecting and measuring scheme described is admittedly only preliminary in nature, there are several considerations requiring some clarification. First, the piezoelectric crystal in the Webster pick-up is virtually insensitive to vertical vibrations; it is more sensitive to horizontal or twisting vibrations. Thus, the position in which the pick-up is placed with respect to the plane of vibration must be carefully considered. Displacements of the specimen in the horizontal plane, on the other hand, most seriously affect the quality of the final image. The electron microscope possesses a relatively large depth of field (*ca.* 0.5μ) which permits tolerating a fair amount of vibration in the vertical plane.

It is not intended to accept any vibration measurements obtained at places external to the specimen holder in the electron microscope as being representative of, or equivalent to, the actual vibrations extant on the specimen itself. This scheme is intended primarily as a *guide* to critical electron microscopy. Over and beyond the simple monitoring function of this method, however, it should be said that information of a more pertinent nature might well be obtained if a crystal pick-up system were permanently attached to the objective lens where the evaluation of vibration data would undoubtedly have greater significance. Completely absolute data describing the vibration of the specimen itself would be exceedingly difficult to measure. The virtue of the scheme described herein lies in its usefulness.

In order to achieve greater accuracy in relating the frequency and amplitude of vibration with image displacements, a Brush direct inking oscillograph Model BL-211 could be used. This instrument would provide a permanent record of the exact data for the relatively low frequencies usually encountered in the average laboratory. Errors inherent in estimating the length of an oscillographic trace would thus be precluded.

Although the procedure described in this paper enjoys advantages of simplicity and low cost, other methods are applicable. References[4] to these adaptable techniques are cited.

DISCUSSION OF ELECTRON MICROGRAPHS

The use of an auxiliary optical magnifier (RCA EMX-1) facilitates the detection of small image shifts in the electron microscope due to vibration, specimen drift, electrostatic charging, etc. At a total final magnification of 350,000×, image shifts on the order of 20A can be detected.

Although the effects of specimen drift and vibration are both almost invariably directional, a distinction can be made by careful examination of the image. Specimen drift can be detected at once by comparing the relative positions of the image on the five frames of the photographic plate. Conversely, serious vibration may cause the formation of a secondary image which is equally as sharp as the primary image. The displacement of these two images is a function of the vibration amplitude. If the vibration amplitude is small, a distinct "ghost" image may not be observable; instead the resultant 5 or 10A image shift normal to the direction of vibration appears only as a *broadened* white halo in an underfocused image. Fresnel fringes in underfocused images are an indication of good instrument performance. These interference fringes, on the other hand, may be observed in well-focused images which are affected by vibration.

The electron micrographs presented here were taken during periods when the oscillographic vibration data were recorded, with the exception of Fig. 1. The pertinent data are given in Table II. Image quality should be considered in terms of these data. All micrographs were taken at an instrument magnification of 20,000× with an exposure time of 15 sec. In general, the images are all somewhat underfocused. This is of no significance in this study.

Figure 1 is a high quality image of diatoms taken during a period when no oscillographic data were recorded. However, this micrograph was taken under optimum conditions for another purpose, and is presented here as an example of a micrograph in which no directional motions were present to affect the image. It should be used for comparison with subsequent micrographs most of which exhibit image displacements.

Slight specimen drift is illustrated in some of the following figures. This accidental factor is extremely difficult to avoid, and cognizance of this drift has been taken. It does not alter the significance of this vibration study in any sense. The arrows in the micrographs indicate the direction of the vibratory motion.

Figures 2 and 3 represent the first and second frames of the same plate. The mechanical forepump had been turned off during the second and fourth exposures. The level of vibration during the exposure of Fig. 3 was observed to be very low. A very slight specimen drift occurred during the photographing of this series, but it was a constant for each 15-sec. exposure and is of no significance in comparing these micrographs. The oscillographic signal induced by the deck vibrations indicates that there should have been *no* prohibitive vibration for any of the five exposures. Accordingly the presence of mechanical motion in Fig. 2 must be due to forepump action, which has a greater effect on the microscope column than on the deck; the forepump is connected to the microscope column through the valving block. This behavior has been observed repeatedly, although good quality pictures have occasionally been taken with the forepump on. All of the electron micrographs used in this paper were taken only when the effects of the vibration persisted in the instrument for periods of 30 sec. or more. In this way possible accidental effects from other sources than vibration are safely eliminated.

[4] W. Jay Kennedy, J. Opt. Soc. Am. 31, 99 (1941); H. H. Scott, J. Acoust. Soc. Am. 13, 46 (1941); R. O. Fehr, Gen. Elec. Rev. 45, 695–699 (1944); H. J. King, J. Inst. Elec. Eng., Part II 93, 435–62 (1946); A. J. Cogman, Electronic Eng. 19, 70–74, 109–13, 152–6 (1947).

The image illustrated in Fig. 4 resulted from an abnormally large vibration (cf. Table II) traced to the moving of a relatively light dolly down a nearby hall. Although this represents an exceptional case, it serves to relate in a semiquantitative way the relationship between image motion, and the mechanical displacement at the microscope deck. This image displacement in Fig. 4 is on the order of 200A.

Figures 5 and 6 depict the same field photographed within a 30-min. period. The vibration level indicated in Fig. 5 is typical of a good portion of the average working day. The seriousness of this condition is quite evident; the image shift is on the order of 100A. In Fig. 6 the same field is shown under somewhat better than average conditions. No attempt is made here to demonstrate high resolution; this micrograph is presented for comparison with that of Fig. 5 only. A first-order Fresnel fringe indicating a somewhat underfocused image suggests good instrument performance.

The decrease in the size of the hole in the diatom with prolonged exposure to the electron beam, which incidentally was never at maximum intensity, is apparent by comparing Fig. 6 with the previously photographed Fig. 5. A subsequent micrograph, not illustrated, exhibited a further decrease in the size of the opening. Specimen contamination alone cannot be held responsible for this change. Presumably silica in this thickness is expanded to a serious degree by the electron beam.

CONCLUSIONS

A convenient scheme for determining the proper location of an electron microscope and for serving as a guide to high resolution electron microscopy, when serious vibration is a factor, has been described. While the technique is only preliminary in nature its usefulness has been demonstrated by its constant use in this laboratory. This oscillographic method is especially useful for detecting relatively minor floor vibrations which may cause an image shift of only 10A.

The relation between image shift and microscope deck vibration is in general only qualitative. At present, the data available suggests that an instrument deck displacement of about 2 mils at 15 c.p.s. can be related to an image displacement of 200A, and a similar displacement of 1.5 mils appears to result in an image displacement of about 100A. This has been illustrated by a series of electron micrographs.

A Rotating Specimen Mount for Use with X-Ray Spectrometer in Measuring Crystallite Orientation of Cellulosic and Other Textile Fibers

Leon Segal, Joseph J. Creely, and Carl M. Conrad
Southern Regional Research Laboratory,[*] New Orleans, Louisiana

(Received January 5, 1950)

The quantitative evaluation of crystallite orientation in textile fibers by x-ray methods is discussed. It is found that photographic recording and photometering of the resulting films can be replaced by automatic recording on a strip chart with the aid of an x-ray spectrometer with Geiger-Mueller counter. The design and details are given for a specimen holder capable of properly positioning and rotating a bundle of fibers in the x-ray beam so that the 002 or other selected diffraction arc passes before the window of the counter. A tentative procedure is outlined for evaluating, with the aid of this apparatus, the crystallite orientation of a bundle of cellulose fibers. Some typical recordings of the intensity curves of the 002 arcs from ramie, cotton, and high tenacity rayon are presented.

INTRODUCTION

SISSON and Clark[1] originally developed and applied the quantitative x-ray method for the estimation of cellulose crystallite orientation which, with some modifications, is largely in use at the present time. It was based on the concept, previously outlined by Weissenberg,[2] that the intensities of the diffraction arcs at any angle to the equator are proportional to the number of crystallites in the fiber at the same critical angle to the fiber axis. They made intensity measurements with a microdensitometer equipped with a rotat-

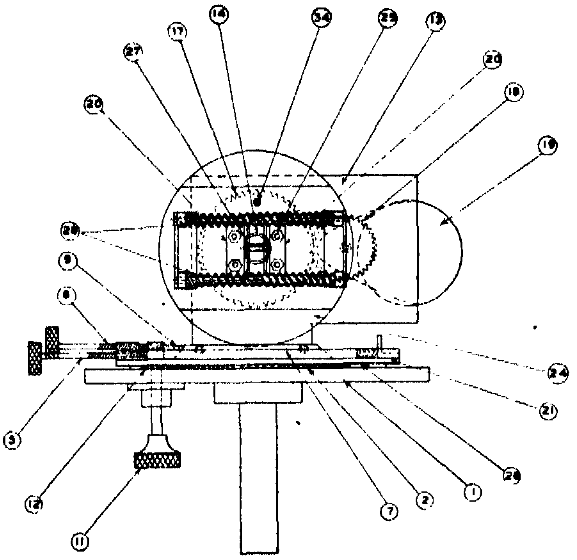

FIG. 1. Front view of assembled rotating specimen holder.

ing stage[1, 3] so that the flat photographic plate could be rotated through 360° while measurements of density were made around the selected diffraction arcs, particularly the 002 arc. The method was considerable refined by Berkley and co-workers[4, 5] who designed and applied a microphotometer for the purpose.

When a bundle of parallelized cotton fibers is placed in and perpendicular to the x-ray beam, the centers of the principal (equatorial) diffraction arcs on the flat plate are found to be located at right angles to the direction of the bundle or fiber axis. Providing the bundle has been well centered and held in a plane normal to the beam, these arcs will be symmetrical and concentric about the spot where the primary x-ray beam irradiates the fibers. It is obvious, then, that if the bundle axis is maintained in the plane normal to the x-ray beam and the bundle itself is rotated about the irradiated area as a center, the diffraction arcs also will rotate.

If, now, an efficient Geiger counter tube is placed at the proper angle to intercept a diffraction ray, then as the bundle is slowly rotated, the counter will actually measure, by counting the x-ray quanta, the changing intensity of the rotating diffraction arcs.

According to Friedman[6] the development of Geiger counter tubes and techniques has progressed to the point where one count is produced for almost every x-ray quantum entering the tube, as compared to the 10^4 to 10^5 quanta required to produce minimum detectible blackening on film. The Geiger counter, then, provides a very sensitive means of directly measuring radiation and when incorporated in x-ray diffraction equipment has been found by Buhler,[7] Decker,[8] Klug[9] and others to remove the limitations imposed by recording diffraction patterns photographically.

In the recording x-ray spectrometer where the Geiger counter output signals are led into a strip chart recorder, the x-ray intensities are plotted directly since the excursions of the recorder pen are proportional to the received intensities. By synchronizing the chart speed with bundle rotation, an automatic recording can be made of the intensities of the diffraction arcs being scanned. If the arcs from the 002 diffraction plane of cotton are selected for scanning in this manner, the resulting trace should be essentially comparable to the photometer curves of photographically recorded diffraction patterns obtained by Sisson[10] and by Berkley.[5]

The introduction of the Geiger tube eliminates in one step the entire problem of photographic recording with its limitations of proper exposure, rigid control of processing, non-linearity of film response, and tedious manual photometering of the diffraction patterns.

The present paper describes a specimen holder for rotating the fiber bundle in the x-ray beam together with suitable controls for centering and other adjustments.

THE SPECIMEN HOLDER

The design of the specimen holder provides the following essential conditions: (1) The size and shape of the entire unit conforms to the limitations imposed by the shape and construction of the spectrometer's x-ray
